Abstract

Phosphatidylinositol binding clathrin assembly protein (PICALM), also known as clathrin assembly lymphoid myeloid leukemia protein (CALM), was originally isolated as part of the fusion gene CALM/AF10, which results from the chromosomal translocation t(10;11)(p13;q14). CALM is sufficient to drive clathrin assembly in vitro on lipid monolayers and regulates clathrin-coated budding and the size and shape of the vesicles at the plasma membrane. However, the physiological role of CALM has yet to be elucidated. Here, the role of CALM in vivo was investigated using CALM-deficient mice. CALM-deficient mice exhibited retardation of growth in utero and were dwarfed throughout their shortened life-spans. Moreover, CALM-deficient mice suffered from severe anemia, and the maturation and iron content in erythroid precursors were severely impaired. CALM-deficient erythroid cells and embryonic fibroblasts exhibited impaired clathrin-mediated endocytosis of transferrin. These results indicate that CALM is required for erythroid maturation and transferrin internalization in mice.

Introduction

Clathrin-coated vesicles mediate endocytosis of plasma membrane receptors, channels, and transporters, as well as transmembrane proteins and various soluble macromolecules. As the main component of clathrin-coated pits and vesicles, clathrin forms structures termed triskelia, each composed of three heavy and three light chains [1–5], which in turn assemble into a lattice-like structure on the surface of coated pits. The major proteins that drive coated pit formation are the adaptor protein complex AP-2 [1,6,7] and clathrin assembly proteins such as phosphatidylinositol-binding clathrin assembly protein (PICALM), also known as clathrin assembly lymphoid myeloid leukemia protein (CALM). The neuronal homolog of CALM, AP180, has been shown to be sufficient for clathrin lattice assembly on lipid monolayers and for regulation of clathrin-coated buds and the size and shape of vesicles at the plasma membrane [8–11].

CALM possesses an AP180 N-terminal homology (ANTH) domain that binds to membrane lipids [9,12–15] and specific motifs that bind to clathrin and AP-2, which are the primary components of clathrin-coated vesicles [11,14,15]. Cellular depletion of CALM by RNA interference results in the formation of clathrin-coated structures of abnormal size and shape, which suggests that CALM regulates the proper formation of clathrin-coated vesicles [11].

CALM was originally isolated as a fusion gene, CALM/AF10, which results from the chromosomal translocation t(10;11)(p13;q14). This translocation is a cytogenetic abnormality found in acute lymphoblastic leukemia, acute myeloid leukemia and in malignant lymphomas [16]. In a murine bone marrow transplantation model, expression of CALM/AF10 in primary murine bone marrow cells results in the development of an aggressive form of leukemia [17,18]. These data suggest that CALM may play an important role in the growth and differentiation of hematopoietic cells. This notion is supported by reports that fit1 mutants, which contain nonsense point mutations in the CALM gene, are anemic, display numerous peripheral blood defects, and are deficient in early hematopoietic progenitor cell populations [19–23]. Detailed analysis of the hematopoietic defects of fit1 mutants has yet to be reported, and so the physiological role of CALM remains elusive.

Using a genetic approach to elucidate the function of CALM in mammals, we established CALM-deficient mice through gene
targeting. CALM-deficient mice were growth retarded in utero and remained dwarfed throughout their shortened life-span. In addition, CALM-deficient mice suffered from severe anemia due to ineffective erythropoiesis in the bone marrow. These phenotypes resembled those of floxed mutants. Moreover, the maturation and iron content of erythroid precursors were severely impaired in CALM-deficient mice. In addition, erythroid cells and murine embryonic fibroblasts (MEFs) isolated from CALM-deficient mice exhibited impaired clathrin-mediated internalization of transferrin. These data collectively demonstrate that CALM is required for erythroid maturation and transferrin internalization in mice.

Materials and Methods

Ethics Statement
This study received specific approval from the Committee of Animal Experiments, Nara Women’s University (approval ID 06-15).

Generation of CALM-deficient mice
A genomic clone encompassing the exon that contained the initiation codon (methionine) of CALM was isolated from a C57BL/6 BAC library (BACPAC) using Red/ET methods. A targeting vector was constructed in which the marker gene PGK-neo-pA was inserted into this exon. A DT-A fragment was ligated into the 5’ end of the targeting vector for negative selection. The targeting vector was linearized by Sal I digestion and introduced into TT2 embryonic stem (ES) cells by electroporation [24]. Of 96 G418-resistant clones, 22 were positive for homologous recombination, as determined by PCR (http://www.cdb.riken.jp/arg/Methods.html), eight clones had undergone homologous recombination, as determined by PCR (http://www.cdb.riken.jp/arg/Methods.html), eight clones had undergone homologous recombination as determined by Southern blot analysis. Three clones were injected into 8-cell stage embryos. Chimeras were mated with C57BL/6J females and germline transmission of the disrupted CALM allele was confirmed. Heterozygous F1 mice were intercrossed to produce homozygous CALM-deficient mice (Acc. No. CDB0683K: http://www.cdb.riken.jp/arg/mutant%20mice%20list.html). Genotyping was carried out using PCR and specific primers designed to amplify either the mutant or wild-type allele. The sequences of the primers used for PCR analysis were as follows: primer A: 5’-ATGTCATGGCAGAGAGCTGACG-3’ and calm typing C: 5’-GGTGCTGGAGAGGATGCGGGGGGTCTAC-3’ for the wild-type allele; and Neotg-1: 5’-CTGACGCTTTCTGCAGTCTTACG-3’ and calm typing C for the knockout allele.

Antibodies
For analysis by fluorescence-activated cell sorting (FACS), the following antibodies were purchased from BD Pharmingen: anti-c-Kit (2B8), -Sca-1 (D7), -TER119 (specific for erythroid lineage cells), -Mac-1 (M1/70), -Gr-1 (RB6-8C5), -CD11c (HL3), -B220 (RA3-6B2), -CD44 (IM7), and -CD3e (145-2C11). For immunohistochemistry, an anti-transferrin receptor antibody was purchased from Zymed. Alexa488-conjugated anti-mouse IgG was obtained from Invitrogen. For immunoblot analysis, an anti-β-actin antibody was purchased from Sigma, the anti-CALM polyclonal antibody (G-17) was purchased from Santa Cruz, and the horseradish peroxidase (HRP)-conjugated anti-mouse IgG and anti-goat IgG antibodies were purchased from Thermo Fisher Scientific.

Immunoblot Analysis
Immunoblot analysis was performed as described previously [25]. Briefly, cells were lysed in SDS-PAGE sample buffer, separated by SDS-PAGE, and then transferred to a nitrocellulose membrane. The membranes were incubated in blocking buffer (140 mM NaCl, 1 mM EDTA, and 20 mM Tris-HCl, pH 7.4) containing 5% bovine serum albumin and 0.02% Tween 20, followed by incubation for 1 h at room temperature with primary antibody. Membranes were incubated with the appropriate secondary antibodies diluted in blocking buffer, and then immunoreactive proteins were visualized by enhanced chemiluminescence (GE Healthcare).

Flow cytometry
Flow cytometry were performed using a BD FACS Canto II system (BD Biosciences). The data were analyzed using BD FACSDiva software (BD Biosciences) or FlowJo software (TreeStar, Ashland, OR).

Purification of murine Lin- Sca-1+ c-Kit+ (LSK) cells
Murine fetal liver (FL) cells were harvested from embryonic day 14.5 (E14.5) embryos and mononuclear cells (MNCs) were obtained by density gradient centrifugation. MNCs were incubated with a cocktail of anti-lineage antibodies (Abs): biotinylated anti-CD3ε (145-2C11), -CD45R/B220 (RA3-6B2), -Gr-1 (RB6-8C5), and -TER119 (TER-119) Abs; fluorescein isothiocyanate (FITC)-conjugated anti-Sca-1 (D7); alkaliphosphocyanin (APC)-conjugated anti-c-Kit (2B8); and streptavidin-PE-cy7 (BD Biosciences). LSK cells were obtained by FACS using FACS Aria (BD Biosciences). Staining with 7-amino-actinomycin D (Calbiochem) was used to eliminate non-viable cells.

Hematopoietic stem cell (HSC) transplantation
LSK cells (1×106) obtained from the fetal livers of CALM-deficient and wild-type E14.5 embryos (CD45.2) were transferred into irradiated (1,300 rad) recipients along with 1×106 wild-type LSK cells (CD45.1). The relative contributions from the transferred HSCs were analyzed 9 weeks after transplantation.

Analysis of intracellular labile iron pool (LIP)
Cellular LIP was measured using the fluorescent metalosensor calcein-AM/CA-AM (Invitrogen), as previously reported, with some modifications [26,27]. Briefly, cells were incubated for 1 h with or without 500 μM deferoxamine (DFO) (Sigma) in serum-free media (α-MEM). Following washing with phosphate-buffered saline (PBS), cells were incubated with 250 nM CA-AM in serum-free media (α-MEM) for 30 min at 37°C in PBS, washed twice, and then resuspended at a density of 1×105/mL in PBS containing 1% bovine serum albumin at room temperature. In addition to CA-AM, as indicated, cells were also resuspended with APC-conjugated anti-TER119 and PE-conjugated anti-CD71 Abs. Fluorescence intensity was measured using FACS Canto II (BD Biosciences) in continuous mode. LIP was calculated as the difference in CA mean fluorescence intensity between DFO-treated and -untreated cells.

Image analysis
Microscopic images of May-Grünwald–Giemsa-stained peripheral smears were obtained using an Olympus BX51 microscope equipped with a digital camera (Olympus DP71) and processed with DP Controller software.

CALM-deficient embryonic fibroblastoid cell lines
Primary MEFs were generated from mated wild-type or CALM-deficient mice 14.5 days after conception. Primary MEFs were immortalized by transfection with a plasmid containing SV40 genomic DNA. Briefly, primary MEFs were plated in six-well
plates and transfected with 1 μg of total DNA using Lipofectamine 2000 Reagent (Invitrogen, CA), according to the manufacturer’s instructions. Stable immortalized cell clones were obtained by serial dilution. The expression of CALM protein was assessed by immunoblot. MEFs were cultured in Dulbecco’s modified Eagle’s medium (DMEM) supplemented with 10% fetal calf serum (FCS) and antibiotics (penicillin/streptomycin) at 37°C and 5% CO₂.

**Internalization assay**

To evaluate the uptake of transferrin by erythroblasts, single cell suspensions from fetal liver or bone marrow were incubated in serum-free medium at 37°C for 2 h.

Cells were labeled with 50 μg/ml Alexa Fluor 647-conjugated human transferrin (Invitrogen) in binding buffer (RPMI1640 containing 20 mM HEPES pH 7.4, 1% BSA) on ice for 30 min. After washing to remove unbound transferrin, internalization of transferrin was induced by incubating the cells in buffer (RPMI1640 containing 10% fetal bovine serum) at 37°C for various times. Any transferrin that remained bound to the plasma membrane was removed by incubating the cells in pre-chilled acidic buffer (20 mM MES pH 5.5, 130 mM NaCl, 50 μM deferoxamine, 2 mM CaCl₂ and 0.1% BSA) on ice for 20 min. After washing three times, cells were labeled with FITC-conjugated anti-TER119 Ab and the fluorescence intensity of internalized transferrin in the erythroblast cell population (TER119-high cells) was quantified by FACS Canto II (BD Biosciences).

To detect the internalization of transferrin in MEFs, cells on coverslips were incubated with 10 μg/ml Alexa Fluor 488-conjugated human transferrin (Invitrogen) for 20 min at 37°C, and then fixed with 3.7% formaldehyde in PBS for 15 min at room temperature. After washing with PBS, cover slips were mounted on glass slides using Prolong Gold (Invitrogen) and then analyzed by spinning disc confocal microscopy (CSU10; Yokogawa Electric Co.) using an inverted microscope (IX-71; Olympus) equipped with an Ar/Kr laser, as described previously [25]. To quantitate the internalization of transferrin in MEFs, the fluorescence intensity of randomly selected individual cells (total cell area) was measured and processed using Image J software (http://rsweb.nih.gov/ij/index.html).

**Results**

**Generation of CALM-deficient mice**

To address the functional role of CALM in mice, CALM-deficient mice were generated using a gene targeting approach. The CALM-targeting construct was designed with an expression cassette containing the neomycin-resistance gene (neo) inserted just after the initiation ATG codon in exon 1 of the CALM gene (Fig. 1A). Eight clonal ES cell lines bearing the targeted allele were identified by Southern blot analysis, of which three were used to generate chimeric male mice. Among the F2 offspring, three were used to generate chimeric mice (Fig. 1A).

**CALM-deficient mice exhibit significant growth defects and a shortened life-span**

CALM-deficient mice were obtained at the expected Mendelian ratios (Table 1). The CALM-deficient mice were smaller in size compared to their wild-type littermates (Fig. 2A), and more than 90% died between birth and weaning (Table 1). To characterize the retarded growth phenotype of CALM-deficient mice in more detail, the body weight of CALM-deficient mice and their wild-type littermates was assessed. As shown in Figure 2B, CALM-deficient mice weighed, on average, 35.3% (for males) and 39.7% (for females) of the weight of normal littermates at weaning (28 days of age). Because CALM-deficient mice exhibited a growth retardation phenotype at birth, we also assessed whether CALM was necessary for normal prenatal growth. The weight of CALM-deficient embryos was compared to that of their wild-type littermates at E14.5. CALM-deficient embryos were approximately 74% of the size of normal littermates (data not shown), which suggested that CALM is also required for normal prenatal growth. The phenotype of CALM-deficient mice therefore was retarded growth in utero with mice remaining dwarfed throughout their life-span.

It should be noted that after back-crossing five times with C57B6/J mice, no CALM-deficient mice were obtained, which suggested that CALM deficiency may result in a lethal phenotype that is dependent on the genetic background of B6 and CBA mice.

**CALM-deficient mice suffer from severe anemia**

Many of the tissues in CALM-deficient mice, including liver, kidney and tibia, were smaller compared to wild-type mice (Fig. 2C, E). By marked contrast, however, the spleens of CALM-deficient mice were larger than those of their wild-type littermates, which was indicative of splenomegaly (Fig. 2D). Histologic examination revealed that follicles were absent in the spleens of CALM-deficient mice, which indicating a defect in the B cell population. This was confirmed by FACS analysis, which was consistent with impaired B cell maturation in the spleens of CALM-deficient mice (data not shown). In addition, there were fewer bone marrow cells in CALM-deficient mice and the isolated cell pellets were pale in appearance (Fig. 2F), which suggested a defect in the regulation of hematopoiesis. In fact, the number of TER119-positive erythroid cells in the bone marrow of CALM-deficient mice was significantly reduced compared to control littermates (Fig. 2G). We also observed a ballooning and granular degeneration of hepatocytes (data not shown), indicative of hepatocyte damage. As shown in Table 2, the number of red blood cells (RBCs) in CALM-deficient mice was significantly reduced compared to control littermates, and the mice were severely anemic, with dramatically lower hemoglobin levels. Additionally, peripheral blood in CALM-deficient mice contained hypochromic RBCs (Fig. 2H).

**Maturation of erythroid cells is impaired in CALM-deficient mice**

To investigate whether the severe anemia in CALM-deficient mice was due to defects in erythroid differentiation, the expression of transferrin receptor 1 (CD71) and TER119 was analyzed by FACS, which allows the different stages of maturation of murine erythroblasts to be distinguished [28]. Bone marrow cells were immunostained with FITC-conjugated anti-TER119 Ab and the fluorescence intensity of transferrin receptor 1 (CD71) and TER119 was analyzed by FACS, which was indicative of splenomegaly (Fig. 2D). Histologic examination revealed that follicles were absent in the spleens of CALM-deficient mice, which indicating a defect in the B cell population. This was confirmed by FACS analysis, which was consistent with impaired B cell maturation in the spleens of CALM-deficient mice (data not shown). In addition, there were fewer bone marrow cells in CALM-deficient mice and the isolated cell pellets were pale in appearance (Fig. 2F), which suggested a defect in the regulation of hematopoiesis. In fact, the number of TER119-positive erythroid cells in the bone marrow of CALM-deficient mice was significantly reduced compared to control littermates (Fig. 2G). We also observed a ballooning and granular degeneration of hepatocytes (data not shown), indicative of hepatocyte damage. As shown in Table 2, the number of red blood cells (RBCs) in CALM-deficient mice was significantly reduced compared to control littermates, and the mice were severely anemic, with dramatically lower hemoglobin levels. Additionally, peripheral blood in CALM-deficient mice contained hypochromic RBCs (Fig. 2H).
suggested that erythroid maturation at the stage of proerythroblast to immature erythroblast is impaired in \textit{CALM}-deficient mice. To confirm these results, we also analyzed the expression levels of CD44 and TER119, the relative levels of which have been shown to correlate with different maturation stages of murine erythroblasts [29]. Bone marrow cells were subjected to immunostaining with FITC-conjugated anti-TER119 and APC-conjugated CD44 Abs (Fig. 3 B, D). As shown in Figure 3B and D, \textit{CALM}-deficient mice had significantly lower numbers of cells in region III compared with their wild-type littermates, which supported the idea that erythroid maturation from proerythroblast to immature erythroblast is impaired in \textit{CALM}-deficient mice. These data collectively suggested that the maturation of erythroid cells is severely impaired in \textit{CALM}-deficient mice.

To confirm these results, we also analyzed the expression levels of CD44 and TER119, the relative levels of which have been shown to correlate with different maturation stages of murine erythroblasts [29]. Bone marrow cells were subjected to immunostaining with FITC-conjugated anti-TER119 and APC-conjugated CD44 Abs (Fig. 3 B, D). As shown in Figure 3B and D, \textit{CALM}-deficient mice had significantly lower numbers of cells in region III compared with their wild-type littermates, which supported the idea that erythroid maturation from proerythroblast to immature erythroblast is impaired in \textit{CALM}-deficient mice. These data collectively suggested that the maturation of erythroid cells is severely impaired in \textit{CALM}-deficient mice.

### The erythroid defects in \textit{CALM}-deficient mice are cell autonomous

HSC activity was analyzed by transplantation assay. Fetal liver cells from wild-type or \textit{CALM}-deficient embryos (CD45.2) were transplanted into X-ray irradiated host mice along with a one-tenth fraction of wild-type cells (CD45.1) as a competitor. After 9 weeks, CD45.2-positive hematopoietic cells derived from \textit{CALM}-deficient embryos had repopulated the bone marrow at the same rate as wild-type cells (Fig. 4A). However, after 12 weeks, impaired maturation of early to late stage erythroblasts and abnormal erythroid cells were observed only in host mice transplanted with fetal liver cells from \textit{CALM}-deficient embryos (Fig. 4B and C).
impaired maturation of erythroid cells was confirmed by anti-CD44 staining (data not shown).

In addition, host mice transplanted with fetal liver cells from CALM-deficient embryos were anemic and had fewer RBCs and lower hemoglobin levels than wild-type transplanted mice (data not shown). These results indicated that the observed erythroid defects in CALM-deficient mice were cell autonomous and not a result of the hematopoietic environment.

It should be noted that host mice transplanted with fetal liver cells from CALM-deficient embryos also exhibited splenomegaly, and that there was a similar pattern of progenitor activity in spleen cells as in bone marrow (data not shown). On the other hand, no progenitor activity was detected in spleen cells from host mice transplanted with fetal liver cells from wild-type embryos.

**Incorporation of iron is reduced in erythroid cells of CALM-deficient mice**

Erythroid cells from CALM-deficient mice were severely anemic and erythroid maturation was impaired (Fig. 2, 3 and 4). Since iron deficiency is known to inhibit erythroid differentiation and

doi:10.1371/journal.pone.0031854.g002
induce anemia [30,31], we investigated whether an iron-deficiency in erythroid cells in CALM-deficient mice was the cause of the anemia.

Iron bound to transferrin is taken up by cells via transferrin receptor 1-mediated endocytosis. This is the main pathway of iron intake in erythroid cells. We first analyzed the amount of ferritin and transferrin in the plasma of wild-type and CALM-deficient mice, whereas ferritin levels, which directly correlate with the total amount of iron stored in the body, were three-times higher in CALM-deficient mice than wild-type mice. This suggested that there was an excess of iron in the body of CALM-deficient mice, despite the hypochromic and microcytic anemic phenotype.

Table 2. Hematopoietic parameters of control and CALM−/− mice.

| Genotype | WBC | RBC | Hb  | HCT  | MCV | MCH  | MCHC | PLT |
|----------|-----|-----|-----|------|-----|------|------|-----|
| +/+      | 3.7±0.98 | 875.3±65.5 | 13.2±0.85 | 47.4±3.29 | 54.1±0.44 | 15.0±0.18 | 27.8±0.17 | 80.0±54.45 |
| +/−      | 2.3±0.49 | 840.0±52.4 | 12.6±0.88 | 46.5±2.42 | 55.4±2.13 | 15.0±0.97 | 27.1±0.74 | 103.0±29.90 |

Data were obtained from 3-week-old mice. WBC, white blood cell count (x10⁹/µl); RBC, red blood cell (x10⁹/µl); Hb, hemoglobin (g/dl); HCT, hematocrit (%); MCV, mean corpuscular volume (fl); MCH, mean corpuscular hemoglobin (pg); MCHC, mean corpuscular hemoglobin concentration (g/dl); PLT, platelet count (x10⁹/µl). Data are the mean ± SD of four wild-type, four CALM−/−, and five CALM+/+ mice. Statistical analysis was carried out using the unpaired t-test. **P<0.01, *P<0.05.

Several reports show that CA is pumped out of cells via the multidrug resistance machinery [32]. There were no apparent differences in mean CA-fluorescence intensity in DFO-treated wild-type and CALM-deficient cells, which indicated that there were similar levels of CA in both cell types (Fig. 5D). Thus, it is unlikely that the differences in LIP were due to the multidrug resistance machinery. Taken together, these results indicated that the iron content of erythroid cells at stages I and II is lower in CALM-deficient mice compared to their wild-type littermates. Therefore, altered distribution of iron in CALM-deficient mice inhibits erythroid maturation and results in anemia.

Reduced incorporation of transferrin into erythroid cells and MEFs derived from CALM-deficient mice

Transferrin receptor 1, also known as CD71, is highly expressed in erythroblasts, and uptake of iron-bound transferrin through transferrin receptor 1 is the main pathway of iron uptake in erythroid precursors [33,34]. It is also well established that inhibition of this process inhibits erythroid maturation. Because transferrin is internalized via clathrin-dependent endocytosis [6,35], and CALM localizes to clathrin-coated pits, clathrin-mediated endocytosis of transferrin in CALM-deficient mice was assessed [11,15].

Transferrin uptake by erythroid cells from fetal liver was assessed by FACS, as described in Materials and Methods. The level of transferrin receptor (CD71) expression in TER119-positive erythroid cells from CALM-deficient mice was about 2.5-fold higher than that seen in wild-type cells (3365±1398 and 855±1681 MFI±S.D., respectively; n = 3), which could reflect differences in the internalization of transferrin receptors. Thus, transferrin uptake was normalized to transferrin receptor level for this analysis. In wild-type cells, 62% of bound transferrin was rapidly internalized after 3 min. On the other hand, only 19% of bound transferrin was internalized by CALM-deficient cells (Fig. 6A). Similar results were obtained using wild-type and CALM-deficient erythroid cells derived from neonatal bone marrow (data not shown).

To examine this defect in transferrin internalization in more detail, MEFs were established from wild-type and CALM-deficient E14.5 embryos. Wild-type MEFs expressed the transferrin receptor and transferrin was internalized in a constitutive manner (Fig. 6B). However, CALM knock-out MEFs derived from CALM-deficient embryos failed to incorporate transferrin (Fig. 6B), despite similar overall levels of transferrin receptor (Fig. 6C). Transferrin uptake in wild-type and CALM-deficient MEFs was quantitated and the results are shown in Fig. 6D. Uptake of transferrin by wild-type MEFs was approximately twice that seen in CALM-deficient cells. These results indicated that the internalization of transferrin receptors is abrogated in CALM-deficient cells. Thus, the erythropoietic defects in CALM-deficient mice may be due to inhibition of transferrin endocytosis in the absence of CALM.
Discussion

In this report, we established CALM-deficient mice and showed that these mice exhibit retarded growth in utero and remain dwarfed throughout their shortened life-span. CALM-deficient mice suffer from severe anemia, similar to what has been reported for fit1 mutant mice [21]. In addition, the maturation of erythroid precursors was severely impaired in mice lacking CALM. The iron content of erythroid precursors was lower in CALM-deficient mice compared to their wild-type littermates. Importantly, those
Phenotypes were reconstituted in transplantation experiments. The amount of ferritin in CALM-deficient mice was three-times higher than that in wild-type mice, suggesting that there is an excess of iron in the plasma of mice deficient in CALM.

It is well established that iron deficiency inhibits erythroid maturation [26,27,33,34]. Anemia is the most obvious manifestation of iron deficiency due to the large amount of iron required for hemoglobin production in developing erythroid cells. Transferrin receptor 1-deficient mice die during embryogenesis due to the lack of transferrin-mediated iron uptake [31]. Slc11a2 is the only transmembrane transporter protein known to be required for iron entry into cells and is required for normal hemoglobin production during the development of erythroid precursors. Slc11a2-deficient mice also exhibit severe anemia after birth [30]. Our results suggest that iron deficiency in CALM-deficient mice results in inhibition of erythroid maturation and subsequent anemia.

The question then arises as to which molecule involved in iron uptake is affected by CALM-deficiency in mice. Transferrin receptor 1 (TFR1), also known as CD71, is one such candidate molecule. TFR1 is highly expressed in erythroblasts, and the uptake of iron-bound transferrin through TFR1 is the main pathway by which iron enters erythroid precursors [33,34]. It is also well established that inhibition of this process prevents erythroid maturation due to iron deficiency [31]. Transferrin is taken up by cells through clathrin-dependent endocytosis [6,35]; thus, it is likely that impaired transferrin endocytosis in CALM-deficient mice underlies the inhibition of erythroid maturation. However, the involvement of CALM in clathrin-dependent endocytosis of transferrin remains controversial. While one study has shown that over-expression of full-length CALM and CALM fragments that contain clathrin-binding domains can block transferrin endocytosis [15], another study reports that over-expression of CALM had no effect on transferrin endocytosis [36]. CALM depletion experiments using small inhibitory (si)RNA did not demonstrate an effect on transferrin endocytosis, although there was partial inhibition of epidermal growth factor (EGF) receptor endocytosis [36,37]. Based on these reports, CALM is not believed to be an essential component of clathrin-associated endocytosis of transferrin [11,36,37]. The CALM-deficient mice generated in the current study provided an excellent model system for probing the role of CALM in clathrin-dependent endocytosis of transferrin. Transferrin uptake by erythroid cells was analyzed by FACS, and the results suggested that transferrin uptake is significantly attenuated in CALM-deficient erythroid cells. We also established CALM knock-out (KO) MEFs from CALM-deficient embryos and clearly demonstrated that CALM KO MEFs fail to

Figure 4. CALM is required for normal erythropoiesis. (A) CD45 profile of peripheral blood cells from transplanted mice 9 weeks after transplantation. (B) FACS analyses of erythroblasts at different maturation stages from transplanted mice using anti-TER119 and anti-CD71 Abs. (C) Peripheral blood smears from mice transplanted with fetal liver cells from either wild-type littermates or CALM-deficient embryos. Scale bar, 50 μm. In A, B, and C, (+/+), (−/−) and (+/−) represent host mice transplanted with cells from wild-type and CALM-deficient mice, respectively. doi:10.1371/journal.pone.0031854.g004
Figure 5. Flow cytometry analysis of the LIP. (A) Representative flow cytometry histograms. Erythroblasts at different stages of maturation were identified by double staining with APC-conjugated anti-TER119 and PE-conjugated anti-CD71 Abs (upper). These cells were simultaneously loaded with calcein (CA-AM) for the LIP assay (lower). (B) Quantification of CA-negative fractions in regions I to IV of (A) (data represent means ± SD; n = 3). (C) Representative flow cytometry histograms of E14.5 fetal liver cells. Erythroblasts at different stages of maturation were identified by double staining with APC-conjugated anti-TER119 and PE-conjugated anti-CD71 Abs. Cells were treated for 1 h with the iron chelator DFO, loaded with CA-AM for 10 min, and then analyzed. (D) Representative fluorescence (FL1-high) histograms of CA-stained cells treated with or without DFO are shown, along with mean fluorescence intensity (MFI). (E) The LIP is represented by the difference in MFI between DFO-treated and -untreated cells (data represent means ± SD; n = 3). *, P<0.05 vs. control. In A, B, C and D, (+/+) and (−/−) represent wild-type and CALM-deficient mice, respectively.

Figure 6. Impaired transferrin internalization in CALM-deficient erythroid cells and MEFs. (A) Uptake of transferrin in wild-type or CALM-deficient erythroid cells. Single cell suspensions from fetal livers were analyzed as described in Materials and Methods. Transferrin uptake was normalized to the ratio of mean anti-CD71 (transferrin receptor 1) fluorescence intensity between wild-type and CALM-deficient cells to control for...
incorporate transferrin. Thus, CALM does indeed appear to be involved in transferrin endocytosis in erythroid cells and MEFs. In addition, the LIP in erythroid cells, which represents a crossroads of iron metabolic pathways, was determined. The iron content of erythroid cells was lower in CALM-deficient mice compared to their wild-type littermates. Our results collectively suggest that defective transferrin endocytosis in CALM-deficient mice results in altered distribution of iron in the body and inhibition of erythroid maturation, resulting in an anemic state.

Discrepancies between the results obtained by RNA interference using cell lines and those derived from genetic models in mice are reported for several proteins involved in clathrin-mediated endocytosis, such as SMAP1, epsin 1 and epsin 2 [36–42]. In these cases, impaired endocytosis was reported in response to the inhibition of protein expression by siRNA but not in gene-deficient mice. As suggested previously for other proteins, differences between our results and those of previous studies in terms of the involvement of CALM in transferrin endocytosis could be due to incomplete inhibition of protein expression using siRNA [36,37].

CALM was originally isolated as a component of the CALM/AF10 fusion gene, which results from the chromosomal translocation t(10;11)(p13;q14) [16]. In a murine bone marrow transplantation model, expression of CALM/AF10 in primary murine bone marrow cells results in the development of an aggressive form of leukemia [17,18]. These data suggest that CALM or clathrin-mediated endocytosis may play an important role in leukemogenesis. Recent reports demonstrate that the clathrin-binding domain of CALM is important for leukemogenesis by CALM-AF10 [43,44]. The fact that deletion of CALM resulted in disruption of clathrin-mediated endocytosis of transferrin suggests that clathrin-mediated endocytosis may play a role in leukemogenesis. A number of other proteins that are important for hematopoiesis are substrates of clathrin-mediated endocytosis [45–47]. Thus, the CALM-deficient mice and MEFs established in this study will be useful tools for elucidating the involvement of CALM in leukemogenesis.

CALM plays an important role in the central nervous system (CNS). For example, reduction of CALM expression in hippocampal neurons results in dendritic dystrophy [48]. Although the current study focused mainly on hematological changes in CALM-deficient mice, we did some preliminary analyses of the mouse brain to assess any pathology of the neural system. Although there were no differences observed in the hippocampus and dentate gyrus between wild-type and CALM-deficient mice, there was significant atrophy of the cortex and ventricles were markedly enlarged in CALM-deficient mice (data not shown). A detailed analysis of these observations will be reported elsewhere.

In summary, our analysis of CALM-deficient mice supports an important role for CALM in erythroid maturation and transferrin incorporation via clathrin-dependent endocytosis. A number of other proteins that are important for hematopoiesis are also incorporated into cells via clathrin-mediated endocytosis [45–47]; thus, CALM-deficient mice and MEFs established from these mice should prove to be useful for studying the involvement of CALM in other important hematopoietic processes. Several such experiments are currently underway in our laboratory.

Acknowledgments

We would like to thank Dr. Issay Kitabayashi (National Cancer Center Research Institute, Tokyo, Japan) for stimulating and useful discussions, advice, and helpful comments on our results.
