April 7, 2004

Abstract. Muon pair production through the radiative return is of importance for a measurement of the hadronic production cross section in two ways: it provides an independent calibration and it may give rise to an important background for a measurement of the pion form factor. With this motivation the Monte Carlo event generator PHOKHARA is extended to include next-to-leading order radiative corrections to the reaction $e^+e^- \rightarrow \mu^+\mu^-\gamma$. Furthermore, virtual ISR corrections to FSR from pions are introduced, which extends the applicability of the generator into a new kinematical regime. Finally, the effect of photon vacuum polarization is introduced into this new version of the generator.

1 Introduction

The high luminosity of currently operating $\Phi$- and $B$-meson factories offers the unique opportunity to measure the famous ratio $R \equiv \sigma(e^+e^- \rightarrow \text{hadrons})/\sigma_{\text{point}}$ over a wide range of energies in one single experiment, through the radiative return. This possibility was suggested a long time ago for pion-pair production\textsuperscript{[1]}. In view of the capabilities of the currently operating machines, the idea was revived in\textsuperscript{[2]}, where a Monte Carlo event generator EVA was constructed, which simulates the production of a pion pair plus one hard photon from initial- and final-state radiation (ISR and FSR). The program includes additional collinear radiation from the incoming electrons through structure function techniques and was used to demonstrate the feasibility of such a measurement in ongoing experiments.

* Work supported in part by BMBF under grant number 05HT9VKB0, EC 5th Framework Programme under contract HPRN-CT-2002-00311 (EURIDICE network), TARI project HPRI-CT-1999-00088, Polish State Committee for Scientific Research (KBN) under contract 2 P03B 017 24, BFM2002-00568, Generalitat Valenciana under grant GRUPOS03/013, and MCyT under grant FPA-2001-3031.

The generator was subsequently extended to simulate the production of other hadronic final states: four pions in\textsuperscript{[3,4]} and nucleon pairs in\textsuperscript{[5]}, as well as muons\textsuperscript{[6]}. The influence of collinear lepton pair radiation on these measurements was investigated in\textsuperscript{[7]}.

An important step forward was the evaluation of the complete one-loop corrections to ISR\textsuperscript{[8,9]} and the construction of the event generator PHOKHARA\textsuperscript{[6]}, which included these virtual corrections and the corresponding radiation of two photons. PHOKHARA, like EVA, can be easily used to simulate reactions with arbitrary hadronic final states, once a specific model has been chosen for the relevant matrix element of the hadronic current; it is currently available for $2\pi$, $4\pi$, $pp$ and $n\bar{n}$ production\textsuperscript{[6,8,9]} and of course for muon pairs. A number of cross section measurements based on the radiative return, which have made use of simulations based on EVA and PHOKHARA, have been presented recently: a precise measurement of the pion form factor made by the KLOE Collaboration\textsuperscript{[10,11]}; preliminary results on four-prong final states have been obtained by the BABAR Collaboration\textsuperscript{[12,13]}. Extensive discussions of theoretical and experimental aspects of the radiative return, including various topics not covered by the present paper, can be found in the literature\textsuperscript{[15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30]}. Considerations related to the radiative return can be found in\textsuperscript{[31,32]}; perspectives of its use outside hadronic cross section measurements and the long term potential of the method are outlined in\textsuperscript{[33]}.

Considering measurements with a precision close to one percent, FSR starts to become an issue, in particular the contribution from the two-step process \( e^+e^- \rightarrow \gamma\gamma \rightarrow \pi^+\pi^-\pi^-\) [13]. FSR has to be modeled separately for every different mode. In leading order (LO), it is now included in PHOKHARA for the \( \pi^+\pi^- \) and the \( \mu^+\mu^- \) modes, in next-to-leading order (NLO), i.e. for the two-step process with one hard photon from ISR and real plus virtual radiation from the final state for \( \pi^+\pi^- \) only.

It is the purpose of the present paper to extend the same approach to final states with muon pairs. This is motivated, on the one hand, by the fact that this reaction is an important background for the pion form factor measurement, on the other hand, that it may be used for a measurement of the ratio between hadronic final states and muon pairs of the same invariant mass. This might lead to a direct determination of the \( R \)-ratio, with the cancellation of many uncertainties that arise in the absolute cross section determination.

Although, technically speaking, the treatment of muons is quite similar to that of pions, a number of physics aspects are quite different. First of all, in contrast to radiation from muons, the amplitude for photon radiation from pions can only be parametrized by a model form factor, and the model dependence becomes particularly relevant for energetic photons. Then, at larger cms energies, relevant e.g. to the \( B \)-factories, the leading order FSR with only one photon in the final state is strongly suppressed in the pion case, as a consequence of the pion form factor, whereas the point-like behaviour of the muon leads to important contributions from ISR as well as FSR in leading order.

In order to arrive at a full result for muon pair production at NLO, corrections with combined virtual emission from the initial state and real hard emission from the final state (Fig. 1c) must be included, and combined with those from “simultaneous” soft real ISR and hard FSR (Fig. 1a).

![Fig. 1. NLO corrections to the reaction \( e^+e^- \rightarrow \mu^+\mu^-\gamma \): (a) double real emission, (b) virtual corrections to final-state vertex, and (c) virtual corrections to initial-state vertex. Only representative Feynman diagrams are depicted.](image)

To offer a uniform program, the same contributions will also be included for pion pair production. However, we will demonstrate that their effect is small already for KLOE energies, in particular for the standard KLOE cuts, and completely irrelevant for higher energies.

Finally we study the influence of the leptonic and hadronic vacuum polarization on the radiative return, where we adopt the parametrization suggested in [54]. For the measurement of the integrated cross section with cuts suppressing FSR, vacuum polarization just leads to a multiplicative factor that can be taken into account by correcting the result at the end of the experimental analysis. The forward–backward or the charge asymmetry, however, is affected by vacuum polarization effects in a non-trivial manner.

Let us briefly outline the content of this paper. The amplitudes for real and virtual radiation in NLO for muon pair production, which are the main additional ingredients in the new program, will be introduced in Section 2. Tests of the technical precision of the program and some of its physics results will be presented in Section 3. The ISR correction to real hard FSR for the \( \pi^+\pi^- \) mode will be introduced in Section 4, which also contains a discussion of the influence of this additional term on present experimental studies. The implementation of vacuum polarization and its effect on the cross section and asymmetries will be the subject of Section 5. Section 6 contains a brief summary and our conclusions.

### 2 FSR for muons at next-to-leading order and its implementation in PHOKHARA

The most relevant contributions to FSR at NLO, which are depicted schematically in Fig. 1, consist of double real photon emission diagrams, where one photon is emitted off the initial-state leptons and the other is emitted from the final state (Fig. 1a), final-state vertex corrections to single initial-state photon emission (Fig. 1b), and initial-state vertex corrections to single final-state photon emission (Fig. 1c).

The amplitude for the process depicted in Fig. 1:

\[
e^+(p_1, \lambda_{e^+}) + e^-(p_2, \lambda_{e^-}) \rightarrow \\
\mu^+(q_1, \lambda_{\mu^+}) + \mu^-(q_2, \lambda_{\mu^-}) + \gamma(k_1, \lambda_1) + \gamma(k_2, \lambda_2),
\]

is given by

\[
M_{\text{FSNLO}}(\lambda_{e^+}, \lambda_{e^-}, \lambda_{\mu^+}, \lambda_{\mu^-}, \lambda_1, \lambda_2) = \frac{(-4\pi\alpha)^{3/2}}{Q^2} \left\{ \\
- v^\dagger_{fN}(p_1, \lambda_{e^+}) A(\lambda_{\mu^+}, \lambda_{\mu^-}, \lambda_1, \lambda_2) u_f(p_2, \lambda_{e^-}) \\
+ v^\dagger_{fN}(p_1, \lambda_{e^+}) B(\lambda_{\mu^+}, \lambda_{\mu^-}, \lambda_1, \lambda_2) u_{fN}(p_2, \lambda_{e^-}) \\
+ (k_1 \leftrightarrow k_2, \lambda_1 \leftrightarrow \lambda_2),
\right.
\]

(2)
where the index H indicates that both photons are hard,
\[
A(\lambda_{\mu^+}, \lambda_{\mu^-}, \lambda_1, \lambda_2) = \frac{(\varepsilon^*(k_1, \lambda_1) - k_1^+ - 2\varepsilon^*(k_1, \lambda_1) \cdot p_1) D^- (\lambda_2, \lambda_{\mu^+}, \lambda_{\mu^-})}{2k_1 \cdot p_1} + \frac{D^- (\lambda_2, \lambda_{\mu^+}, \lambda_{\mu^-}) (2\varepsilon^*(k_1, \lambda_1) \cdot p_2 - k_1^+ \varepsilon^*(k_1, \lambda_1)^-)}{2k_1 \cdot p_2},
\]
only, and
\[
B(\lambda_{\mu^+}, \lambda_{\mu^-}, \lambda_1, \lambda_2) = \frac{(\varepsilon^*(k_1, \lambda_1)^+ k_1^- - 2\varepsilon^*(k_1, \lambda_1) \cdot p_1) D^+ (\lambda_2, \lambda_{\mu^+}, \lambda_{\mu^-})}{2k_1 \cdot p_1} + \frac{D^+ (\lambda_2, \lambda_{\mu^+}, \lambda_{\mu^-}) (2\varepsilon^*(k_1, \lambda_1) \cdot p_2 - k_1^+ \varepsilon^*(k_1, \lambda_1)^+)}{2k_1 \cdot p_2},
\]
with
\[
\hat{Q} = p_1 + p_2 - k_1 = q_1 + q_2 + k_2, \quad s' = \hat{Q}^2.
\]
\(D^\mu\) is the current describing the \(\mu^+\mu^-\gamma\) final state which we report below for completeness
\[
D^\mu (\lambda_2, \lambda_{\mu^+}, \lambda_{\mu^-}) = i \epsilon \left\{ u^\dagger_1(q_2, \lambda_{\mu^-}) \tilde{A}^\mu (\lambda_2) v_1(q_1, \lambda_{\mu^+}) + u^\dagger_1(q_2, \lambda_{\mu^-}) \tilde{B}^\mu (\lambda_2) v_1(q_1, \lambda_{\mu^+}) \right\},
\]
with
\[
\tilde{A}^\mu (\lambda_2) = \frac{(2q_2 \cdot \varepsilon^*(k_2, \lambda_2) + \varepsilon^*(k_2, \lambda_2)^- k_2^+)}{2k_2 \cdot q_2} - \frac{\sigma^{-} (2q_1 \cdot \varepsilon^*(k_2, \lambda_2) + k_2^+ \varepsilon^*(k_2, \lambda_2)^-)}{2k_2 \cdot q_1},
\]
\[
\tilde{B}^\mu (\lambda_2) = \frac{(2q_2 \cdot \varepsilon^*(k_2, \lambda_2) + \varepsilon^*(k_2, \lambda_2)^+ k_2^-)}{2k_2 \cdot q_2} - \frac{\sigma^{+} (2q_1 \cdot \varepsilon^*(k_2, \lambda_2) + k_2^- \varepsilon^*(k_2, \lambda_2)^+)}{2k_2 \cdot q_1},
\]
and \(\sigma^{\pm} = (I, \pm \sigma_i)\), where \(\sigma_i\), \(i = 1, 2, 3\), are the Pauli matrices and \(a^{\pm} = a^\pm a^{\mp}\) for any four-vector \(a^\mu\).

The virtual (Fig. 11) plus soft photon corrections to the final-state vertex can be written as
\[
d\sigma_{\text{FSNLO},i}^{\gamma+S} = \frac{\alpha}{\pi} \delta^{\gamma+S}(s, E^{-}_{\text{min}}) ds_{\text{ISR}}(s),
\]
where \(d\sigma_{\text{ISR}}^{(0)}\) is the leading order \(e^+e^- \rightarrow \mu^+\mu^-\gamma\) cross section, with the photon emitted off the initial leptons
\[
\eta^{\gamma+S}(s', E^{\text{cut}}) = -2 \left[ \frac{1 + \beta_{\mu}^2}{2 \beta_{\mu}} \log(t) + 1 \right] \log(2w')
\]
\[
- \frac{\log(t)}{s' \beta_{\mu}} \left[ \frac{5}{2} s' - 7m_{\mu}^2 + 3m_{\mu}^2 x_{\mu} \right] - 2 + \log \left( \frac{1 - \beta_{\mu}^2}{4} \right)
\]
\[
- \frac{1 + \beta_{\mu}^2}{\beta_{\mu}} \left[ 2 \log \left( \frac{2 \beta_{\mu}}{1 + \beta_{\mu}} \right) - \frac{\pi^2}{2} - \log(t) \log \left( \frac{1 + \beta_{\mu}}{2} \right) \right].
\]
\(E^{\text{cut}}\) is the maximal energy of the soft photon in the \(s'\) rest frame, and
\[
\beta_{\mu} = \sqrt{1 - 4m_{\mu}^2/s'}, \quad t = \frac{1 - \beta_{\mu}}{1 + \beta_{\mu}},
\]
\[
w' = E^{\text{cut}} / \sqrt{s'}, \quad \frac{1}{x_{\mu}} = \frac{s'}{2m_{\mu}^2} + 1.
\]
The virtual (Fig. 11) plus soft photon corrections to the initial-state vertex can be written as
\[
d\sigma_{\text{FSNLO},i}^{\gamma+S} = \frac{\alpha}{\pi} \delta^{\gamma+S}(s, E^{-}_{\text{min}}) ds_{\text{ISR}}^{(0)}(s),
\]
where \(E^{\text{min}}\) is the maximal energy of the soft photon (or the minimal energy of the hard photon) in the \(s\) rest frame, while
\[
L = \log \left( \frac{s}{m_t^2} \right) \quad \text{and} \quad w = E^{-}_{\text{min}} / \sqrt{s}.
\]
To match hard, soft and virtual radiation smoothly, the energy cutoff \(E^{\text{cut}}\) has to be transformed from the rest frame of the \(\mu^+\mu^-\gamma\) system (with the photon emitted from the final state) to the laboratory frame \(e^+e^-\) cms frame \(E^{\text{min}}\). In fact it is necessary to recalculate the soft photon contribution, as the cut on \(Q^2 = (q_1 + q_2)^2\) depends in the latter case on the angle between the two emitted photons. Now
\[
\eta^{\gamma+S}(s', E^{\text{cut}}) = -2 \left[ \frac{1 + \beta_{\mu}^2}{2 \beta_{\mu}} \log(t) + 1 \right]
\]
\[
\times \left[ \log(2w') + 1 + \frac{s'}{s'-s} \log \left( \frac{s}{s'} \right) \right] - 2 + \log \left( \frac{1 - \beta_{\mu}^2}{4} \right)
\]
\[
- \frac{\log(t)}{s' \beta_{\mu}} \left[ \frac{5}{2} s' - 7m_{\mu}^2 + 3m_{\mu}^2 x_{\mu} \right] - 1 + \frac{\beta_{\mu}^2}{\beta_{\mu}} \left[ 2 \log \left( \frac{2 \beta_{\mu}}{1 + \beta_{\mu}} \right) - \frac{\pi^2}{2} - \log(t) \log \left( \frac{1 + \beta_{\mu}}{2} \right) \right].
\]
Using Eqs. (2) to (15) the implementation of FSR in combination with ISR is straightforward.
Table 1. Total cross section (nb), corresponding to the $Q^2$ distributions from Fig. 2, for the process $e^+e^- \rightarrow \mu^+\mu^-\gamma$ at NLO, for different values of the soft photon cutoff.

| $w$  | $\sqrt{s} = 1.02$ GeV | 10.52 GeV |
|------|------------------------|-----------|
| 10^{-4} | 28.237(1)             | 0.19854(7) |
| 10^{-5} | 28.236(1)             | 0.19883(14) |

We have not included diagrams where two photons are emitted from the final state, neither final-state vertex corrections with associated real radiation from the final state \cite{37}. This constitutes a radiative correction to FSR and will give non negligible contributions only for those cases, where at least one photon is collinear with one of the muons. Box diagrams with associated real radiation from the initial- or the final-state leptons, as well as pentagon diagrams, are also neglected. As long as one considers charge symmetric observables only, their contribution is neither divergent in the soft nor the collinear limit and thus of order $\alpha/\pi$ without any enhancement factor. We want to stress that we have included only C-even gauge invariant sets of diagrams (see Fig. 9 of Ref. \cite{18} for a graphical representation of the equivalent set of diagrams in pion pair production). The box and pentagon diagrams that we have neglected are related to ISR-FSR interferences, and therefore are suppressed after suitable kinematical cuts used within the radiative return method. One could also neglect some small contributions from the diagrams taken into account, but they are kept for the sake of completeness, as the full 1-loop radiative corrections will be considered in a future publication. At this point these small contributions will become relevant allowing accurate calculations not restricted to radiative return physical configurations.

3 Tests of the Monte Carlo program and discussion of physical results

A number of tests were performed to ensure the technical precision of the new version of PHOKHARA. The square of the matrix element, summed over polarizations of the final particles and averaged over polarizations of the initial particles, was calculated with FORM \cite{38}, using the standard trace method. External gauge invariance was checked analytically when using the trace method and numerically for the amplitude calculated with the helicity amplitude method. The two results for the square of the matrix element summed over polarizations were compared numerically. The code based on the result from the trace method was written in quadruple precision to reduce cancellations. The code based on the result obtained with the helicity amplitude method uses double precision for real and complex numbers and is now incorporated in the code of PHOKHARA 4.0. Agreement of 13 significant digits (or better) was found between the two codes. The sensitivity of the integrated cross section to the choice of the cutoff $w$ can be deduced from Fig. 2 and Table 1. For simplicity the same separation parameter $w$ was chosen for ISR and FSR corrections. Choosing $w = 10^{-4}$ or less, the result becomes independent of $w$, up to expected systematic differences of order $10^{-4}$. These systematic differences are visible already in Fig. 2a, where $\chi^2/d.o.f = 30/14$, while in Fig. 2b statistical errors are about 0.1%, and $\chi^2/d.o.f = 3.5/7$. The tests prove that the analytical formula describing soft photon emission as well as the Monte Carlo integration in the soft photon region are well implemented in the program.

For the purpose of further tests we have also calculated the integrated contribution of hard photon emission from the final state to the ISR spectrum. Integrating over all angles and energies, from $E^2_{cut}$ (defined in the $s'$ rest frame) to the kinematical limit of the final-state photon,
we find that this contribution can be written as

$$d\sigma_{\text{FSNLO},t}^H = \frac{\alpha}{\pi} \eta^H (s', E_2^{\text{cut}}) d\sigma_{\text{ISR}}^{(0)} (s'),$$  \hspace{1cm} (16)$$

where

$$\eta^H (s', E_2^{\text{cut}}) = -1 + \frac{\beta_\mu^2}{\beta_\mu} \left[ \text{Li}_2 \left( \frac{1 - \frac{t_m}{t}}{t} \right) - \text{Li}_2 (t_m t) \right] + \zeta (2) + \frac{\log^2 (t)}{2} - \log (t_m - t) \left[ \frac{1 + \beta_\mu^2}{\beta_\mu} \log \left( \frac{t_m t}{t} \right) - 2 \right] + \frac{\log (t_m)}{\beta_\mu} \left[ \frac{1 - \beta_\mu^2}{\beta_\mu} \text{Li}_2 (t_m) \right] + \log (2) \left[ \frac{1 + \beta_\mu^2}{\beta_\mu} \left( 1 - \frac{\beta_\mu^2}{1 - \beta_\mu^2} \right) \right] + \log \left( \frac{2 \beta_\mu}{1 - \beta_\mu^2} \right)

+ \frac{1}{8} \left[ 17 - \beta_\mu^2 - 2 x_\mu \right] - \frac{x_\mu}{4 \beta_\mu^2} \left[ 33 - 17 \beta_\mu^2 \right] - 2 \log (1 - t_m t),$$  \hspace{1cm} (17)

t, x_\mu and \beta_\mu are defined in Eq. (14), and

$$\beta_\mu = \sqrt{1 - \frac{4 m_\mu^2}{Q_m^2}}, \quad t_m = \frac{1 - \beta_\mu}{1 + \beta_\mu}.$$

Here $Q_m^2$ is the maximum value of $Q^2$

$$Q_m^2 = s' - 2 E_2^{\text{cut}} \sqrt{s'}. $$

For small $E_2^{\text{cut}}$, $w = E_2^{\text{cut}}/\sqrt{s'} \ll 1$, the function $\eta^H$ reduces to

$$\eta^H (s', E_2^{\text{cut}}) \simeq \log (2 w) \left[ 2 + \frac{1 + \beta_\mu^2}{\beta_\mu} \log (t) \right] + \frac{1 + \beta_\mu^2}{\beta_\mu} \left[ \text{Li}_2 (t^2) - \zeta (2) - 2 \log (t) \log \frac{1 + \beta_\mu}{2} \right] + \frac{\log (t)}{8 \beta_\mu} \left[ -5 + \beta_\mu^2 + 6 x_\mu \right] - 2 \log \left( \frac{4 \beta_\mu^2}{1 - \beta_\mu^2} \right)

+ \frac{3}{2} x_\mu + \frac{11}{4}.$$

Adding virtual, soft (Eq. (14)) and hard (Eq. (15)) corrections, the familiar correction factor [39]

$$\eta (s') = \frac{1 + \beta_\mu^2}{\beta_\mu} \left[ 4 \text{Li}_2 (t) + 2 \text{Li}_2 (-t) \right]

- \log (t) \log \left( \frac{1 + \beta_\mu}{8 \beta_\mu^2} \right) + 3 \log \left( \frac{1 - \beta_\mu^2}{4 \beta_\mu^2} \right) - \log (\beta_\mu)

+ \frac{2}{\beta_\mu (3 - \beta_\mu^2)} \left[ \frac{3 \beta_\mu^2}{8} (5 - 3 \beta_\mu^2) - \frac{3}{48} \log (t) \right] \left( 33 + 22 \beta_\mu^2 - 7 \beta_\mu^4 \right)$$

(19)

is recovered.

\begin{figure}[h]
\centering
\includegraphics[width=0.8\textwidth]{fig3.png}
\caption{Comparison between the LO FSR cross section calculated analytically (Eq. (20)) and calculated by PHOKHARA for a fixed value of $w = E_2^{\text{cut}}/\sqrt{s}$. Errors represent one sigma statistical errors.}
\end{figure}

For single-photon emission from the final state and no further photon radiation, a formula similar to Eq. (16) holds:

$$\sigma_{\text{FSR}}^H (s, E_\gamma^{\text{min}}) \sigma_{e^+e^- \rightarrow \mu^+\mu^- \gamma} (s),$$

with $\eta^H$ defined in Eq. (17), $E_\gamma^{\text{min}}$ defined now in the $s$ rest frame and $\sigma_{e^+e^- \rightarrow \mu^+\mu^- \gamma}$ the lowest order cross section of the process $e^+e^- \rightarrow \mu^+\mu^-\gamma$.

The results of the tests are collected in Figs. 3 and 4 proving the excellent technical precision of this part of PHOKHARA, well below 0.05%. Results of similar tests at NLO are collected in Fig. 5 where results of PHOKHARA are compared with the analytical result of Eq. (19). The latter checks the technical precision of the implementation of double-photon emission, where one photon is emitted from the initial state and the other from the final state, together with the corresponding virtual and soft corrections to the final-state vertex. An agreement of 1% on the function $\eta$ means in fact an agreement better than $10^{-4}$ on the cross section thanks to the additional factor $\alpha/\pi$ (compare Eq. 3 and Eq. 20).

The relative size the NLO FSR contributions to the $e^+e^- \rightarrow \mu^+\mu^-\gamma$ cross section introduced in PHOKHARA depends on the event selection used. In the following, we will indicate some of its characteristic features. In Fig. 6 the $Q^2$ differential cross section is shown with two peaks at low (‘soft’ muon pair production) and large $Q^2$ (soft photon emission) values. In Fig. 7 the corresponding relative NLO FSR contributions are shown. They are $Q^2$-dependent and might be as big as a few per cent. As seen by comparison of Figs. 3 and 5 the relative size of this contribution does depend on the event selection used.

At KLOE, the process $e^+e^- \rightarrow \mu^+\mu^-\gamma$ is a background to the measurement of the $e^+e^- \rightarrow \pi^+\pi^-$ cross
section by the radiative return method, due to possible pion–muon misidentification. The angular cuts used by now by KLOE diminish the low pion–muon misidentification. The angular cuts used by the radiative return method, due to possible statistical errors.

The process $e^+e^- \rightarrow \mu^+\mu^-\gamma(\gamma)$ is even more important for BABAR, where it is used as $Q^2$-dependent luminosity monitoring. As a result the accuracy requirement is higher. In Fig. 5 some features of the newly implemented corrections are shown in the interesting $Q^2$ range, from the point of view of using the radiative return method for measurements of the hadronic cross section. In Fig. 5 the $Q^2$ differential cross section is given, including and excluding NLO FSR corrections. As seen from Fig. 5, the relative size of those corrections is quite small, of the order of 1%, if no angular cuts are applied; but, as shown in Fig. 5, their relevance depends on the event selection and the corrections can be as big as 10% for some event selection and $Q^2$ range.

4 ISR corrections to FSR real hard emission for two-pion final state

Initial-state vertex corrections to FSR for the reaction $e^+e^- \rightarrow \pi^+\pi^-\gamma$ (Fig. 9a) were not included in version 3.0 of PHOKHARA, and therefore, for consistency, double photon radiation (Fig. 9b) was restricted to emission from the final state, are expected to be smaller, but will be relevant anyhow if the precision requirement for the background estimate is of the order of a few per cent.

The process $e^+e^- \rightarrow \mu^+\mu^-\gamma(\gamma)$ is even more important for BABAR, where it is used as $Q^2$-dependent luminosity monitoring. As a result the accuracy requirement is higher. In Fig. 5 some features of the newly implemented corrections are shown in the interesting $Q^2$ range, from the point of view of using the radiative return method for measurements of the hadronic cross section. In Fig. 5 the $Q^2$ differential cross section is given, including and excluding NLO FSR corrections. As seen from Fig. 5, the relative size of those corrections is quite small, of the order of 1%, if no angular cuts are applied; but, as shown in Fig. 5, their relevance depends on the event selection and the corrections can be as big as 10% for some event selection and $Q^2$ range.

We report here also formulae analogous to Eqs. (10) and (15), as we have found representations simpler than
H. Czyż et al.: Radiative return at $\Phi$- and $B$-factories: FSR for muon pair production at next-to-leading order

Fig. 6. The size of the NLO FSR corrections (IFSNLO) compared with the sum of NLO ISR and LO ISR and FSR contributions (IFSLO) to the $e^+e^-\rightarrow\mu^+\mu^-\gamma(\gamma)$ cross section: a) $Q^2$ differential cross sections with no angular cuts; b) relative difference of the cross sections with angular cuts used by KLOE; c) relative difference of the cross sections with angular cuts used by KLOE (no track mass cut); c) relative difference of the cross sections with angular cuts used by KLOE (with track mass cut). The track mass cut allows only for two-photon events and here IFSR stands for two- and one-photon ISR + one-photon FSR, while ISR stands for two-photon ISR only.

Fig. 7. The size of the NLO FSR corrections (IFSNLO) compared with the sum of NLO ISR and LO ISR and FSR contributions (IFSLO) to the $e^+e^-\rightarrow\mu^+\mu^-\gamma(\gamma)$ cross section: a) $Q^2$ differential cross sections with angular cuts used by KLOE; b) relative difference of the cross sections with angular cuts used by KLOE (no track mass cut); c) relative difference of the cross sections with angular cuts used by KLOE (with track mass cut). The track mass cut allows only for two-photon events and here IFSR stands for two- and one-photon ISR + one-photon FSR, while ISR stands for two-photon ISR only.
Fig. 8. The size of the next-to-leading FSR corrections (IF-SNLO) compared with the sum of NLO ISR and LO FSR contributions (IFSLO) to the $e^+e^-\rightarrow \mu^+\mu^-\gamma(\gamma)$ cross section: a) $Q^2$ differential cross sections with no angular cuts at $B$-factories; b) relative difference of the cross sections with no angular cuts; c) relative difference of the cross sections with angular cuts resembling the BABAR detector (in $e^+e^-$ cms). If two photons are emitted, both hard (with energy $>100$ MeV) photons are required to be within indicated angular cuts.

Fig. 9. Virtual (a) and real (b) radiative corrections to real FSR emission from two-pion final state.

previously reported in [15]. The virtual plus soft corrections, with soft photon energy cut $E^\text{cut}_\gamma$ in the $s'$ rest frame, read

\[
\eta^{V+S}(s', E^{\text{cut}}_{\gamma}) = -2 \left[ \frac{1 + \beta^2_{\pi}}{2 \beta_{\pi}} \log(t_{\pi}) + 1 \right] \log(2w) - \frac{2 + \beta^2_{\pi}}{\beta_{\pi}} \log(t_{\pi}) - 2 + \log \left( \frac{1 - \beta^2_{\pi}}{4} \right) - \frac{1 + \beta^2_{\pi}}{2 \beta_{\pi}} \left\{ -2 \log(t_{\pi}) \log \left( \frac{1 + \beta_{\pi}}{2} \right) + 4 \text{Li}_2 \left( \frac{2 \beta_{\pi}}{1 + \beta_{\pi}} \right) - \pi^2 \right\},
\]

where $w = E^{\text{cut}}_\gamma / \sqrt{s}$, $\beta_{\pi} = \sqrt{1 - 4m_{\pi}^2/s'}$ and $t_{\pi} = (1 - \beta_{\pi})/(1 + \beta_{\pi})$, while, with a soft photon energy cut $E^{\text{min}}_{\gamma}$
depends on the event selection. If no angular cuts are imposed they contribute up to 2–3% to the \( Q^2 \) differential cross section, as shown in Fig. 10. However, for KLOE cuts used for low-angle measurements of the pion form factor, the additional IFSNLO corrections, not included in PHOKHARA 3.0, are well below 0.1%, as anticipated in [13]. It is shown in Fig. 11 for event selections with and without the track mass cut. It is worth mentioning that the IFSNLO corrections change also the ratio

\[
\mathcal{R}(Q^2) = \frac{4(1 + \frac{2w^2}{Q^2}) \beta_\mu \frac{d\sigma}{dQ^2}}{\frac{d\sigma}{dQ^2}},
\]

which is expected to be 1 for ISR only, when no cuts are applied. From Figs. 12 and 13 it is clearly visible that one has to take the IFSNLO corrections into account and use a Monte Carlo event generator, when extracting the pion form factor from the ratio of pion and muon cross sections. This is true at both \( \Phi \)- and \( B \)-factories. A similar situation can be expected for other hadronic final states.

5 Vacuum polarization implementation

PHOKHARA 4.0 includes also vacuum polarization corrections for all final hadronic states and muon production, with the actual implementation of Ref. [34]. As can be anticipated from Fig. 11 the vacuum polarization corrections are calculated at different scales for different types of diagrams \((Q^2, Q^2, s, \text{etc.})\). In the energy range that is important for measurements of the components of the hadronic cross section through the radiative return method, the vacuum polarization corrections have a non-trivial behaviour (see Fig. 14) due to the hadronic contributions. For event selections, for which only ISR corrections are important, the vacuum polarization contribution is just a multiplicative factor depending on \( Q^2 \), so that one can correct the event generator results even after generation. However, for event selections where other contributions are also important, event generation with complete implementation of vacuum polarization might become necessary. An example is shown in Fig. 15 where the vacuum polarization contributions do change the forward–backward asymmetry of the pion polar angle distribution. The effect, of up to 5%, is mainly caused by the choice of \( s \) in the close vicinity of the \( \Phi \) resonance, which is nothing but the KLOE case. As seen in Fig. 15 the vacuum polarization around the \( \Phi \) is much larger than at lower energies. As a result, the vacuum polarization correction to the ISR–FSR interference, which contributes to the numerator of the asymmetry, is larger than the corresponding corrections to its denominator, which is dominated by ISR. Therefore, vacuum polarization corrections do not drop in the ratio. This effect has to be taken into account, when studies of model dependence of FSR are performed.

6 Summary and Conclusions

Precision measurements of the hadronic cross section through the radiative return to an accuracy of about 1% require the
Fig. 12. The ratio \( R \) of Eq. \ref{eq:ratio} for \( \sqrt{s} = 1.02 \) GeV, for three different event selections.

Fig. 13. The ratio \( R \) of Eq. \ref{eq:ratio} for \( \sqrt{s} = 10.52 \) GeV and two different event selections.

Fig. 14. The energy dependence of \( \Delta \alpha \) calculated by the program of Ref. \cite{34}. 

\[ \sqrt{s} = 1.02 \text{ GeV} \]
\[ 0^\circ < \theta_\gamma < 180^\circ \]
\[ \theta_\gamma < 15^\circ \quad \text{or} \quad \theta_\gamma > 165^\circ \]

\[ \sqrt{s} = 10.52 \text{ GeV} \]
\[ 20^\circ < \theta_\gamma < 160^\circ \]
\[ 30^\circ < \theta_\gamma < 150^\circ \]
full understanding of radiative corrections and their implementation in a Monte Carlo event generator. For this reason a number of new features have been introduced into the Monte Carlo event generator PHOKHARA.

In a first step we presented the formulae for real and virtual radiation, which are required to describe FSR for muon pair production through the radiative return in next-to-leading order. This includes a specific set of virtual corrections as well as real radiation. The Monte Carlo event generator PHOKHARA has been upgraded and, in its present form, also simulates the contribution from the “two-step” reaction $e^+e^- \rightarrow \gamma\gamma^* (\rightarrow \mu^+\mu^-)$. The technical precision of the generator in this new mode has been demonstrated to be better than $10^{-4}$. It is shown that the relative importance of this NLO correction depends strongly on the details of the experimental cuts.

The program has also been extended to the case of pion production. In particular corrections from virtual plus soft ISR, in combination with hard FSR, have been introduced. Although the impact of this additional piece is small, as far as actual measurements at KLOE or the B-factories are concerned, it is required for a complete NLO treatment of the radiative return for pion-pair production. Another straightforward upgrade is the introduction of vacuum polarization in the photon propagator. As far as charge-symmetric cross section measurements are concerned, this effect can just be considered as a multiplicative, $Q^2$-dependent change of the normalization. However, interference terms between amplitudes with virtual photons of different virtualities, which are relevant to e.g. the forward–backward asymmetry, do lead to modifications of the results at the level of several per cent.
