**Abstract**

Background: *Fusobacterium nucleatum* is a Gram-negative anaerobic bacterium associated with periodontal disease. Some oral bacteria, like *Porphyromonas gingivalis*, evade the host immune response by inhibiting inflammation. On the other hand, *F. nucleatum* triggers inflammasome activation and release of danger-associated molecular patterns (DAMPs) in infected gingival epithelial cells.

Methods: In this study, we characterized the pro-inflammatory response to *F. nucleatum* oral infection in BALB/c mice. Western blots and ELISA were used to measure cytokine and DAMP (HMGB1) levels in the oral cavity after infection. Histology and flow cytometry were used to observe recruitment of immune cells to infected tissue and pathology.

Results: Our results show increased expression and production of pro-inflammatory cytokines during infection. Furthermore, we observe that *F. nucleatum* infection leads to recruitment of macrophages in different tissues of the oral cavity. Infection also contributes to osteoclast recruitment, which could be involved in the observed bone resorption.

Conclusions: Overall, our findings suggest that *F. nucleatum* infection rapidly induces inflammation, release of DAMPs, and macrophage infiltration in gingival tissues and suggest that osteoclasts may drive bone resorption at early stages of the inflammatory process.

The oral cavity is colonized with hundreds of different species of bacteria which compose the oral microbiome [1,2]. Some common bacteria found in individuals afflicted with periodontitis include *Fusobacterium nucleatum*, *Porphyromonas gingivalis*, and *Aggregatibacter actinomycetemcomitans* [3,4]. Gingivitis is diagnosed when the gingiva, or gums, reveals signs of swelling, redness, or chronic bleeding [5], usually associated with gingival infection. However, chronic inflammation can lead to development of periodontitis with signs of deep periodontal pockets, alveolar bone resorption, and tooth loss [6,7].

The tooth is surrounded by the gingival epithelium. This microenvironment is optimal for growth of anaerobic bacteria and provides an opportunity for pathogenic bacteria to attach and coaggregate into biofilms [8]. *F. nucleatum* is one of the predominant bacteria and contributes to biofilm formation [9–11]. The bacteria utilize adhesion mechanisms of lectin-like and non-lectin-like interactions and adhesion peptides, such as FadA (*Fusobacterium* adhesin A) for attachment [12–16]. These interactions facilitate coaggregation or infiltration into lymphocytes, polymorphonuclear neutrophils, erythrocytes, epithelial cells, and fibroblasts [11,12,14,17,18].

The oral epithelium defends against bacterial colonization by secretion of antimicrobial peptides called defensins [4,19–21]. β-defensins target bacteria as the peptides are electrostatically attracted to their negative charged membranes and induce pore formation [4,19,22]. Antimicrobial peptides can also act as chemotacticants and recruit other immune cells, neutrophils or T cells [4,7,19]. Thus, β-defensins play an active role as part of innate and adaptive responses to oral infection.

Gingival epithelial cells (GECs) represent a major barrier to infection by invasive bacteria, and also contribute to immune recognition of the pathogens and the immune response [23,24]. When pathogen-associated molecular patterns (PAMPs) of bacteria are recognized by host pathogen recognition receptors (PRRs) on GECs, they activate NF-κB and induce expression of cytokines and chemokines, and recruit neutrophils and macrophages [25–27]. Recognition of *F. nucleatum* and *A. actinomycetemcomitans* infection results in production of cytokines such as IL-1β [28–30]. TNF-α and IL-17 can also synergize with IL-1β to enhance expression and production of other cytokines (e.g., IL-6) and defensins, along with endothelial activation to enhance the immune response [31–36].

Although the goal of inflammation is to resolve oral infection, it can also lead to bone resorption. Alveolar bone is one of the most dynamic bones in the body, as osteoclasts and osteoblasts continually induce bone remodeling to maintain homeostasis [37–40]. Osteoclasts are resorptive cells that are activated and differentiated by macrophage-colony stimulating factor, receptor activator of nuclear factor kappa-B ligand (RANKL)-RANK signaling, interleukins, and TNF-α [38,39,41–43]. Once osteoclasts adhere to bone, a ruffled border is created between the activated osteoclast and bone [38,40], and osteoclasts are able to degrade the mineral matrix [38,40]. Degraded bone matrix is removed as it is transcytosed in vesicles through osteoclasts, and fuses with cytoplasmic vesicles containing tartrate-resistant acid phosphatase (TRAP) to be released in the extracellular matrix [38,44]. Phagocytes remove the debris and osteoblasts are recruited for bone formation after osteoclasts detach from the bone [38].

*F. nucleatum* mechanisms for invasion and host response have been evaluated both in *vitro* and in *vivo* [3,45–48]. We have previously reported that *F. nucleatum* infection induces inflammasome activation and release of cytokines and danger signals in human GECs in *vitro* [29,46]. In this study, we examined the immune response to *F. nucleatum* oral infection in BALB/c mice, which had not been previously characterized.

**Materials and methods**

**Bacteria**

*F. nucleatum* (ATCC 25586) was cultured at 37 °C under anaerobic conditions in brain-heart infusion broth supplemented with yeast extract (5 mg/mL), hemin (5 μg/mL), and menadione (1 μg/mL). Erythromycin (5 μg/mL) was used as a selective agent for *F. nucleatum* as previously described [49]. After 24 h of growth, bacteria were collected by centrifugation at 6000 × g for 10 min at 4 °C, washed twice and resuspended with phosphate-buffered saline (PBS). Quantification of bacteria was measured by optical density (OD) to obtain a concentration of 10⁹ colony-forming units (CFU)/ml using a reference standard.

**Mice and oral challenge with *F. nucleatum***

BALB/c mice were obtained from the animal facility of the Institute of Biophysics Carlos Chagas Filho at the Federal University of Rio de Janeiro. All protocols used in this study followed the guidelines and were approved by the Institutional Animal Care and Use Committee at the Federal University of Rio de Janeiro (CEUA-UFRJ 076/15).

Six-to eight-week-old male BALB/c mice were given ad libitum water containing 10 mL of Bactrim (Roche) comprised of sulfamethoxazole/trimethoprim for 10 days. Then antibiotic-free water was given to the mice for 3 days prior to infection. The protocol for oral infection was adapted from Baker et al. [50]. On days of infection, mice were anesthetized with 100 μL of ketamine-xylazine solution (100 mg/ml and 20 mg/ml) by intraperitoneal injection. Anesthetized mice
were orally challenged with *F. nucleatum* at $10^9$ bacteria in 100 μl of PBS with 2% carboxymethylcellulose (Sigma), or were sham-infected with the same solution containing no bacteria three times over 2-day intervals.

**Collection of maxilla**

Maxillas were surgically removed collected at days 1, 4, and 7 after the last infection day. Half maxilla was placed in TRIzol Reagent (Life Technologies) for PCR analysis and the other half in cell lysis buffer (Sigma) containing protease inhibitor (Roche) for western blotting analysis. Then the samples were macerated and homogenized using TissueLyser LT (Qiagen) for 5 min at 50 Hz. After centrifugation at 1000 g for 10 min supernatants were transferred to new tubes and used for experiments. Prior to protein assays, maxilla halves from each group of mice were pooled together and quantified using Pierce BCA Protein Assay Kit (Thermo Fisher Scientific) for equal loading.

**Isolation, processing and analysis of murine gingival cells**

The isolation, processing and analysis of murine maxilla gingival cells collected from uninfected or *F. nucleatum*-infected mice was as described by Mizraji et al., 2013 [51]. Briefly, after the protocol for oral infection, mice were euthanized and both upper and lower mandibles were collected. The mandibles were cut into hemi-maxillae and the palatal tissue was trimmed until reaching the alveolar bone. Gingival tissues were peeled using forceps (without teeth), placed in 1 ml PBS - 2% FCS, 2 mg/mL of collagenase type II and 1 mg/mL of DNase type 1, well minced and incubated in a shaker incubator for 20 min at 37 °C, 200 rpm, plus an additional 10 min after adding 20 μl of EDTA 0.5 M. Samples were washed with 12 ml of PBS - 2% FCS and centrifuged at 4 °C, 400 × g for 8 min. Cells were resuspended with 2 ml PBS + 2% FCS and filtered on a 70 μm cell-strainer. The collected samples were centrifuged at 4 °C, 320 × g for 5 min and resuspended with 300 μl PBS + 2% FCS for cellular quantification and antibody staining.

**Flow cytometry analysis**

Freshly isolated murine gingival cells were immunostained for flow cytometry analysis. 5 × $10^5$ cells were stained with 0.1 μg/mL Fixable Viability Stain 510 (FVS510) – BD Horizon™ for 15 min at room temperature to distinguish live and dead cells. After washing with PBS, cells were blocked for nonspecific binding with 5 μg/mL with CD16/32 mAb for 20 min on ice and stained with the following monoclonal antibodies (eBioScience) for 30 min at 4 °C: 1 μg/mL anti-CD90 (Thy-1.2) APC (Clone 53–2.1), 1 μg/mL anti-F4/80 Antigen eFluor® 450 (Clone BM8), 1 μg/mL anti-Ly-6C PE (clone 1A8-Ly6g), 2.5 μg/mL anti-CD11b Alexa Fluor® 488 (Clone M1/70). Cells were washed with PBS, fixed with 4% paraformaldehyde for 20 min at room temperature and kept at PBS until their acquisition by flow cytometry. Fluorescence was evaluated by acquiring 50,000 events/sample using FACSCanto II (BD Biosciences, San Jose, California, USA). Results were analyzed using the FACSDiva (BD Biosciences, San Jose, California, USA) and presented as percentage of positive events.

**RNA extraction and quantitative PCR**

Following the manufacturer's instructions, total RNA was extracted using Trizol Reagent (Life Technologies). Total RNA was quantified by using NanoDrop (Thermo Fisher Scientific). RNA was converted to cDNA using High-Capacity cDNA Reverse Transcription Kit (Life Technologies). Quantitative PCR was performed using SYBR-green fluorescence quantification system (SYBR Select Master Mix (Life Technologies)). Real-time PCR cycling parameters were as follows: 95 °C for 10 min and then 40 cycles of 95 °C for 30 s, 60 °C for 1 min, and 72 °C for 1 min. The following primers were used as previously described: IL-1β forward, 5'-TTCACGGACGGCAATGATCCTC-3', IL-1β reverse, 5’-CCACGGAAAGACACAGGTAG-3'; TNFα forward, 5’-TTTCTATGGGCCAGACCTCTCA-3'; TNFα reverse, 5’-GGTGTGTTGCTACCGAGCGTG-3'; IL-6 forward, 5’-TTTCAAGATGGGAGGAGCCG-3'; IL-6 reverse, 5’-TGTTGAGATTGAGGGACC-3'; IL-17 forward, 5’-TCACGCGTGTCCCAAACACTG-3'; IL-17 reverse, 5’-GACTTGGAGGTTGACCTTCAT-3'; GAPDH forward, 5’-GGTCATCCCAAGCTGACAC-3'; GAPDH reverse, 5’-TTCGCTGTTGAACTCAGAGC-3' [52]. Relative expression levels were calculated against GAPDH as the reference gene using the comparative cycle threshold method. Quantification of infected mice results were normalized against control mice.

**PCR**

The PCR was performed following the protocol from Liu et al. [53]. Maxilla RNA targeted a 360-bp region using *F. nucleatum* forward, 5’-AGAGGTGTAGTCTGCGCTG-3' and reverse, 5’-GTATCGCGACACAGAGATTGTC-3' primer sequences [53]. The samples were amplified using GoTaq Green Master Mix (Promega) under the same conditions of 5 min at 94 °C and 30 cycles, with each cycle consisting of denaturation at 94 °C for 30 s, annealing at 58 °C for 30 s, extension at 72 °C for 1 min, and final extension for 10 min. PCR products were loaded onto a 2% gel in Tris-acetate buffer with EDTA. The gel was stained with GelRed nucleic acid gel stain (Biotium) and visualized under UV light.

**ELISA**

Homogenized maxilla were used for ELISA experiments. IL-1β, IFN-γ, and TNF-α cytokine levels were measured using Mouse IL-1β, IFN-γ, and TNF-α ELISA kits (R&D Systems). ELISAs were performed following manufacturer's instructions.

**Western blot**

Protein samples were dissolved in 6X Laemmli buffer and boiled. Then they were run on SDS-PAGE gels and transferred to PVDF membranes. Membranes were blocked with 5% BSA and incubated with anti-HMGCR (Abcam) overnight. After primary incubation, the membranes were washed and incubated with HRP conjugated anti-goat IgG antibody (Millipore). Finally, the membranes were developed with Lumi-nata Forte (Millipore) substrate. Images were acquired using ImageQuant LAS 4000 system and analyzed using NIH-Image.
Fig. 1 Gene expression is upregulated in the maxilla during F. nucleatum infection. (A–E) Relative IL-1β, IFN-γ, TNF-α, IL-6, and IL-17 mRNA gene expression compared with control was evaluated by real-time PCR (qPCR) from the maxilla of F. nucleatum infected BALB/c mice. Days 1, 4, and 7 post-infection were tested. Results represent an average of three independent experiments with at least 4 mice in each group per experiment. Error bars represent the mean ± SD. (*<0.05, **<0.01, Student’s t-test).

Histopathology and immunohistochemistry

For morphological studies mandibles were collected and were immediately immersed in zinc-formaldehyde for fixation for 72 h. Next, tissues were decalcified in Morse’s solution for 7 days. The complete decalcification of bones was manually assessed. Tissues were then washed in water and dehydrated crescent solutions of ethanol, clarified in xylene and embedded in paraffin. Five-micrometer sections were cut and stained with hematoxylin-eosin (H&E). For immunohistochemistry, paraffin sections were collected onto charged histological slides. A rat monoclonal antibody F4/80 (Abd Serotec) was used to detect macrophages. Briefly, after dewaxing and rehydrating, sections were submitted to endogenous peroxide inhibition (15 min with 3% H2O2 in methanol), followed by an enzymatic antigen retrieval, with a 0.1% trypsin solution for 14–18 h, at 4 °C, in a humid chamber. The sections were then washed in 0.25% Tween-phosphate saline buffer (PBS) solution for 5 min and then the secondary antibody conjugated to peroxidase were incubated for 1 h at room temperature (Nichirei). The chromogen substrate was diaminobenzidine (Dako). Negative control slides were incubated with rat nonimmune serum or with the antibody diluent solution.

Histomorphometry

Histomorphometry was performed using a computer-assisted image analysis system comprising a Nikon Eclipse E-800 microscope connected via a digital camera (Evolution, Media Cybernetics Inc., Bethesda, MD) to a computer. The graphical interface software Q-Capture 2.95.0, version 2.0.5 (Silicon Cybernetics Inc., Bethesda, MD) to a computer. The graphical interface software Q-Capture 2.95.0, version 2.0.5 (Silicon Graphic Inc., Milpitas, CA) was used. Ten high quality photomicrographs (high-quality images, 2048 × 1536 pixel buffer) were randomly captured from tissues of each animal using the 40× objective lens.

Quantification of the number of F4/80 macrophages

The number of macrophages was quantified in F4/80-stained sections. Results were expressed as the number of macrophages/histological field.

AFM force spectroscopy

For force spectroscopy studies, uninfected and 1, 4 and 7 days infected mandibles were collected and immediately immersed in PBS. After, tissues were cleaned, and the region of alveolar bone was exposed to start the measurement. Bone region was examined in a Dimension Icon Scanning Probe Microscopy (Bruker, Santa Barbara – CA). RTESPA-300 AFM probe (Bruker, Camarillo – CA) was used and its cantilever elastic constant was obtained by thermal noise method. Force curves were acquired in air using contact mode and young modulus elasticity was extracted by those curves using NanoScope Analysis 1.5 software (Bruker, Santa Barbara – CA).

Statistical analysis

Results are shown as mean ± standard deviation (SD). Statistical significance was calculated by two-tailed Student’s t-test and differences were considered significant at P < 0.05.

SPM results were evaluated by one-way Anova followed by Dunnett’s test and differences were considered significant at p < 0.05.

Results

F. nucleatum infection induced pro-inflammatory cytokine expression in maxilla

To assess cytokine expression in F. nucleatum-infected mice, we isolated RNA from the maxilla at various time points post-infection. Since F. nucleatum infection in GECs led to a time-dependent increase of IL-1β gene expression in vitro [46], we determined whether oral infection of F. nucleatum in mice would similarly upregulate IL-1β gene expression over a course of 7 d.p.i. (days post infection) [Fig. 1A]. Indeed, we observed a significant induction of IL-1β 1 d.p.i. compared to uninfected mice followed by a decrease in the transcriptional response thereafter. Because it was already known that F. nucleatum-infected BMDMs trigger cytokine production (such as IL-1β, TNF-α, and IL-6) through the Toll-like receptor (TLR) signaling pathway [54], we analyzed mRNA expression of other pro-inflammatory cytokines in our in vivo model of F. nucleatum infection. IFN-γ and IL-6 mRNA expression followed the same time-dependent response...
described for IL-1β, with an increase of gene expression at 1 d.p.i., decreasing thereafter [Fig. 1B and D]. On the other hand, TNF-α enhancement was delayed (at 4 d.p.i.) but also declined thereafter [Fig. 1C]. Since IL-17 is implicated in bone resorption [52-55], we examine its transcriptional response and found that it was upregulated early during infection, at 1 d.p.i., as observed for IL-1β, IFN-γ, and IL-6 [Fig. 1E]. The results indicated that multiple pro-inflammatory cytokines were upregulated during the course of F. nucleatum infection.

Cytokine production is enhanced in the maxilla during F. nucleatum infection

To directly evaluate cytokine production, we performed ELISA analysis using maxilla samples of infected mice and found that IL-1β and IFN-γ levels increased at 4 d.p.i.; i.e., 3 d after the transcriptional activation of these genes [Fig. 2A and B]. Additionally, a slight (non-statistically significant) increase of TNF-α was noted at 4 d.p.i. [Fig. 2C].

To further analyze the cytokine production, we determined by Western blotting the presence of the immature and mature forms of IL-1β in the maxilla of F. nucleatum-infected BALB/c mice at day 4. Actin (42 kDa) was used as a loading control. (E) Relative protein was measured by quantification of densitometry using NIH-ImageJ. (A–C) represent an average of three independent experiments with at least 4 mice in each group per experiment. (D and E) represent average of 4 mice in each group. Error bars represent the mean ± SD. (*< 0.05, **< 0.01, Student’s t-test).

Fig. 2 F. nucleatum infection induces increased cytokine production in the maxilla. (A–C) The cytokines IL-1β, IFN-γ, and TNF-α were measured by ELISA. Maxilla from days 1, 4, and 7 post-infection with F. nucleatum were evaluated. (D) Western blotting to evaluate immature pro-IL-1β (33 kDa) and mature IL-1β (17 kDa) protein expression from the maxilla of F. nucleatum-infected BALB/c mice at day 4. Actin (42 kDa) was used as a loading control. (E) Relative protein was measured by quantification of densitometry using NIH-ImageJ. (A–C) represent an average of three independent experiments with at least 4 mice in each group per experiment. (D and E) represent average of 4 mice in each group. Error bars represent the mean ± SD. (*< 0.05, **< 0.01, Student’s t-test).

F. nucleatum infection results in recruitment of immune cells to the maxilla

Given that inflammatory cytokine production is increased over time in F. nucleatum infected mice, we next characterized the dynamics of leukocyte infiltration in tissue sections
To confirm this result, we quantified total inflammatory bone at 1, 4 and 7 d.p.i., when compared with uninfected mice (Fig. 4B). Increased numbers of infiltrating leukocytes near the alveolar bone and the DAMP, HMGB1, in the maxilla at 4 d.p.i. These effects were observed from 1 d.p.i. on, culminating in bone resorption by osteoclasts. Indeed, we detected bone resorption pits in the alveolar bone (7 d.p.i.) compared to the uninfected group (Fig. 6), which may have resulted from osteoclast involvement.

Bone resorption during F. nucleatum infection

Osteoclast activation leads to their attachment to the bone, resorption of the bone through its secretory factors, and detachment from the resorption site [60,61]. Previous studies have shown that IL-1β, and TNF-α enhance osteoclast development [41,62,63]. Since the production of these cytokines was elevated during F. nucleatum infection, we determined whether these inflammatory responses were coupled to bone resorption by osteoclasts. In vivo, we determined that F. nucleatum-infected mice expressed an elastic constant average of 7.95 ± 10.73 GPa [Fig. 7]. Infected mice had a significantly lower elasticity when compared with uninfected mice. These differences were more obvious between uninfected and infected mice 1 d.p.i, when elasticity decreased to 2.76 ± 5.56 GPa. Elasticity values at days 4 and 7 were 5.61 ± 7.88 GPa and 3.44 ± 3.42 GPa, respectively [Fig. 7].

Discussion

Previous studies have examined the mechanisms involved in the adhesion and metabolic growth interactions between F. nucleatum and other periodontal bacteria, such as P. gingivalis and A. actinomycetemcomitans [64–67], but monomicrobial oral infection with F. nucleatum in BALB/c mice had never been reported.

Our studies demonstrated that F. nucleatum can rapidly trigger inflammatory responses, manifested as increased mRNA for pro-inflammatory cytokines such as IL-1β, IFN-γ, IL-6 and IL-17 at 1 d.p.i., and secreted high levels of IL-1β and IFN-γ and the DAMP, HMGB1, in the maxilla at 4 d.p.i. These effects were followed by immune cell infiltration in gingival tissue observed from 1 d.p.i. on, culminating in bone resorption detected as early as 7 d.p.i. Alveolar bone softness was detected soon after, at 1 d.p.i.

Different oral bacteria can negatively or positively regulate the production of pro-inflammatory cytokines in GECS. While P. gingivalis subverts innate immunity by dampening IL-1β and HMGB1 release during infection in GECS, A. actinomycetemcomitans can stimulate IL-6 and TNF-α production in BMDMs [54,68]. Likewise, infection with F. nucleatum stimulates cytokine production through the activation of Toll-like receptor (TLR)-2 and TLR-4 [54,69,70], or alternatively, through TLR-independent pathways [70,71]. Our results show that F. nucleatum-infected mice upregulate IL-1β, IL-6, TNF-α, and HMGB1, consistent with previous in vitro studies on GECS and BMDMs infected with F. nucleatum [46,54].

Given the heightened inflammatory response induced by F. nucleatum infection, it was not surprising to see a recruitment of immune cells.

Fig. 3 HMGB1 levels augmented at day 4 post-infection. (A) HMGB1 (25 kDa) was detected by Western blot from the maxilla of BALB/c mice infected with F. nucleatum over a time-course of day 1, 4, and 7 post-infection. Actin (42 kDa) was used as a loading control. (B) Relative protein was measured by quantification of densitometry using NIH-Image. Results represent an average of three independent experiments with at least 4 mice in each group per experiment. Error bars represent the mean ± SD. (*< 0.05 Student’s t-test).
of immune cells to the alveolar bone during infection. Macrophages are known to reside in dental pulp [72]. Their activation relies on exposure to IFN-\(\gamma\), TNF-\(\alpha\), and LPS [73–75]. IFN-\(\gamma\) is important for antibacterial activity and is augmented by stimulation with LPS [76–78]. We found that \textit{F. nucleatum} infection induced significant levels of IFN-\(\gamma\). In addition, immunohistochemistry revealed the recruitment of macrophages throughout the oral cavity.

It remains to be determined whether IFN-\(\gamma\) promotes or inhibits osteoclast activation [39,62,79,80]. However, in our

Fig. 4 Immune cells are recruited near the alveolar bone during \textit{F. nucleatum} infection. (A) Sections from mandible of infected BALB/c mice were stained with H&E. Arrows indicate area of immune cells localized near the bone in dark stain. Bar represents 100 \(\mu\)m. (B) Total immune cells recruited to the murine gingival tissue of \textit{F. nucleatum}-infected BALB/c mice at day 4. Graph shows mean ± SD of immune cell numbers found in the murine gingival tissue of infected mice. Results show an average of 6 mice in each group (**<0.01, Student's t-test).

Fig. 5 \textit{F. nucleatum} infection increases immune cell recruitment in the dental pulp and in gingival tissue. (A) Immunohistochemistry for F4/80\(^+\) macrophages in the dental pulp of infected BALB/c mice. Bar represents 50 \(\mu\)m. (B) Quantification of macrophages from 10 histological fields. Total (C) neutrophils (CD11b\(^+\) Ly6G\(^+\)) and (D) lymphocytes (CD90\(^+\)) recruited to the murine gingival tissue of \textit{F. nucleatum}-infected BALB/c mice at day 4. Graphs show the mean ± SD of immune cells numbers found in the murine gingival tissue of infected or uninfected mice. (C and D) each point represents 2 mice in each group. study, IFN-γ may have contributed to activation of osteoclasts as they were observed localized near the bone after *F. nucleatum* infection. Moreover, TNF-α and IL-17 synergize with IL-1β, and can facilitate osteoclast activation, further supporting a role for these cytokines in bone loss in the mandible [81,82] during infection with *F. nucleatum*.

Conflicts of interest

The authors declare that they have no conflicts of interest.

Fig. 6 *F. nucleatum* infection induces bone resorption. Mandibles of infected BALB/c mice were stained with H&E. Arrows indicate areas of bone resorption. Bar represents 50 μm.

Fig. 7 Alveolar bone is more elastic in *F. nucleatum*-infected mice. Young modulus of alveolar bone was measured with an atomic force microscope. Results represent an average of at least 160 measurements from 4 different mice per group. Error bars represent the mean ± SD. Multiple comparisons were corrected with Dunnett’s method.
