Abstract
Recrystallization of phosphorous deoxidised copper used for strength critical applications at elevated temperatures was investigated by means of in situ heated stage EBSD analysis using a Gatan Murano heated stage mounted within a Carl Zeiss Sigma FEGSEM electron microscope. The influence of applied strain as the result of deformation within a Nakajima test as an analogue for industrial forming on the recrystallization temperature was investigated, the impact of increased heating rates on microstructural evolution was also investigated. Inverse pole figure plots combined with regions of reduction in local misorientations and variations in geometrically necessary dislocations were used to establish the point of recrystallization and the recrystallized fraction of the material. Recrystallization was observed to occur at temperatures as low as 130 °C in highly strained samples compared to around 300 °C within the annealed samples dependent upon heating rate. Increased heating rates were observed to produce a finer final grain structure but had little effect on presence of <111> 60° grain twins, which was influenced more by initial material condition.

1 Introduction
Industry design specifications are based on material properties either derived experimentally or from supplier’s specifications. Important properties such as recrystallization temperature are so heavily dependent on material condition and other external factors that they cannot be accurately quoted for a material. Applied strain leads to a significantly altered microstructure, with increased numbers of dislocations and stored energy within a material; at this point the material is no longer within the suppliers’ specification. Elevated operating temperatures in formed parts will then lead to stress release and recrystallization of the material at a temperature lower than specified.

Typically with applied temperature, recovery of a material initiates prior to any recrystallization, for complete recovery to occur there must be some light deformation to the microstructure to provide sufficient energy for this process [1]. If a material has been sufficiently strained so that it is heavily work hardened then it may undergo recrystallization with little or no recovery occurring [2]. A greater understanding of the initiation of recrystallization within as received annealed material in comparison to strained material is required to improve the industrial design process.

Grain twins are an important microstructural feature of fcc metals such as copper; fcc metals already deform freely via slip planes and twins offer another deformation mechanism by acting as regions to accommodate deformation arising from recrystallization [3]. Various studies have looked at the influence of grain twins on the resultant material texture [4, 5], grain boundary distribution [6, 7] and grain orientation [8, 9]. Studies on the recrystallization of heavily deformed copper have shown that annealing twins have a significant influence on grain growth, with twins allowing growth to continue when this process has stagnated [10].

Studies have investigated the recrystallization of various grades of copper, using both in-situ and post facto analysis [11–13]. Cold drawn copper wire with a 38% reduction was observed to recrystallize above 200 °C [14], other studies have reported the initiation of recrystallization at 210 °C [15]. This study investigates the recrystallization of Cu-DHP
phosphorous deoxidised copper utilized in a strength critical industrial applications under specific conditions.

2 Materials and Methods

Pre-rolled commercially available C106-DHP (99.85% Cu, 0.15% P) was used throughout this study. The material was nominally supplied in the annealed condition as 0.5 mm sheet. The material was investigated in the as received annealed condition directly from supplier and following straining within a biaxial Nakajima test to mimic strains which would be imparted during industrial forming processes. Unstrained samples had a nominal thickness of 0.5 mm. Strained samples were taken from near to the failure region of Nakajima test pieces and had an equivalent strain in the region of 50%. Equivalent strain is based on localised thinning of the material, where $T_o$ is original thickness and $T_s$ is strained thickness.

$$\left( \frac{T_o}{T_s} - 1 \right) \times 100$$

Samples were prepared for EBSD analysis by sectioning and mounting in Bakelite resin; samples were polished mechanically firstly using SiC grit papers then water based diamond solutions, a final stage polish employing 5% hydrogen peroxide was employed to provide a light etch and highlight grain boundaries. Following polishing samples were cut from the resin and the surface cleaned with isopropanol using a previously established technique [16].

In situ observations were conducted using a 70° pretilted Gatan Murano heated stage operating in a Sigma Zeiss FEG-SEM with Oxford Aztec software and Symmetry EBSD detector. Scans were conducted with a voltage of 20 keV at 200 Hz with a 0.5 µm step size yielding a total scan time of 70 s per region. No external fiducial markers were imparted on the surface, existing surface features were employed to account for thermal drift during heating ramps in between EBSD scans. Comparative FSD and SE images were used to ensure the same region of interest was observed throughout. Samples were taken up to a maximum temperature of 550 °C at rates ranging from 0.01 to 50 C s$^{-1}$ to look at the influence of heating rate on the material recrystallization.

3 Results and Discussion

Previous studies had established the requirement for an initial ramp to 200 °C to degas materials within the SEM prior to incremental steps to investigate microstructural evolution [16]. As illustrated in Fig. 1 EBSD analysis following this heating showed that strained material (b) had already undergone recrystallization whereas the unstrained material (a) remained unaffected. Local misorientations and grain boundaries remained unaltered within the unstrained material affirming the fact that the grain structure remained unaffected by the heat treatment. IPF maps clearly show a recrystallized structure within the strained material with no evidence of the parent grains remaining; local misorientations were significantly reduced; and a prevalence of <111>
60° twin boundaries was evident accounting for around 59% of the total grain boundaries compared to 10% for the unstrained material.

Strain energy imparted by deformation is stored within the microstructure in the form of dislocations [17], to understand this unexpected recrystallization the GND (geometrically necessary dislocation) density within both samples were investigated using Oxford channel 5 software. Figure 2 illustrates the GND density maps for both strained and unstrained copper samples, the strained sample having a 4.2×10^{14}/m² compared to 1.6×10^{14}/m² within the unstrained material. This increase in GND density and therefore increased stored energy explains the unexpected recrystallization observed.

Following this discovery degassing was conducted at 110 °C within incremental steps of 20 °C at 0.01 C s⁻¹. The resultant IPF orientation maps with corresponding local misorientation maps are given in Fig. 3. Nucleation sites were not always observable with nucleation typically taking place beneath the sample surface [18]. The grain structure remained unchanged at 110 °C, following heating to 130 °C recrystallization was evident with regions of reduced local misorientations and increased twin boundaries observed. GNU Gimp 2.0 software was used to analyse the number of pixels in regions of reduced local misorientations to give a percentage fraction of recrystallized material.

At 130 °C approximately 5% of the sample was recrystallized, incremental steps to 150 °C increased this to 10% and at 170 °C to 10%. Increasing the temperature to 190 °C increased the recrystallized fraction to approximately 70% of the structure being recrystallized, 95% of the sample was recrystallized at 205 °C and exposure to 225 °C lead to a fully recrystallized structure illustrated in Fig. 3. Heating was continued up to 400 °C but no further changes were observed within the microstructure. Regions of recrystallized material were typified by a prevalence of <111> 60° twin boundaries, at least 50% of the grain boundaries within recrystallized regions being twin boundaries.

This increase in recrystallization kinetics typified by initiation at lower temperature was expected due to the increased stored energy within the stained samples which is known to be the most influential factor in how quickly copper with recrystallize [17]. With no secondary particles present within the studied material the driving force for recrystallization was purely polygonization, the kinetics of which are dependent upon dislocation density, which is significantly increased within deformed material. Prior to testing the recrystallization temperature was expected to be greater than 200 °C, studies had shown that copper does recrystallize at a lower temperature than this but these studies had been conducted on material which had undergone ECAP processes which lead to massive levels of localised strain and stored energy in [19].

Regions of recrystallized material were typified by reduced local misorientations and by reduced GND density as shown in Figs. 3 and 4. Within regions of reduced GND density the microstructure was typified by <111> 60° twins illustrated in Fig. 4b. With increased heating GND densities were seen to decrease and the total percentage of <111> 60° twins to increase proportionally. The fully recrystallized material having a GND density of 0.92×10^{14}/m² and around 65% of grain boundaries being comprised of <111> 60° twins. This relationship and the relationship between temperature and recrystallized fraction being illustrated in Fig. 5a, b.

With no evidence of any microstructural evolution within the unstrained material at 200 °C samples were then degassed at 200 °C and incremental steps of 25 °C with a ramp rate of 0.1 C s⁻¹ were applied to observe the initiation of recrystallization. The microstructure remained unchanged up to 400 °C with local misorientations and grain boundaries remaining the same as the initial condition. On raising the

**Fig. 2** a GND density of unstrained copper, b GND density of strained copper, c histograms of GND densities of copper in both conditions showing the shift to a higher average within the strained sample
temperature to 425 °C the material was observed to very rapidly recrystallize to a relatively stable microstructure with no evidence of parent grains.

GND density within the sample initially was $2.65 \times 10^{14}$/m$^2$ this value remained virtually unchanged up to 400 °C with a slight reduction to $2.44 \times 10^{14}$/m$^2$ which is indicative of some recovery within the microstructure. Upon heating to 425 °C the GND density was reduced to $0.85 \times 10^{14}$/m$^2$ indicating a fully recrystallized structure, following further heating the GND density was seen to remain stable, showing that the recrystallization process had completed.

Due to the speed of recrystallization at these temperatures it was not possible to estimate the percentage fraction at different steps as for the strained sample. Further heating to 500 °C showed no further evolution of the microstructure, a prolonged dwell at 550 °C for an hour showed some limited evidence of abnormal grain growth within the microstructure but the driving force for this evolution at this point is very low.

Rapid heating of the material at 25 °C s$^{-1}$ to 500 °C lead to a fine microstructure with an average grain diameter of 16 µm, and approximately 70% of the grain boundaries comprising of $<111> 60°$ twins as shown in Fig. 6a. Heating of the material at a lower rate of 0.1 C s$^{-1}$ to the same temperature produced a much coarser microstructure with average diameters of 65 µm, the greater length of time and slower rate of heating allowing for greater recovery prior to recrystallization and also subsequent grain coalescence and growth. Following heating, grain boundaries were observed to be comprised of approximately 70% $<111> 60°$ twins as seen in the material heated rapidly.

Samples of strained material were exposed to identical heating rates and the same pattern was observed, slow heating at 0.1 C s$^{-1}$ lead to a coarser 51 µm average diameter microstructure compared to 9 µm average in the rapidly heated material shown in Fig. 6b. The microstructure was seen to comprise of approximately 60% $<111> 60°$ twins for both heating rates. The finer resultant microstructure of that material is as expected due to the greater stored energy within grain boundaries and dislocations following straining prior to heating. It should be noted that some of the changes observed may be surface effects, however previous studies have shown good correlation between in situ EBSD and bulk

analysis of materials, samples from this study also showed close agreement with bulk analysis [20].

4 Conclusions

This study established the fact that strained Cu-dhp will recrystallize at much lower temperatures than expected due to the greater stored energy in dislocations driving polygonization of the material; evidence of recrystallization was evident at temperatures as low as 130 °C. Final grain size is heavily influenced by both initial condition; strained initial material yields a finer final microstructure; and heating rates, with faster heating leading to finer average grain sizes due to increased recrystallization kinetics. The presence of $<111>60°$ grain twins appeared to be independent of heating rates, but have a slight dependence on initial condition with approximately 10% less grain twins in material that had initially undergone deformation.
