Abstract

We study the molecular gas content of 24 star-forming galaxies at $z = 3$–4, with a median stellar mass of $10^{9.1} M_\odot$ from the MUSE Hubble Ultra Deep Field (HUDF) Survey. Selected by their Ly$\alpha$ A1216 emission and $H_{\text{F160W}}$-band magnitude, the galaxies show an average (EW$_{\text{Ly}\alpha}$) $\approx$ 20 Å, below the typical selection threshold for Ly$\alpha$ emitters (EW$_{\text{Ly}\alpha} > 25$ Å), and a rest-frame UV spectrum similar to Lyman-break galaxies. We use rest-frame optical spectroscopy from KMOS and MUSE, and the UV features observed with MUSE, to determine the systemic redshifts, which are offset from Ly$\alpha$ by $\langle \Delta z_{\text{Ly}\alpha} \rangle = 346$ km s$^{-1}$, with a 100 to 600 km s$^{-1}$ range. Stacking $^{12}\text{CO}$ $J = 4 \rightarrow 3$ and $^{13}\text{CO}$ $J = 3 \rightarrow 2$ and $^{12}\text{CO}$ $J = 3 \rightarrow 2$ to $^{12}\text{CO}$ $J = 1 \rightarrow 0$, we determine 3σ upper limits on the line luminosities of $4.0 \times 10^{6}$ K km s$^{-1}$ pc$^2$ and $5.6 \times 10^{8}$ K km s$^{-1}$ pc$^2$, respectively (for a 300 km s$^{-1}$ line width). The inferred gas fractions, under the assumption of a “Galactic” CO-to-H$_2$ conversion factor and gas-to-dust ratio, are in tension with previously determined scaling relations. This implies a substantially higher $\alpha_{\text{CO}} > 10$ and $\delta_{\text{DGR}} > 1200$, consistent with the subsolar metallicity estimated for these galaxies ($12 + \log(O/H) \approx 7.8 \pm 0.2$). The low metallicity of $z > 3$ star-forming galaxies may thus make it very challenging to unveil their cold gas through CO or dust emission, warranting further exploration of alternative tracers, such as [C II].

1. Introduction

The recent decade has witnessed a tremendous advance in the characterization of the cold molecular gas content of star-forming galaxies at $z > 1$. Evidence is now mounting that the cold gas fraction of massive star-forming galaxies strongly increases up to at least $z \approx 3$ (e.g., Genzel et al. 2010, 2015; Tacconi et al. 2010, 2013, 2018; Geach et al. 2011; Dessauges-Zavadsky et al. 2015, 2020; Aravena et al. 2019, 2020; Tacconi et al. 2020). As the cold H$_2$ gas is radiatively dark, the molecular gas has to be traced by the emission from the ground-state rotational transition of carbon monoxide ($^{12}\text{CO}$, hereafter CO), or other tracers such as the emission from neutral atomic carbon ([C II]) or the long-wavelength dust continuum. Yet, observations of CO in (optically selected) star-forming galaxies at $z > 3$ remain challenging and have been limited to massive Lyman-break- or main-sequence-selected galaxies and/or strongly lensed systems, with known redshifts (Baker et al. 2004; Coppin et al. 2007; Riechers et al. 2010; Livermore et al. 2012; Magdis et al. 2012, 2017; Tan et al. 2013; Saintonge et al. 2013; Dessauges-Zavadsky et al. 2015, 2017; Pavesi et al. 2019; Cassata et al. 2020), sometimes serendipitously detected and only identified as such a posteriori (Gowardhan et al. 2019).

The Atacama Large Millimeter Array Large Program ASPECS (The ALMA Spectroscopic Survey in the Hubble Ultra Deep Field (HUDF); Walter et al. 2016; Decarli et al. 2019) provides a unique opportunity to study the gas content of star-forming galaxies at $z \geq 3$. ASPECS consists of spectral scans in ALMA Bands 3 (85–115 GHz) and 6 (212–272 GHz), probing molecular gas and dust in galaxies without any target preselection. These data unveil emission from CO, [C I], and dust continuum in several star-forming galaxies at $z = 1$–4 (Boogaard et al. 2019, 2020; González-López et al. 2019, 2020), providing key constraints on the empirical scaling relations describing the evolution of the gas and dust content in galaxies (Aravena et al. 2019, 2020), the evolution of the cosmic molecular gas density (Decarli et al. 2019, 2020), and the baryon cycle (Walter et al. 2020).

Key to the exploration of the ASPECS data are the large number of spectroscopic redshifts provided by the Multi Unit
Galaxies with \( < z < 3.812 \) as a function of redshift. The open circles show the parent sample of all 2017 (e.g., Shapley et al. 2003; Verhamme et al. 2018; Muzahid et al. 2020) where the bright H I Ly\( \alpha \) transition, the photons are easily scattered by the neutral gas in the interstellar medium. In this paper, we constrain the molecular gas content of star-forming galaxies at \( < 3.812 \) by stacking their line emission. However, the MUSE redshifts at \( < 3.812 \) are used for stacking. Because Ly\( \alpha \) cannot be used for stacking for which the redshifts are determined automatically. These sources have subsequently been verified by several independent groups of experts that inspect the redshift and the multiwavelength counterpart associations, and assign a confidence flag (ZCONF; where confidence \( \geq 2 \) implies a secure redshift, determined by at least two spectral features). Specifically, we use the following criteria:

1. Select all objects with \( 3.0115 < z < 3.812 \) and ZCONF \( \geq 2 \) that have an HST counterpart in the Rafelski et al. (2015) catalog.
2. Restrict to objects that lie within the 4.55 arcmin\(^2\) region of the ASPECS Band 3 mosaic where the sensitivity is \( \geq 40\% \) of the primary beam peak sensitivity at 99.5 GHz.\(^{16}\)
3. Remove three X-ray-detected sources that are classified as having an active galactic nucleus (AGN; MUSE-1051, MUSE-1056, and MUSE-6672), based on the Chandra 7 MS data (Luo et al. 2017).

There are a total of 168 galaxies in the parent sample constructed this way. The \( H_{F160W} \) magnitude of the parent sample is shown in Figure 1. Because of the sensitivity of MUSE to faint emission-line sources, it consists almost exclusively of galaxies that are selected by their Ly\( \alpha \) emission. Only six galaxies are not marked as such: one is MUSE-50, which shows double-peaked Ly\( \alpha \) emission in the stacks \( \sigma \) at the 3\( \sigma \) level and discusses the implications of this nondetection on metallicity, the CO-to-H\( _2 \) conversion factor \( (\alpha_{\text{CO}}) \), and gas-to-dust ratio \( (\delta_{\text{GDR}}) \) in Section 4. The results highlight that the metallicity evolution of star-forming galaxies makes it increasingly challenging to infer the molecular gas content at higher redshifts, which warrants the further theoretical and observational exploration of alternative tracers, in particular the [C II] \( \lambda 158 \) \( \mu \)m line. Throughout this paper, we report wavelengths in vacuo and magnitudes in the AB system (Oke & Gunn 1983) and adopt a Chabrier (2003) initial mass function. We use log to denote log\_10 and ln for the natural logarithm. We adopt a concordance cosmology with \( H_0 = 70 \) km s\(^{-1}\) Mpc\(^{-1}\), \( \Omega_m = 0.3 \), and \( \Omega_\Lambda = 0.7 \), in good agreement with the measurements from Planck Collaboration et al. (2016).

2. Observations and Sample Selection

2.1. Parent Sample Selection and Physical Properties

We construct a parent sample of galaxies from the MUSE HUDF Survey Data Release 2 catalog,\(^{15}\) which is an updated and revised version of the DR1 catalog (Bacon et al. 2017; Inami et al. 2017). In short, the catalog contains both emission-line-selected sources (from ORIGIN; Mary et al. 2020) and continuum-selected sources (from the Hubble Space Telescope (HST) catalog by Rafelski et al. 2015) for which the redshifts are determined automatically. These sources have subsequently been verified by several independent groups of experts that inspect the redshift and the multiwavelength counterpart associations, and assign a confidence flag (ZCONF; where confidence \( \geq 2 \) implies a secure redshift, determined by at least two spectral features). Specifically, we use the following criteria:

1. Select all objects with \( 3.0115 < z < 3.812 \) and ZCONF \( \geq 2 \) that have an HST counterpart in the Rafelski et al. (2015) catalog.
2. Restrict to objects that lie within the 4.55 arcmin\(^2\) region of the ASPECS Band 3 mosaic where the sensitivity is \( \geq 40\% \) of the primary beam peak sensitivity at 99.5 GHz.\(^{16}\)
3. Remove three X-ray-detected sources that are classified as having an active galactic nucleus (AGN; MUSE-1051, MUSE-1056, and MUSE-6672), based on the Chandra 7 MS data (Luo et al. 2017).

There are a total of 168 galaxies in the parent sample constructed this way. The \( H_{F160W} \) magnitude of the parent sample is shown as a function of redshift in Figure 1. Because of the sensitivity of MUSE to faint emission-line sources, it consists almost exclusively of galaxies that are selected by their Ly\( \alpha \) emission. Only six galaxies are not marked as such: one is MUSE-50, which shows double-peaked Ly\( \alpha \) emission in the stacks of strong Ly\( \alpha \) absorption, as well as strong UV lines. The other five indeed show little Ly\( \alpha \) emission: one is a faint C IV \( \lambda \lambda 1548, 1551 \)-only emitter, while the other four have

\(^{15}\) DR2 v0.1: R. Bacon, et al., in preparation

\(^{16}\) This area fully encompasses the ASPECS Band 6 mosaic.
bright enough UV continuum to have their systemic redshifts determined from absorption lines (see Section 2.2.1).

Because the Lyα emission may peak in the halo of a galaxy, the association of a MUSE source with an HST counterpart can be ambiguous and is typically resolved during the redshift determination process. The associations adopted here are listed in Table 3 and are in all cases supported by a second tracer of the systemic redshift. In the case of MUSE-6518, the photometry is completely blended with a $z = 0.83$ foreground object, and we do not use it to obtain physical properties.

We determine a stellar mass ($M_*$) and star formation rate (SFR) for all galaxies in the parent sample by fitting 11 bands of HST (Rafelski et al. 2015) and 4 bands of Spitzer/IRAC photometry, using the high-$z$ extension of the spectral energy distribution fitting code MAGPHYS (Da Cunha et al. 2008, 2015). As in Labbé et al. (2006, 2010, 2015), the deblended Spitzer/IRAC photometry was measured with MOPHONGO, using the HST observations as a template, in the deep $\sim$200 hr data from the GREATS program (M. Stefanon et al., submitted). The latter provides constraints on the rest-frame optical part of the spectral energy distribution redward of the 4000 Å break and is critical to pin down the stellar masses of our galaxies. The results are listed in Table 3 for the galaxies in the systemic redshift sample.

As part of the DR2, the spectra of all galaxies are modeled with PYPLATEFIT (R. Bacon, et al., 2021, in preparation), the Python implementation of the spectrum fitting code PLATEFIT, originally developed for the Sloan Digital Sky Survey (Brinchmann et al. 2004, 2008; Tremonti et al. 2004). The most salient features of PYPLATEFIT, relevant to this work, are that it can simultaneously model both the emission and absorption lines, as well as the stellar continuum, allowing for velocity differences between groups of lines (such as Lyα and other UV lines). All lines are modeled using Gaussians except Lyα, for which a (double) asymmetric Gaussian is used (double if the Lyα line is double peaked).

2.2. Measurement of Systemic Redshifts

We obtain systemic redshifts for galaxies in our parent sample from either the rest-frame UV features using MUSE (Section 2.2.1) or the rest-frame optical emission lines with near-IR spectroscopy (Sections 2.2.2 and 2.2.3). For the near-IR follow-up, targets were selected by their $H_{\text{F}160W}$ magnitude (as a proxy for stellar mass) and the absence of a systemic redshift from MUSE in the DR1 reductions. Fainter targets were sometimes observed because brighter targets were no longer accessible given the small size of the HUDF and physical limitations in the positioning arms and slits of multiobject spectrographs.

2.2.1. MUSE

For a subset of galaxies we can determine the systemic redshift directly from the MUSE spectra, using the weaker rest-frame UV emission lines, or absorption features. We identify objects in the parent sample that are cataloged as having a signal-to-noise ratio ($S/N > 3$ in at least one UV emission line. We focus specifically on O III $\lambda\lambda1661, 1666$; S III $\lambda\lambda1883, 1892$; C III $\lambda\lambda1907, 1909$; and a selection of absorption lines that trace the systemic redshift. We also fit narrow He II $\lambda1640$ together with the emission lines, finding it at a similar velocity offset as the other UV lines. We do not use the resonant lines, such as C IV $\lambda\lambda1548, 1551$, which can be offset from the systemic velocity like Lyα. To identify absorption-line redshifts, we inspect all objects with $V_{\text{f606W}} \leq 27$ and/or $i_{\text{7775W}} \leq 27$, finding that we can determine these in several galaxies down to $i_{\text{7775W}} = 26$. We use PYPLATEFIT to fit the selected spectra, performing 200 bootstrap iterations to obtain a more robust estimate of the uncertainties (both on Lyα and the other features). We only keep the objects that remain at $S/N > 3.5$ in at least one emission line or the sum of the absorption features. In addition, we keep MUSE-1360 as a tentative candidate, having both a tentative detection in the KMOS data and an absorption-line redshift at $S/N = 3$. The $z_{\text{Ly}α}^\text{red}$ and $z_{\text{sys}}$, with their bootstrapped uncertainties, are provided in Table 3 (where $z_{\text{Ly}α}^\text{red}$ is the redshift of the red peak of Lyα). We note that three of these sources were also part of the study of Lyα velocity offsets by Verhamme et al. (2018).

In principle, one could estimate the systemic redshift by using half of the peak separation for Lyα lines with a blue bump (Verhamme et al. 2018). Indeed, a few galaxies in our sample also show blue-bump emission. However, systematic searches for blue-bump Lyα emitters are still ongoing, and we therefore do not include such a sample at this stage. Furthermore, the presence of a blue bump requires specific radiative transfer conditions, and selecting a sample in such a way may introduce a bias in the stack.

2.2.2. KMOS

The KMOS observations were taken in two ESO periods as part of 099.A-0858(A) (PI: Bouwens) and 0101.A-0725(A) (PI: Boogaard). We used the HK grating (with a spectral resolution of $\lambda/ \Delta \lambda \approx 1800$) in five observing blocks (OBs) per period, with an ABA ABA AB sky-offset pattern between the science (A) and sky (B) frames with 300 s integrations and 0″2 dithering offsets. In total we targeted 17 galaxies, with (final) on-source times ranging between 200 and 250 minutes. We also included a bright quasar on all masks to control the astrometry, from which we measure the image quality to be around 0″75 and 0″85 in the reduced P99 and P101 data, respectively.

We reduce the data using ESO KMOS pipeline version 2.1.0 (Davies et al. 2013), using the standard star observations for the zero-point, response, and telluric correction. We enable the background flag to correct for differences in the residual background level between the exposures by applying a constant offset, estimated by taking the mode of the pixel values after excluding the brightest 25%. We discard the data from one detector for the second A frame of the first OB in period 99, which shows a strong background offset. We experimented with further reducing the sky-line residuals using the sky-tweak and molecfit options of the pipeline, but found that these sometimes introduce artifacts in the data. As our lines were selected to be away from the sky lines as much as possible, we therefore do not apply these corrections. Because of the density of the sky lines around $[O II] \lambda\lambda3727$ in the $H$ band, we focus on the $[N II] \lambda\lambda6583$ and $[O III] \lambda\lambda4960$.
5008 in the K band. We apply radial velocity corrections\(^\text{19}\) to shift every reduced A–B frame to the solar system barycentric frame (the mean $v_r = 17.3$ km s\(^{-1}\)).

We correct for positional shifts between the different OBs by centering on the continuum position of the reference quasar, which we model with a 2D Gaussian. As objects were placed on different integral field units between periods, their position relative to the reference quasar changes. We therefore first combine and analyze the data from each period separately. To identify the spatial position of each (emission-line-only) object on its integral field unit in each period, we

(i) extract spectra at the a priori expected position (that is, the quasar position or the center of the cube) using the 2D fit of the reference quasar as a spatial model,

(ii) identify the brightest spectral line, [O III] $\lambda 5008$, based on the Ly$\alpha$ redshift and determine its central wavelength and line width using a Gaussian fit,

(iii) collapse the cube over the channels with line emission to make a “narrow band” through multiplication with the Gaussian fit along the wavelength axis, and

(iv) identify the spatial position in the narrowband image.

We iterate steps (i)–(iv) until we converge on spatial position. Finally, we combine the data from both periods using the best positions and repeat the same steps to obtain the final spectra.

We conservatively only consider the objects for which we can identify the line(s) in each half of the data separately, which gives strong confidence that the line(s) are not (caused by) sky-line residuals. We exclude one source where the blueshift of the lines relative to Ly$\alpha$ resulted in them being too close to the sky lines to determine the centroid and four more sources where a tentative feature was only seen in one period.

In total, we confidently detect the rest-frame optical line(s) in 7/17 galaxies. As an example, we show the MUSE and KMOS spectrum for one of the galaxies in Figure 2. The spectra of the remaining galaxies are shown in Figure 12 in Section A.

Finally, we determine the redshift by simultaneously fitting Gaussians (in vacuo) to the H$\beta$ $\lambda 4863$ and [O III] $\lambda 4960, 5008$ lines (using LMFIT; Newville et al. 2021). We use the inverse of the error spectrum as weights and subtract a running median continuum from the spectrum prior to the fitting. The resulting redshifts are reported in Table 3.

### 2.2.3. MOSFIRE

The MOSFIRE observations were taken on the night of 28 November 2018 as part of 2018B_N182 (PI: Riechers). We observed a single K-band mask with $0''7$ slits ($\lambda/\Delta \lambda \approx 3610$). We used an AB dither pattern with 180 s exposures, totaling 108 minutes of exposure time on source, with an average seeing of $0''7$. The data were reduced using the standard MOSFIRE Data Reduction Pipeline (Release 2018),\(^\text{20}\) using the neon arc lamps for the wavelength calibration. As our objects generally do not show any continuum, we determine the redshift and determine its central wavelength and line width using a Gaussian fit along the wavelength axis, and

\[
\lambda' = \lambda_0 (1 + v_c/c) / (1 - v_r/c),
\]

where $\lambda'$ and $\lambda$ are the corrected and uncorrected wavelengths, respectively, $c$ is the speed of light, and $v_r$ is the radial velocity correction to the solar system barycenter, computed with \texttt{astropy.coordinates.SkyCoord.radial_velocity_correction}.

model for the spatial profile. As all data were taken on a single night, we apply the radial velocity correction to the final spectra ($v_r = -9.2$ km s\(^{-1}\)).\(^\text{21}\)

In total, we detect the rest-frame optical lines in 4/7 of the galaxies on the mask that are part of our parent sample (including MUSE-6518, with blended HST photometry). Their spectra are shown in Figure 12. We measure the redshifts as described in Section 2.2.2 and report the results in Table 3.

### 2.3. Final Systemic Redshift Sample

In total, we use MUSE, KMOS, and MOSFIRE to obtain systemic redshifts for 24 galaxies, 20 of which are originally identified by their Ly$\alpha$ emission, with an average redshift of $\langle z \rangle = 3.45$. The $H_{F160W}$ magnitude of the final sample is shown in comparison to the MUSE parent sample in Figure 1. We have a systemic redshift for most galaxies in the parent sample down to $H_{F160W} = 26$. Because the parent sample is Ly$\alpha$ selected, this raises the question of how representative our sample is for the broader population of galaxies at these epochs. We therefore compare our (parent) sample to all galaxies at the same redshift and over the same field, from the photometric redshift catalog by Rafelski et al. (2015, updated with the MUSE redshifts) after excluding the X-ray AGNs (Luo et al. 2017, as we did for the parent sample) see Figure 1.

We show a histogram of the physical properties of the galaxies in Figure 3. The median stellar mass and SFR of the sample are $10^{9.1} M_\odot$ and $10 M_\odot$ yr\(^{-1}\). The sample encompasses $\geq 50\%$ of the galaxies in the MUSE parent sample in the bins down to $M_* \geq 10^8 M_\odot$ and SFR $\geq 3 M_\odot$ yr\(^{-1}\) and $\geq 20\%$ of the galaxies in the broader photometric catalog, down to the same limits.

Our galaxies are faint Ly$\alpha$ emitters in comparison to narrowband-selected samples. The typical Ly$\alpha$ luminosity of our sample is $L_{Ly\alpha} = 10^{42}$ erg s\(^{-1}\) $\approx 0.2 L_{Ly\alpha}$ at $z = 3.5$ (e.g., Ouchi et al. 2008; Drake et al. 2017; Herenz et al. 2019). The average rest-frame equivalent width of our sample, $(EW_{Ly\alpha}^2) \approx 20$ Å, is also small, especially when considering that $\approx 25$ Å is the typical lower limit for the definition of a (narrowband-selected) Ly$\alpha$ emitter (LAE; e.g., Matthee et al. 2016). This is likely due to our selection toward objects that are bright in $H_{F160W}$. As such, our galaxies are not necessarily comparable to the typical sample of LAEs, but arguably more similar to the average population of (low-mass) star-forming galaxies.

To illustrate this point, we stack the MUSE spectrum of all the galaxies in our sample, using the systemic redshifts, following Feltre et al. (2020). We perform a median and weighted mean stack after normalizing each of the spectra by the median flux density at $1267–1276$ Å (matching Rigby et al. 2018). The result is shown in Figure 4. We compare the composite MUSE spectrum to the average spectrum of $z \sim 3$ Lyman-break Galaxies (LBGs; Shapley et al. 2003), the composite spectrum of 14 strongly lensed, star-forming galaxies at $1.6 < z < 3.6$ from the MeGaSaURA sample (Rigby et al. 2018) and the composite MUSE spectrum of all 220 LAEs at $2.9 < z < 4.6$ from Feltre et al. (2020). The median spectrum of the galaxies in our sample shows significantly

---

\(^\text{19}\) See footnote 19.

\(^\text{20}\) https://github.com/Keck-DataReductionPipelines/MosfireDRP

\(^\text{21}\) See footnote 19.
weaker Lyα emission than the median spectrum of all MUSE LAEs (that includes a majority of LAEs with a fainter $H_{F160W} > 26$). Instead, the similarities in the literature spectra of LBGs and star-forming galaxies and the (median) composite spectrum of our sample support the case that our galaxies are more similar to the population of star-forming galaxies at these epochs.

The broad distribution in Figure 5 also reflects the smoothing function by which the stacking signal would be diluted if $z_{\text{red}}$ would be used for stacking, in particular because the ALMA data has a higher velocity resolution. This highlights the need for systemic redshifts.

3.2. ALMA Stack

With the systemic redshifts in hand, we turn to the ALMA data. We use the ASPECS Band 3 (Decarli et al. 2019; González-López et al. 2019) and Band 6 (Decarli et al. 2020; González-López et al. 2020) data cubes at their native resolution ($\sim 20$ km s$^{-1}$ in both cases). The rms error spectra reach $\approx 0.2$ and 0.5 mJy beam$^{-1}$ channel$^{-1}$ in Band 3 and Band 6, respectively (at the center of the field, varying with frequency).

Before extracting the spectra, we first shift the ALMA cubes from the kinematic local standard of rest to the barycentric frame using the CASA task imreimage ($\Delta v = -16.78$ km s$^{-1}$), such that all our spectroscopic data are on the same velocity frame. We then extract pixel spectra at the HST positions that includes a majority of LAEs with a fainter $H_{F160W} > 26$ in both cases). The rms error spectra reach $\approx 0.2$ and 0.5 mJy beam$^{-1}$ channel$^{-1}$ in Band 3 and Band 6, respectively (at the center of the field, varying with frequency).

Before extracting the spectra, we first shift the ALMA cubes from the kinematic local standard of rest to the barycentric frame using the CASA task imreimage ($\Delta v = -16.78$ km s$^{-1}$), such that all our spectroscopic data are on the same velocity frame. We then extract pixel spectra at the HST positions that includes a majority of LAEs with a fainter $H_{F160W} > 26$ in both cases). ### 3. Results

#### 3.1. Velocity Offsets

We plot the velocity offset of Lyα $\lambda 1216$ with respect to the systemic redshift in Figure 5, defined as $\Delta v(Ly\alpha) = c(z_{\text{red}} - z_{\text{sys}})/(1 + z_{\text{sys}})$, where $c$ is the speed of light. Our galaxies show a mean velocity offset of $\langle \Delta v(Ly\alpha) \rangle = 346$ km s$^{-1}$, with a range from 100 to 600 km s$^{-1}$.

For comparison, the mean $\Delta v(Ly\alpha) = 200$–250 km s$^{-1}$ in the LAE samples at $z = 2$–3 (Erb et al. 2014; Trainor et al. 2015), while at the $z \approx 3$ LBG sample from Shapley et al. (2003) shows a greater mean velocity offset of 650 km s$^{-1}$. The relatively large velocity offsets imply a higher H I column density and lower Lyα escape fraction, consistent with the low EW$_{Ly\alpha}$ of our galaxies (Shapley et al. 2003; Erb et al. 2014; Yang et al. 2017).

The Astrophysical Journal, 916:12 (19pp), 2021 July 20

Boogaard et al.
$1.5'5 \times 1'7$1 in Band 6). Their spatial extent in the rest-frame UV is significantly smaller, with a median effective radius in $H_{F160W}$ of $\approx 0''2$ (van der Wel et al. 2012).

Inspecting the spectra around the systemic redshift, none of the galaxies are individually detected in their CO or [C I] emission lines at the 3$\sigma$ level. We therefore stack the spectra as follows (Boogaard et al. 2020; cf. Spilker et al. 2014). We first create a grid in velocity space, centered around zero, with 300 km s$^{-1}$ wide channels. The channel width was chosen based on the mean rest-frame UV/optical line width ($\approx 200$ km s$^{-1}$), such that $> 90\%$ of the stacked line flux is expected to fall within the single central channel. We convert each observed spectrum to velocity space, centered around the line, and bin it onto the velocity grid. We then stack the spectra by taking the 1/$\sigma^2$ weighted mean in each velocity channel (where $\sigma$ is the error) and determine the uncertainty by propagating the error spectrum in the same manner. We finally measure the flux density and the corresponding uncertainty in the zero-velocity channel.

The stacked spectra are shown in Figure 6. None of the lines are detected in the stack at an S/N greater than 3. The stack of CO $J=9 \rightarrow 8$ shows some signal at the 2$\sigma$–3$\sigma$ level, but we do not consider this a detection. The high-$J$ lines of CO are primarily sensitive to the gas heating (and not the gas mass) and we include the constraints on these lines mainly for completeness and future reference. We compute 3$\sigma$ upper limits on the integrated line flux, $S_\nu \Delta \nu$, from the uncertainty in the zero-velocity channel of the stacked spectrum (at 300 km s$^{-1}$ resolution). We determine the corresponding upper limits on the line luminosities via

$$L' = 3.255 \times 10^7 S_\nu \Delta \nu d_L^2 r_{\text{obs}}^{-2} (1 + z)^{-3} \text{ K km s}^{-1} \text{ pc}^2$$

(Solomon et al. 1992; Carilli & Walter 2013), adopting the luminosity distance ($d_L$) and observed frequency ($r_{\text{obs}}$) at the average redshift of the sample, $z=3.45$. The results can be found in Table 1. We also perform additional stacks, including only the galaxies with the highest stellar masses ($M_*=10^{10.6}$, $\geq10^{9.5}$, and $\geq10^{10} M_\odot$) and the highest star formation rates (SFR $\geq 3.2$ and $\geq 10 M_\odot$ yr$^{-1}$), but do not obtain any detections. Stacking all the different CO lines together does not yield a detection either (regardless of whether [C I] is also added to this stack).

None of the galaxies are individually detected at the 3$\sigma$ level in the deep 1.2 mm dust-continuum map (Aravena et al. 2020; González-López et al. 2020). In addition to the line stack, we therefore also perform a weighted mean stack of the 1.2 mm dust-continuum data for the full sample (following the approach from Bouwens 2016; Bouwens et al. 2020, again applying the astrometric offset). We do not obtain a detection, measuring a flux of $S_\nu = 1 \pm 3$ mJy (Figure 7), implying an upper limit of $\leq 9$ mJy (3$\sigma$). Following the same procedure for the 3 mm continuum results in an upper limit of $\leq 1.2$ mJy (3$\sigma$). In the following, we focus on the limit from the deep 1.2 mm continuum, as it provides the strongest constraints on the mass in dust and gas.

4. Discussion

4.1. Molecular Gas Masses

Stacking the $\langle z \rangle = 3.45$ star-forming galaxies in the HUDF by their systemic redshifts, we find that $L'_{CO J=4 \rightarrow 3} \leq 4.0 \times 10^8$ K km s$^{-1}$ pc$^2$. This result puts an upper limit on the molecular gas mass via

$$M_{\text{mol}} = \alpha_{CO} r_{J1} L'_{CO J-J-1},$$

where $\alpha_{CO}$ is known as the CO-to-H$_2$ conversion factor (a light-to-mass ratio) and $r_{J1}$ is the excitation correction, needed to convert the observed CO luminosity to $L'_{CO J=1 \rightarrow 0}$. There is no direct measurement of the CO excitation in the galaxies under consideration. Valentino et al. (2020) measured an average $r_{J1} = 0.36 \pm 0.06$ in their sample of star-forming galaxies at $z=1.25$, while Tacconi et al. (2018) assume an average $r_{J1} = 0.42$, constant with redshift. Boogaard et al. (2020), however, have shown that there is significant evolution.
Table 1
Stacking Results for the CO and [C I] Lines

| Transition   | \( \nu_0 \) (GHz) | \( \Delta z \) | Band | N  | \( S_\text{\Delta v} \) (mJy km s\(^{-1}\)) | \( S_\text{\Delta v} \) (mJy km s\(^{-1}\)) | \( L^* \) (K km s\(^{-1}\) pc\(^2\)) |

(5) Number of objects in the stack. (6) Line flux in the stack. (7) 3\(\sigma\) upper limit on line flux. (8) 3\(\sigma\) upper limit on line luminosity.

Figure 5. Histogram of the velocity offset of Ly\(\alpha\) 1216 with respect to the systemic redshift, \(\Delta v(Ly\alpha)\). The vertical lines indicate the mean and median velocity offset in the sample. The typical \(\pm\)1\(\sigma\) uncertainty on the velocity offset is indicated in the top right.

in the CO excitation of gas-mass-selected samples, with the average \( r_{41} \) increasing from 0.3 up to 0.6 between \( z = 1-2 \) and \( z = 2-3 \). Indeed, Dessauges-Zavadsky et al. (2017) find \( r_{41} = 0.60 \pm 0.17 \) in the strongly lensed MACS J0032-arc at \( z = 3.6 \), with a similar \( M_\star \approx 10^{9.7} M_\odot \) as our sample average (though significantly higher SFR \(\approx 50 M_\odot \text{yr}^{-1}\)). If the excitation scales with SFR surface density (Daddi et al. 2015; Valentino et al. 2020; Boogaard et al. 2020), this may suggest the excitation to be lower in our galaxies on average. We therefore loosely assume that \( r_{41} = 0.5 \pm 0.2 \), broadly encompassing the literature values. Note that higher excitation implies a smaller gas mass (Equation (2)). As we are dealing with an upper limit on the gas mass in the first place, we effectively assume a lower limit on the excitation of \( r_{41} \geq 0.3 \), in good agreement with observations.

A major uncertainty in the molecular gas estimate comes from \( \alpha_{\text{CO}} \). For star-forming galaxies at high redshift, “Galactic” conversion factors are typically assumed, consistent with observations in massive star-forming galaxies (Daddi et al. 2010a). However, the value of \( \alpha_{\text{CO}} \) has been observed to increase strongly at low metallicity (Z; Maloney & Black 1988; Israel 1997), where the decreased shielding leads to dissociation of CO deeper into the clouds (e.g., Wolfire et al. 2010; see Bolatto et al. 2013 for a review). Several calibrations for the metallicity dependence of the CO-to-H\(_2\) conversion factor exist in the literature, both determined empirically (e.g., Leroy et al. 2011; Genzel et al. 2012; Magdis et al. 2012; Schruba et al. 2012; Sandstrom et al. 2013) as well as theoretically (e.g., Wolfire et al. 2010, see also Bolatto et al. 2013).

We adopt the relation from Genzel et al. (2015), also adopted by Tacconi et al. 2018; Dessauges-Zavadsky et al. 2020

\[
\alpha_{\text{CO}}(Z) = \alpha_{\text{CO}}^{\text{MW}} \times \sqrt{10^{-1.27(12+\log(O/H)-8.67)}} \times 0.67 \exp(0.36 \times 10^{-((12+\log(O/H)-8.67))}) \tag{3}
\]

which is the geometrical mean of the curves from Genzel et al. (2012, which follows a power law, as the other literature relations do) and Bolatto et al. (2013, which has a steeper, exponential increase toward very low metallicities). Here, 12 + log(O/H) is the gas-phase oxygen abundance, measured on the Pettini & Pagel (2004) scale (for conversion between metallicity scales, see Kewley & Ellison 2008), calibrated to a solar abundance of 12 + log(O/H)\(_\odot\) = 8.67 (Asplund et al. 2009) and \( \alpha_{\text{CO}}^{\text{MW}} = 4.36 M_\odot \text{(K km s}^{-1}\text{pc}^2\text{)}^{-1} \), which includes a factor of 1.36 for helium (Strong & Mattox 1996).

To obtain metallicities in the absence of a direct tracer, the mass–metallicity relation can be used (see Section 4.2 for discussion). Genzel et al. (2015) determined the following
mass–metallicity relation:

$$12 + \log(O/H)_{PP04} = a - 0.087(\log M_* - b(z))^2,$$

(5)

where $a = 8.74(0.06)$ and $b(z) = 10.4(0.05) + 4.46(0.3)$ \log(1 + z) - 1.78(0.4)\log^2(1 + z)$ (uncertainties in brackets), which is determined by combining several relations at different redshifts (Erb et al. 2006; Maiolino et al. 2008; Zahid et al. 2014; Wuyts et al. 2014). Notably, this relation approaches that of Maiolino et al. (2008) determined at $z = 3.5$.

Alternatively, we can determine $M_{mol}$ from [CI], under the assumption of an excitation temperature $T_{ex}$ and a neutral atomic carbon abundance (Weiβ et al. 2005; see Boogaard et al. 2020 for a detailed description). We adopt $T_{ex} = 30$ K (Walter et al. 2011; note that the atomic carbon mass is not a strong function of excitation temperature above $T_{ex} = 20$ K) and an abundance of $[\text{C} II]/[\text{H}_2] = 2 \times 10^{-5}$ (Valentino et al. 2018; Boogaard et al. 2020). We will revisit the latter assumption in Section 4.2.

The dust can be used as a third tracer of the molecular gas mass. We compute the dust mass by relying on assumption that the Rayleigh–Jeans (RJ) tail of the dust blackbody at long wavelengths is nearly always optically thin (Scoville et al. 2016).

Specifically, we follow Magnelli et al. (2020) and assume a dust opacity of $\kappa_{\nu_0} = 0.0431 \, \text{m}^2\text{kg}^{-1}$ at $\nu_0 = 352.6$ GHz (i.e., 850 μm; Li & Draine 2001), a mass-weighted mean dust temperature of $\langle T_{\text{dust}}\rangle_M = 25$ K, and a dust emissivity spectral index of $\beta = 1.8$. As argued by Scoville et al. (2016), the cold dust is the dominant contributor to the dust mass and the RJ tail of the dust emission, and recent studies by Planck and Herschel have found the temperature to be in the range of 15–35 K (e.g., Planck Collaboration et al. 2011; Magnelli et al. 2014). Varying beta between 1.5 and 2.0 (the range typically assumed for the larger grains that dominate the far-infrared emission; e.g., Da Cunha et al. 2008) impacts the dust masses by 20%–40%. Varying the dust temperature between 15 and 35 K has a more significant impact on the inferred gas masses, ranging from a factor of 5.0–0.5, because the observations at rest-frame 275 μm start probing the emission away from the RJ tail and closer to the peak (this is further discussed in Section 4.2).
correct for the impact of the cosmic microwave background on the equilibrium dust temperature and observed flux density (da Cunha et al. 2013), which increases the inferred mass by 10%.

To convert the dust masses to gas masses, we assume a metallicity-dependent gas-to-dust ratio (\( \delta_{GDR} \propto \frac{M_{\text{mol}}}{M_{\text{dust}}} \)), with \( \delta_{GDR}(Z) = 100 \) (Draine et al. 2007), making the common assumption that the gas in our galaxies at \( z = 3.45 \) is predominantly molecular (e.g., Daddi et al. 2010b; Genzel et al. 2015; Tacconi et al. 2018). The \( \delta_{GDR} \propto Z^\gamma \) has been observed to decrease close to linearly toward subsolar metallicities (with \( \gamma \approx -1 \); e.g., Leroy et al. 2011; Magdis et al. 2012; Saintonge et al. 2013; Sandstrom et al. 2013). However, there is increasing evidence of a steeper relation for metallicities below 12+ log(O/H) 8.0–8.1; Remy-Ruyer et al. (2014) find \( \gamma \approx -3.1 \) in local galaxies, while observations at \( z \sim 2 \) suggest that \( \gamma < -2.2 \) (Coogan et al. 2019), in agreement with the fiducial model from Popping et al. (2017). We explore both regimes, assuming the power-law \( \delta_{GDR}(Z) \) relation from Tacconi et al. (2018) for a shallower increase with metallicity. For a steeper \( \delta_{GDR}(Z) \) at low metallicity, we adopt the broken power-law relation from Remy-Ruyer et al. (2014, the XCO,Z case), which we scale to the same assumptions (12 + log(O/H) 8.67; \( \delta_{GDR}(Z) = 100 \)): \( \delta_{GDR}(Z) = \begin{cases} 10^{2+\gamma_H(x-8.67)} & \text{for } x > 8.1 \\ 10^{0.8+\gamma_L(x-8.67)} & \text{for } x \leq 8.1 \end{cases} \) (Equation (6))

with \( x = 12 + \log(O/H) \). Here \( \gamma_H = -1 \) and \( \gamma_L = -3.1 \) are the power-law slopes at high and low metallicity, respectively. The relation from Tacconi et al. (2018) is obtained from Equation (6) by taking the \( x > 8.1 \) solution at all metallicities, with \( \gamma_H = -0.85 \).

4.2. Low Metallicity Driving a High Molecular Gas Mass-to-light Ratio

We show the constraints on the molecular gas in the context of the molecular gas-to-stellar mass ratio (\( \frac{M_{\text{gas}}}{M_{\text{stellar}}} \)) and the gas fraction (\( \frac{\text{gas}}{M_{\text{stellar}} + M_{\text{gas}}} \)), including a literature sample of CO observations at low and high redshifts, in Figure 8. On the basis of the literature sample, we take the mass-selected sample of Sloan Digital Sky Survey galaxies at \( z = 0 \) from xCOLDGASS (Saintonge et al. 2017), together with the massive, main-sequence-selected galaxies at \( z = 0.5–2.5 \) from the Plateau de Bure High-z Blue Sequence Survey (PHTBS1+2) from the Tacconi et al. (2018) compilation and the galaxies from ASPECS at \( z = 1.0–3.6 \) (Aravena et al. 2019; Boogaard et al. 2019). We supplement these with studies that contain observations of CO in (strongly lensed) star-forming galaxies at \( z \geq 3 \) from Magdis et al. (2012, 2017, using the updated values from Tan et al. 2013; Dessauges-Zavadsky et al. (2015, 2017, which include two sources from Riechers et al. 2010), Gowarhdan et al. (2019), and Cassata et al. (2015, based on the sources from Schinnerer et al. 2016). We convert the literature observations to the metallicity-dependent \( \alpha_{CO} \) (Equation (4); using the mass–metallicity relation when needed, Equation (5)) and adopt \( r_2 = 0.77 \) and \( r_1 = 0.55 \) (±0.1; to remain consistent with Tacconi et al. 2018), though we keep the excitation corrections as assumed by the authors in case these are better constrained through additional line measurements (Boogaard et al. 2020; Cassata et al. 2020).24

Assuming conversion factors that apply at solar metallicity (\( \alpha_{CO} = 4.36, \delta_{GDR} = 100 \)), the stacking results imply gas fractions that appear to be in tension with the observed gas fractions in galaxies at \( z \geq 3 \) at a similar stellar mass (see Figure 8). This is in particular true for stringent limit based on the dust, which places our low-mass galaxies among the lowest gas fractions observed at \( z = 3-4 \), with \( f_{\text{gas}} \leq 0.5 \). For CO, the tension becomes clearer once we take into account that our galaxies are over an order of magnitude lower in stellar mass than the typical galaxy studied in molecular gas at high redshift. The gas fraction in star-forming galaxies is observed to increase toward lower masses and expected to be substantial for low-mass galaxies at these epochs (Scoville et al. 2017; Tacconi et al. 2018; Liu et al. 2019). For reference, we show the predicted gas fraction for a main-sequence galaxy with \( M_\text{stellar} = 10^{9.1} \pm 10^{0.2} M_\odot \) from Tacconi et al. (2018),25 taking into account an extra 0.2 dex uncertainty in the average stellar mass, as well as for \( M_\text{gas} = 10^{10} M_\odot \) (that is, more massive than the most massive galaxy in our sample). We also show the predicted gas fractions from Liu et al. (2019), based on dust-continuum measurements only, which are higher than those from Tacconi et al. (2018); the relations from Scoville et al. (2017 predict even higher gas fractions). Taking into account the evolution of the gas fraction in low-mass galaxies, the

---

24 For example, in the case of ASPECS, the measured \( r_1 = 0.8 \) (Boogaard et al. 2020; Riechers et al. 2020) implies a factor of 1.5× higher gas masses than the average value from Tacconi et al. (2018). Note however that, as argued in Section 4.1, differences in the excitation do not affect the upper limit on the gas mass of our star-forming galaxies at \( z = 3.45 \), unless the excitation is significantly lower than our (conservative) lower limit.

25 We adopt the “\( \beta = 0 \)” scaling relation from Tacconi et al. (2018), assuming a main sequence as observed by Whitaker et al. (2014). Using their alternative “\( \beta = 2 \)” relation instead (which predicts a stronger increase in the gas fractions at lower redshift, with a turnover toward decreasing gas fractions above \( z > 3 \)), the upper limits are still below the nominal value, but the limit based on CO falls within the scatter.
upper limit based on the CO is also in tension with the expected gas fraction. At face value, this result suggests that the galaxies in our sample have unexpectedly low molecular gas fractions. However, a more likely explanation is that the assumption of a Galactic $\alpha_{\text{CO}}$ and gas-to-dust ratio does not hold for these systems. Indeed, significantly higher conversion factors would be naturally explained by subSolar metallicities for these systems.

In Figure 9, we show the mass–metallicity (MZ) relation from Equation (5) at the average redshift of our sample. We find that the metallicity at the median mass (16th, 84th percentile) of the sample is $12 + \log(O/H) = 7.7_{-0.2}^{+0.3}$. However, the MZ relation is only an approximate tracer of the metallicity. More directly, the $[\text{O~III}]\lambda5008/\text{H}β\lambda4863$ ratio can be used to trace the metallicity, albeit with significant scatter, as the ratio monotonically increases with decreasing metallicity, up to a turnover at $12 + \log(O/H) \sim 8.0$ (e.g., Curti et al. 2017; Sanders et al. 2020). Because of this turnover, there are two metallicity solutions at a fixed ratio: one on the upper branch (high metallicity) and one on the lower branch (low metallicity). We robustly detect H$β$ in two objects, finding high ratios of $\log([\text{O~III}]\lambda5008/\text{H}β)$ $\approx 0.8$ for two (MUSE-1019 and MUSE-6878). This roughly implies a metallicity at the turnover, $12 + \log(O/H) \sim 8.0$, via the direct method (Curti et al. 2017).26 We also tentatively detect H$β$ for a third object (MUSE-6895), yielding a lower ratio ($0.35$), which implies a high metallicity if it is on the upper branch of the metallicity calibration, in tension with its stellar mass. However, assuming that it follows the (extrapolated) lower branch, this would imply a much lower metallicity of $12 + \log(O/H) \sim 7.35$ (and an extremely high $\alpha_{\text{CO}} \gg 100$), in better agreement with the stellar mass. For the remaining galaxies, we only find (weak) upper limits on the metallicity (conservatively assuming all are on the higher branch).

To obtain an estimate of the average metallicity in the sample, we stack the KMOS spectra using weighted mean and median stacking. Because of the uncertainties in the background level (see Section 2.2.2), we do not normalize the spectra but stack the continuum-subtracted spectra instead, which may introduce a bias toward the brighter objects that go into the stack. Note that, due to the shifting to a common redshift, the skyline residuals are spread throughout the stack, though this problem should be mitigated in the median stack. The stacked spectra are shown in Figure 10. We tentatively detect H$β$ at $2\sigma-3\sigma$, measuring $\log([\text{O~III}]\lambda5008/\text{H}β) \approx 0.9_{-0.3}^{+0.3}$, which broadly implies a metallicity of $12 + \log(O/H) \approx 7.6-8.0$. We do caution against overinterpreting the stack, given the uncertainties mentioned above. It should also be stressed that the mass–metallicity relation only holds on average. For example, Dessauges-Zavadsky et al. (2017) found that the lensed arc at $z = 3.6$ has a higher inferred metallicity from its measured $[\text{O~III}]\lambda5008/\text{H}β$-ratio than predicted from the MZ. While the sample selection could in principle bias the average metallicity, this is not immediately

---

26 http://www.arcetri.astro.it/metallicity/calibrazioni.pl
metallicity of $12 + \log(O/H) \approx 7.8 \pm 0.2$ for the galaxies in our sample.

The average metallicity of our sample implies a significantly higher value of $\alpha_{\text{CO}} \approx 50$, which places our upper limit in comfortable agreement with the predicted gas fractions (see Figure 8). Notice that the strong, nonlinear increase in the conversion factor with metallicity (Equation (4)) makes the exact value uncertain, particularly in the low-mass range. Furthermore, we caution that there is still debate about the exact relation between $\alpha_{\text{CO}}$ and metallicity at low metallicity, mostly due to the difficulty of constraining $\alpha_{\text{CO}}$ at low metallicity. In any case, a minimum value of $\alpha_{\text{CO}} \geq 10$ is required to place the 3σ upper limit on the Tacconi et al. (2018) relation, more than 2 times the Galactic value.

The shallower relations between the gas-to-dust ratio and metallicity yield gas-to-dust ratios that are insufficient to reconcile the observed limit with the scaling relations, which requires a $\delta_{\text{GDR}} \geq 1200$. For example, we find $\delta_{\text{GDR}} \approx 550$ based on Tacconi et al. (2018), see Equation (6)). This points toward a steeper relation between the $\delta_{\text{GDR}}$ and metallicity in the low-metallicity regime, as suggested by, for example, Rémy-Ruyer et al. (2014) and Coogan et al. (2019) (see Section 4.1). Adopting the relation from Rémy-Ruyer et al. (2014, Equation (6)) yields a significantly higher $\delta_{\text{GDR}} \approx 3300$, again placing our upper limit in comfortable agreement with the expected gas fraction. Alternatively, a dust temperature of $T_{\text{dust}} < 20$ K (as opposed to 25 K) can also reconcile the difference with a lower $\delta_{\text{GDR}}$. However, given the stronger radiation field expected at low metallicity, it is not clear that the dust temperatures would be much lower than assumed.

Independent of CO and the dust, we reach similar conclusions using [CI] instead. While a typical abundance ratio of $2 \times 10^{-5}$ predicts a gas mass that is marginally consistent with the scaling relations, assuming a lower abundance (e.g., $8 \times$; loosely based on the metallicity) easily yields a limit that is fully consistent with the scaling relations, with a $\approx 2 \times$ lower abundance being minimally required (see Figure 8). Note that the metallicity impacts CO and [CI] in different ways, however, such that [CI] may be a preferred over CO as a tracer of cold gas in low-metallicity environments (we will come back to this point in Section 4.4).

For reference, we collect the different molecular gas masses and gas-to-stellar mass ratios that are discussed in this section, and shown in Figure 8, in Table 2.

### 4.3. Contribution to the Cosmic Molecular Gas Density

The galaxies under study are below the detection threshold of current $\rho_{\text{mol}}(z)$ surveys (e.g., Decarli et al. 2020; Riechers et al. 2019; Decarli et al. 2019). Still, their potentially high gas mass-to-light ratios imply that they could have a significant contribution to the total cosmic molecular gas density. Assuming the average gas masses derived from the stacks are representative of all 67 galaxies in the photometric catalog down to $H_{\text{F150W}} = 26$ (cf. Figure 1), we compute the total contribution of these galaxies to the cosmic molecular gas density, $\rho(3.0115 < z < 3.812)$. We adopt the solar, the minimum, and the subsolar conversion factors from Section 4.2, and $r_{\text{d}} = 0.5$, and shift the CO-based determinations of $\rho_{\text{mol}}$ at $z > 0$ to match our assumption on $\alpha_{\text{CO}}$. The result can be seen in Figure 11. Because the upper limits are not stringent enough, the results are inconclusive. On one hand, they do not exclude the possibility that a significant amount of molecular gas is missed due to the...
Table 2

| Tracer                  | Conversion factor | $\langle M_{\text{mol}} \rangle$ (x $10^3 \, M_\odot$) | $\langle \mu_{\text{gas}} \rangle$ |
|-------------------------|------------------|--------------------------------------------------|-----------------------------------|
|                         | (1)              | (2)                                              | (3)                               | (4)                            |

| [C II] $^3P_1 \rightarrow ^3P_0$ | $X_{\text{C II}} = 2.5 \times 10^{-6}$ | $< 63.3$                                      | $< 50.3$                          |
| $S_{\nu}(1.2 \, \text{mm})$ | $\delta_{\text{GDR}} = 550$ | $< 5.99$                                      | $< 4.76$                          |
| $S_{\nu}(1.2 \, \text{mm})$ | $\delta_{\text{GDR}} = 3300$ | $< 36.0$                                      | $< 28.6$                          |

Note. Derived from the upper limits (see Section 3.2 and Table 1) for the full systemic redshift sample $(\langle M_* \rangle = 10^{10.1} \, M_\odot)$ as explained in Section 4.1, with metallicity-dependent conversion factors as listed. (1) Molecular gas tracer. (2) Adopted (metallicity dependent) conversion factor $(X_{\text{C II}} = [\text{C II}]/[\text{H}_2])$. (3) Upper limit on molecular gas mass. (4) Upper limit on $(\mu_{\text{gas}}) = (M_{\text{mol}}/(M_*))$.

Figure 11. Cosmic molecular gas density as a function of redshift. The literature data are from Fletcher et al. (2021; xCOLDGASS), Riechers et al. (2019; COLDz), Riechers et al. (2020; VLASPECS), Lenczk et al. (2020; PHIBSS2), Decarli et al. (2020; ASPECS-LP CO), and Magnelli et al. (2020; ASPECS-LP dust), and we also show the best fit from Walter et al. (2020). We show the estimates on the upper limit on the cosmic molecular density for all galaxies with $H_{\text{FIR}} \lesssim 26$ at $3.0115 < z < 3.812$, as derived from CO (red assuming $x_{\text{CO}} = 0.5$) and the dust continuum (black), under the assumption our stacked averages are representative for the larger population. The different limits are for conversion factors $(\alpha_{\text{CO}}, \delta_{\text{GDR}}) = (4.36, 100), (10, 12000),$ and $(50, 3300)$, corresponding to solar metallicity, the minimum value based on Section 4.2, and the best-estimate subsolar metallicity (the CO-based literature data are scaled to match our assumption on $\alpha_{\text{CO}}^{\text{GDR}}$). The upper limits do not rule out a large amount of molecular gas in lower mass galaxies (that would have been missed in previous surveys, due to their high gas mass-to-light ratio), but are equally consistent with a smaller contribution to the total molecular gas budget.

4.4. Implications for Observing Molecular Gas in Low-metallicity Galaxies at High Redshift

The evolution of the metallicity of star-forming galaxies with redshift has significant implications for the detectability of molecular gas at $z \gtrsim 3$. Even in the local universe, detecting CO in low-metallicity dwarf galaxies has been challenging (e.g., Schruba et al. 2012; Hunt et al. 2015). The substantial CO-to-H$_2$ conversion factor and gas-to-dust ratios inferred for our low-mass, low-metallicity galaxies imply that detecting the molecular gas reservoir in these galaxies will be very challenging on an individual basis, even with modern instruments. Similar conclusions are also reached for more massive galaxies at subsolar metallicities (e.g., Tan et al. 2013; Coogan et al. 2019). Tan et al. (2013) have shown that under the assumption of an $M_\text{Z}/\alpha_{\text{CO}}$ relation similar to the one adopted here, the expected CO luminosity for a star-forming galaxy on the main sequence rapidly declines, due to the metallicity evolution. This raises the interesting question of how the molecular gas content can be best constrained in subsolar-metallicity star-forming galaxies at high redshift.

There are significant uncertainties in deriving a total dust and gas mass from the dust continuum in the low-metallicity regime. Variations in the process and balance of dust formation and destruction at low metallicity, as well as differences in grain composition and size distribution can have a major impact on the gas-to-dust ratio, the dust emissivity, and emerging dust spectrum (e.g., Remy-Ruyer et al. 2014; see also Draine et al. 2007). In addition to these complications, the fainter part of the Rayleigh–Jeans tail at long wavelengths has to be probed, such that the blackbody is dominated by cold dust, which dominates the mass and the uncertainty in the (unknown) mass-weighted dust temperature is minimized (e.g., Scoville et al. 2016).

At low metallicity, CO also becomes an increasingly poor tracer of the total molecular gas reservoir. Because of the lower dust abundance at low metallicity, CO is dissociated and ionized into C and C$^+$ deeper into the clouds, while the H$_2$ self-shields against photodissociation (Gnedin & Draine 2014), resulting in an increasing volume of H$_2$ gas that is not traced by CO at low metallicity (e.g., Wolfire et al. 2010). This provides motivation to investigate and develop the theoretical underpinning for other species as tracers of the molecular gas, such...
as the fainter [CII] lines (e.g., Weiß et al. 2003, 2005; Papadopoulos et al. 2004; see also Valentino et al. 2018; Boogaard et al. 2020), but in particular also [CII] $\lambda 158$ $\mu$m.

The bright [CII] $^3P_{1/2} \rightarrow ^3P_{1/2}$ line at $158 \mu$m is one of the foremost cooling lines of the ISM, also at low metallicity (where it is outranked only by the high-ionization line [OIII] $\lambda 5007$ $\mu$m at 35 eV; e.g., Cormier et al. 2015, 2019) and its high luminosity allows it to be observed in star-forming galaxies out to the highest redshifts (Ouchi et al. 2013; Ota et al. 2014; Capak et al. 2015; Maiolino et al. 2015; Knudsen et al. 2016; Pentericci et al. 2016; Bradač et al. 2017; Matthee et al. 2017, 2019; Hashimoto et al. 2018; Smit et al. 2018; Carniani et al. 2018a, 2018b, 2020; Laporte et al. 2019; Bakx et al. 2020; Béthermin et al. 2020; Harikane et al. 2020; Le Fèvre et al. 2020). With an ionization potential of 11.3 eV (that is, lower than H I at 13.6 eV), [CII] can arise in both the neutral and ionized medium, though it becomes an increasingly better tracer of the neutral ISM toward lower metallicities (Croxal et al. 2017; Cormier et al. 2019; see also Díaz-Santos et al. 2017) potentially due to the carbon in the H II regions being further ionized into C$^+$(++ as witnessed by the shift in the ionization balance to high ionization lines, also see in some high-$z$ sources, e.g., Pavesi et al. 2016; Harikane et al. 2020, see also Carniani et al. 2020). While, as a cooling line, [CII] is in principle sensitive to the heating rate (and not the molecular gas mass), it may be calibrated as a molecular gas tracer (Zanella et al. 2018). As such, [CII] can potentially outperform other tracers of the molecular gas mass, in particular in low-metallicity environments (e.g., Madden et al. 2020). As [CII] is already seeing use as a tracer of the molecular gas at high redshift (e.g., Dessauges-Zavadsky et al. 2020), its use to this end should be further investigated both observationally and theoretically.

### 5. Summary and Conclusions

We present constraints on the molecular gas signal for a sample of 24 star-forming galaxies at $(z) = 3.45$, with a median $M_* = 10^{9.1} M_{\odot}$, in the Hubble Ultra Deep Field (HUDF). Based on their $L_{\text{Ly}O}$ and $H_{\text{F160W}}$ Selection (Figure 1), they show relatively low $EW_{\text{Ly}O} \approx 20$ Å ($L_{\text{Ly}O} = 0.2 L^{*}_{\text{Ly}O}$) and rest-frame UV spectra similar to star-forming galaxies at the same epoch (see Figure 4). We efficiently follow-up LyO-selected galaxies from the MUSE HUDF Survey, with near-infrared spectroscopy from KMOS and MOSFIRE to determine their systemic redshifts (Figure 2 and Figure 12) and stack the molecular line emission from the ALMA Spectroscopic Survey in the HUDF (ASPECS). Our main results are as follows:

1. We determine systemic redshifts from the rest-frame UV and rest-frame optical features, finding an average velocity offset of $\langle \Delta v(\text{LyO}) \rangle = 346$ km s$^{-1}$ (with a 100 to 600 km s$^{-1}$ range) consistent with the relatively low $EW_{\text{Ly}O}$ of the sample (Figure 5).

2. Stacking the signal from $^{12}\text{CO} J = 4 \rightarrow 3$ and [CII] $^3P_1 \rightarrow ^3P_0$ (as well as the $^{12}\text{CO} J = 9 \rightarrow 8$ and $J = 10 \rightarrow 9$ lines), we do not find any detections and determine $3\sigma$ upper limits on the line luminosities of $4.0 \times 10^8 K$ km s$^{-1}$ pc$^2$ and $5.6 \times 10^8 K$ km s$^{-1}$ pc$^2$, respectively, for a line width of 300 km s$^{-1}$ (see Figure 6 and Table 1; also for the limits on the higher-$J$ lines). Stacking the dust continuum at 1.2 mm and 3 mm, we find $3\sigma$ upper limits on the flux densities of $S_* \leq 9 \mu$Jy and $1.2 \mu$Jy, respectively (Figure 7).

3. Comparing the inferred molecular fraction from CO and the dust continuum to scaling relations, we find that assuming a “Galactic” $\alpha_{\text{CO}} = 4.36$ and $\delta_{\text{GDR}} = 100$ significantly underpredicts the expected molecular gas mass (Figure 8). In order to reconcile our measurements with the published scaling relations from Tacconi et al. (2018) would require an $\alpha_{\text{CO}} \geq 10$ and $\delta_{\text{GDR}} \geq 1200$. This result either implies that our galaxies have unexpectedly low gas fractions or that the assumption of solar-metallicity conversion factors breaks down.

4. Using the mass–metallicity relation, as well as constraints from $[\text{OIII}] \lambda 5007/\text{H}$β $\lambda 4863$ (Figure 10), we predict an average metallicity of our sample of $12 + \log(O/H) = 7.8 \pm 0.2$, that is, significantly subsolar. This implies a high $\alpha_{\text{CO}} \approx 50$, making our result consistent with the expected (high) gas fractions at $z = 3.5$ (Figure 9).

5. An approximately linear scaling relation between the gas-to-dust ratio and metallicity ($\delta_{\text{GDR}} \propto \gamma^{-0.85}$; Tacconi et al. 2018) yields $\delta_{\text{GDR}} \approx 550$, which is insufficient to reconcile the limit based on the dust with the scaling relations. Using a steeper relation at low metallicity ($\delta_{\text{GDR}} \propto \gamma^{-3.1}$ at $12 + \log(O/H) < 8.1$; Rémy-Ruyer et al. 2014) instead yields $\delta_{\text{GDR}} \approx 3300$, making our upper limit consistent again (Figure 8).

6. Independent of the CO, we find a similar tension from the [CII] luminosity, which implies a [CII]/H$_2$ abundance lower than that in massive star-forming galaxies such as the Milky Way (Figure 8).

7. Based on the results, we compute the upper limit on the contribution of all galaxies with $H_{\text{F160W}} \leq 26$ to the cosmic molecular gas density $\rho_{\text{mol}}(z = 3.0115-3.812)$. The upper limits are not constraining enough to exclude the possibility of a significant contribution from these galaxies, which lie below the detection threshold of current surveys, to the cosmic molecular gas density.

The results of this work exemplify the difficulty in obtaining molecular gas mass estimates in low-metallicity environments, which are expected to be more prevalent in typical star-forming galaxies at $z \geq 3$. Given the uncertainties associated with the dust and CO at low metallicity, we argue for the further observational and theoretical development of alternative tracers of the molecular gas reservoir, such as the bright [CII] $\lambda 158$ $\mu$m line, that should be more easily observable with ALMA. Obtaining accurate constraints on the gas-phase metallicity of high-redshift galaxies will be key in this regard and one of the key pieces of information that the James Webb Space Telescope will be able to provide.

Appendix A
Spectra

The rest-frame UV (MUSE) and near-IR (KMOS, MOSFIRE) spectra of all galaxies in the sample are shown in Figure 12 (except for the galaxy already shown in Figure 2).
Figure 12. Rest-frame ultraviolet and optical spectra for the galaxies with near-infrared follow-up. The left panel shows the MUSE spectrum surrounding the Lyα line. The right panel shows the continuum-subtracted KMOS or MOSFIRE spectrum (indicated in the figure) around the Hβ and [O III] lines. In both panels the vertical blue and red lines indicate the redshift of Lyα and the systemic redshift, respectively, determined from the fit to the spectrum (shown in the same color). All spectra show a positive velocity offset between the red peak of Lyα and the systemic redshift.

Notes: (1) MUSE ID. (2) Rafelski et al. (2015) ID. (3) R.A. (4) decl. (5) Redshift measured from Ly$\alpha$ \(\lambda1216\) (the red peak, in the case of a double-peaked line). (6) Velocity uncertainty on redshift. (7) Systemic redshift. (8) Velocity uncertainty on systemic redshift. (9) Source of systemic redshift (MUSE EMission or ABSoption, KMOS, MOSFIRE). (10) Ly$\alpha$ velocity offset, \(\Delta v(Ly\alpha) = c(z_{Ly\alpha}^{\text{sys}} - z_{Ly\alpha})/(1 + z_{Ly\alpha})\). (11) Stellar mass. (12) Star formation rate from MAGPHYS, with a minimum uncertainty of 0.1 dex.

\(a\) Blended with a \(z = 0.83\) foreground object.
