A water-soluble fluorescent probe (C-GGH) was used for the highly sensitive and selective detection of cyanide (CN–) in aqueous media based on the displacement strategy. Due to the presence of the recognition unit GGH (Gly-Gly-His), the probe C-GGH can coordinate with Cu2+ and consequently display ON-OFF type fluorescence response. Furthermore, the in situ formed nonfluorescent C-GGH-Cu2+ complex can act as an effective OFF-ON type fluorescent probe for sensing CN– anion. Due to the strong binding affinity of CN– to Cu2+, CN– can extract Cu2+ from C-GGH-Cu2+ complex, leading to the release of C-GGH and the recovery of fluorescent emission of the system. The probe C-GGH-Cu2+ allowed detection of CN– in aqueous solution with a LOD (limit of detection) of 0.017 μmol/L which is much lower than the maximum contaminant level (1.9 μmol/L) for CN– in drinking water set by the WHO (World Health Organization). The probe also displayed excellent specificity for CN– towards other anions, including F-, Cl–, Br–, I–, SCN–, PO43–, N3–, NO3–, AcO–, SO42–, and CO32–.

1. Introduction

The development of effective methods for the recognition and sensing of anions has recently received considerable attention due to the importance of these species in biological and industrial processes [1–6]. Among various anions, cyanide (CN–) is considered to be one of the most toxic species due to its capability to bind strongly to ferric ions in cytochrome oxidase and reduce the activity of this enzyme [7]. Assimilation of CN– through skin, lungs, and gastrointestinal tract can lead to convulsion, unconsciousness, and eventually death [8]. According to the World Health Organization (WHO), the maximum permissible level of CN– in drinking water is 1.9 μmol/L [9]. But, on the other hand, cyanide is extremely useful in various industrial processes such as gold mining, electroplating, metallurgy, and production of organic chemicals and polymers [10, 11]. The widespread industrial use of cyanide inevitably causes the accidental release of cyanide into the environment, therefore leading to serious problems. Consequently, it is highly required to exploit effective ways for monitoring the presence of cyanide anion [4, 12].

Various analytical methods and techniques have been developed for the determination of CN–, including titrimetry [13], voltammetry [14, 15], chromatography [16, 17], colorimetry [18, 19], and fluorometry [4, 12]. Many of these methods involve strict requirements of the sample handling, such as acidification of the CN– followed by extraction of HCN. Therefore, quick methods that permit selective in situ determination of CN– with high selectivity are highly required for medical point-of-care, industrial, and environmental online monitoring. Fluorometric assays based on optical probes possess innate advantages over other techniques, because of their simplicity of implementation, fast response times, high sensitivity, and excellent selectivity [20, 21]. Among the fluorescent probes, there are mainly four strategies for CN–...
sensing: (i) coordination to electron-deficient center [15], (ii) nucleophilic addition to the electron-deficient π-system [22, 23], (iii) hydrogen-bonding interaction [24, 25], and (iv) metal-CN⁻ affinity (displacement approach) [26–29]. Among these four approaches, the displacement strategy, where CN⁻ extracts Cu²⁺ from the metal receptor complex to form stable Cu(CN)ₓ, resulting in a detectable optical signal, has attracted special attention. Cu(II) complexes of fluorescent chromophores are usually nonfluorescent due to the paramagnetic quenching effect. Upon the addition of cyanide, CN⁻ ions react with copper ion in such nonfluorescent copper complex to form very stable Cu(CN)ₓ species. This results in the recovery of the fluorescence of the chromophore. Thus, a type of turn-on fluorescent CN⁻ probe has been developed based on Cu(II) ensembles. In designing such probe, fluorophores with high quantum yields are required in order to improve the signal-to-noise ratio. Additionally, a recognition unit with high affinity towards Cu²⁺ should be incorporated to ensure that fluorescence quenching occurs upon addition of Cu²⁺. In the literature, there are few reports on Cu²⁺-ensemble based receptors for the fluorescence turn-on optical detection of CN⁻. However, most of these receptors have the drawbacks of poor selectivity and/or poor water solubility.

In previous work, we reported a fluorescent probe C-GGH by incorporation of a natural tripeptide GGH (Gly-Gly-His) moiety to a coumarin fluorophore. Taking advantage of the natural tripeptide GGH, the probe exhibits excellent biocompatibility and water solubility [30]. Herein, we exploited this probe for the detection of CN⁻ based on a displacement sensing strategy. Due to the specific recognition of Cu²⁺ by GGH, the probe can bind with copper ions to form C-GHH-Cu²⁺ complex, and the paramagnetic Cu²⁺ center has a pronounced quenching effect on the fluorescence of the probe. Then, in the presence of CN⁻, Cu²⁺ can be released from the complex of C-GHH-Cu²⁺, resulting in the luminescence restoration of the probe. The ensemble C-GGH-Cu²⁺ allowed detection of CN⁻ in aqueous solution with high sensitivity and excellent selectivity.

2. Experimental

2.1. Materials and Instrumentation. All chemical reagents and solvents for synthesis were of analytical grade and commercially available and used as received without further purification unless otherwise stated. Deionized water (18 MΩ cm⁻¹) from a water purification system (Simplicity Plus, Millipore Corp., Billerica, MA, USA) was used throughout. C-GGH (coumarin-Gly-Gly-His) was synthesized by following standard solid phase 9-fluorenylmethoxycarbonyl (Fmoc) chemistry according to our previously reported procedure [30].

The fluorescence spectra were carried out on a Varian Cary Eclipse spectrophotometer. The absorbance spectra were recorded on a Varian UV-Vis spectrophotometer. The excitation wavelength was 420 nm. The excitation and emission slit width were set both at 5 nm. All experiments were conducted at room temperature.

2.2. UV-Vis and Fluorescence Titration Experiments. The detection measurements were conducted as follows. First, the stock solution of the sensor was prepared by dissolving the sensor compound in HEPES buffered aqueous solution (10 mmol/L, pH 10.0) containing 1.0 mmol/L CTAB (cetyltrimethylammonium bromide). The stock solution of Na₂S was prepared by dissolving Na₂S in HEPES buffer (10 mmol/L, pH 10.0). Before the measurements, the probe stock solution and the CN⁻ stock solution were diluted with HEPES buffered water (pH 10.0), and then the diluted CN⁻ was added into the diluted probe solution; afterward, the fluorescence spectra were recorded immediately. All spectrum tests were carried out in a HEPES buffered (10 mmol/L, pH 10.0) aqueous solution containing 1 mmol/L CTAB.

2.3. Detection of CN⁻ in Real Sample. To begin with, 10 mL of cyanide-containing gold leach waste solution (taken from a gold mine tailings pond in Hunan, China) was diluted with 90 mL water. And the solution was filtered through a 0.22 μm PTFE filter. Then 4 μL of the above solution was added to 2 mL probe solution. Subsequently, various concentrations of CN⁻ were introduced into the above mixtures and the fluorescent spectra were recorded.

3. Results and Discussion

3.1. Absorption and Fluorescence Spectroscopy of C-GGH to Cu²⁺. The interaction of C-GGH with Cu²⁺ was investigated by UV-Vis spectrophotometric titration in HEPES buffer (10 mmol/L, pH 10.0). The UV-Vis absorption spectrum of C-GGH displayed a strong absorbance band centered at about 430 nm, which is the characteristic absorption profile of 7-diethylaminocoumarin-3-carboxylic acid. Titrations of Cu²⁺ with solutions of C-GGH led to substantial changes in UV-Vis spectra. As shown in Figure 1, upon an increase in the concentration of introduced Cu²⁺ (0-1 equiv. of Cu²⁺),
and Pb

GGH to a paramagnetic Cu

addition of 2 equiv. of K

examined in the presence of various metal species. The properties of observed at 478 nm. First, to gain insight into the sensing (10 mmol/L, pH 10.0), and a strong emission peak was excitation of the fluorophore at 430 nm in HEPES buffer.

dramatic fluorescent quenching in Figure 3(b), the emission band of ions in varying concentrations was conducted. As shown (0–2 equiv.) in HEPES aqueous buffer (10 mmol/L, pH 10.0). Inset shows fluorescence changes of C-GGH at 478 nm as a function of the Cu²⁺ concentration.

The fluorescence spectra of C-GGH were obtained by excitation of the fluorophore at 430 nm in HEPES buffer (10 mmol/L, pH 10.0), and a strong emission peak was observed at 478 nm. First, to gain insight into the sensing properties of C-GGH, the emission characteristics were examined in the presence of various metal species. The addition of 2 equiv. of K⁺, Zn²⁺, Fe³⁺, Fe⁵⁺, Ca²⁺, Cd²⁺, Na⁺, Li⁺, Ba²⁺, Mn²⁺, Mg²⁺, Al³⁺, Pb²⁺, and Ni²⁺ had no obvious effect on the fluorescence emission of C-GGH (Figure 2(a)). When 1 equiv. of Cu²⁺ was added to the probe solution, dramatic fluorescent quenching (quenching efficiency (I₀ − I)/I₀ × 100 = 94%) was observed, suggesting that probe C-GGH shows a specific response to Cu²⁺ which can be ascribed to the selective coordination of GGH to Cu²⁺ and the chelation-enhanced fluorescence quenching (CHEQ) effect of the paramagnetic Cu²⁺ center.

To quantitatively evaluate the luminescence response of C-GGH towards Cu²⁺, fluorescence titration with Cu²⁺ ions in varying concentrations was conducted. As shown in Figure 3(b), the emission band of C-GGH was gradually quenched upon addition of incremental amounts of Cu²⁺. The dose-dependent luminescence quenching shows a good correlation that can be expressed as

\[ I = 377.9 - 349.7 \times (\text{Cu}^{2+} \text{ mol/L}) \] (R = 0.999).

The LOD (limit of detection) of C-GGH for determination of Cu²⁺ was calculated to be 21 nM (S/N = 3). This value is much lower than the maximum contaminant level (~20 μmol/L) for copper in drinking water set by the U.S. Environmental Protection Agency [31], indicating that the probe C-GGH is sensitive enough to monitor Cu²⁺ for environmental assessment.

To investigate the range of pH in which C-GGH can effectively respond to Cu²⁺, we measured the titration curve of fluorescence intensity versus pH of the aqueous solution (Figure 3, curve a). The free C-GGH exhibited strong fluorescence in the studied pH range of 4–12. The effect of pH on the fluorescence of C-GGH-Cu²⁺ exhibited a quite different feature from that of the free probe C-GGH (Figure 3, curve b).

**Figure 2:** (a) Fluorescence responses of C-GGH (1 μmol/L) to different ions (2 equiv. for K⁺, Zn²⁺, Fe³⁺, Fe⁵⁺, Ca²⁺, Na⁺, Mn²⁺, Mg²⁺, Al³⁺, and Pb²⁺; 1 equiv for Cu²⁺) in HEPES buffer aqueous solution (10 mmol/L, pH 10.0). Fluorescence titration of C-GGH (1 μmol/L) with Cu²⁺ (0–2 equiv.) in HEPES aqueous buffer (10 mmol/L, pH 10.0). Inset shows fluorescence changes of C-GGH at 478 nm as a function of the Cu²⁺ concentration.

**Figure 3:** Fluorescence intensity of C-GGH at different pH: (a) free C-GGH, (b) C-GGH and Cu²⁺. Concentration of C-GGH is kept constant at 1.0 μmol/L. Concentration of Cu²⁺ is 1.0 μmol/L. Excitation is selected at 430 nm.
The LOD of $\text{CN}^-$ solution is increased steadily with incremental amounts of As shown in Figure 4, the emission intensity of the probe $\text{Cu}^{2+}$ causes no quenching to the fluorescence of $\text{C}-\text{GGH}$. The final pH value for this sensing system was set at 10.0.

3.2. Fluorescence Response of $\text{C}-\text{GGH-Cu}^{2+}$ to $\text{CN}^-$. Cyanide anion can coordinate with $\text{Cu}^{2+}$ to form a highly stable species $\text{Cu(CN)}_2^-$ which has a much lower solubility product constant ($K = 1.27 \times 10^{-24}$) compared with that of $\text{C}-\text{GGH-Cu}^{2+}$ ($6.58 \times 10^{-6}$) [30]. Therefore, the in situ formed $\text{C}-\text{GGH-Cu}^{2+}$ complex could be a promising "OFF-ON" type luminescent sensor for the $\text{CN}^-$ anion based on displacement approach. To investigate the luminescence response of $\text{C}-\text{GGH-Cu}^{2+}$ towards $\text{CN}^-$ in 100% aqueous media, a luminescence titration experiment was conducted by introducing different concentrations of $\text{CN}^-$ into $\text{C}-\text{GGH-Cu}^{2+}$ ($1 \mu\text{mol}/\text{L}) in 10 \text{mmol/L HEPES buffer of pH 10.0. As shown in Figure 4, the emission intensity of the probe solution is increased steadily with incremental amounts of $\text{CN}^-$, and on addition of about 15 equiv. of $\text{CN}^-$ anion both the intensity and shape of the emission spectrum of $\text{C}-\text{GGH}$ were completely restored. The dose-dependent luminescence enhancement shows good linearity over a concentration range of 0.2–15.0 $\mu\text{mol}/\text{L}$, which can be expressed as $I = 28.36 + 22.45 \times ([\text{CN}^-]/\mu\text{mol}/\text{L}) \ (R = 0.998) \ \text{(Figure 4(b))}$. The LOD of $\text{C}-\text{GGH}$ probe for $\text{CN}^-$ was calculated to be $0.017 \mu\text{mol}/\text{L}$, which lies well below the limit of 1.9 $\mu\text{mol}/\text{L}$ for $\text{CN}^-$ in drinking water set by WHO, indicating that the probe is sensitive enough for practical applications.

It is well known that the most significant behavior of a chemosensor is the high selectivity towards the analyte. In order to evaluate the selectivity of the proposed sensor for $\text{CN}^-$, fluorescence responses of $\text{C}-\text{GGH-Cu}^{2+}$ in the presence of various anions including $\text{F}^-$, $\text{Cl}^-$, $\text{Br}^-$, $\Gamma^-$, $\text{SCN}^-$, $\text{PO}_4^{3-}$, $\text{N}_3^-$, $\text{NO}_3^-$, $\text{AcO}^-$, $\text{SO}_4^{2-}$, and $\text{CO}_3^{2-}$ were measured. All these physiological and environmental important anions induced negligible fluorescence intensity changes (Figure 5(a)). Thus, the in situ generated $\text{C}-\text{GGH-Cu}^{2+}$ complex can behave as a high selective luminescent "OFF-ON" sensor for $\text{CN}^-$. To explore whether the $\text{C}-\text{GGH-Cu}^{2+}$ complex could maintain its sensing response to $\text{CN}^-$ in the presence of various other relevant interferences, competition experiments of $\text{C}-\text{GGH-Cu}^{2+}$ were conducted. Figure 5(b) shows the luminescence responses of $\text{C}-\text{GGH-Cu}^{2+}$ to $\text{CN}^-$ in the presence of various other anions. The results indicated that none of the other anions interfered with $\text{CN}^-$ detection. All other anions only caused very weak background signal, while upon consequent addition of $\text{CN}^-$ to each mixture, immediate enhancement in luminescence response was achieved.

3.3. Detection of $\text{CN}^-$ in Real Sample. To assess the ability of $\text{C}-\text{GGH-Cu}^{2+}$ for practical application, the probe was applied to monitor $\text{CN}^-$ in a cyanide-containing gold leach waste solution. The accuracy of the assay was evaluated by spiking a known amount of standard $\text{CN}^-$ solution and calculating its recovery. The results were summarized in Table 1. The recoveries of different known amounts of $\text{CN}^-$ added were obtained from 96.0% to 102.0% with satisfactory analytical precision (RSD ≤ 4.3%), which confirmed the feasibility and reliability of the present probe.

4. Conclusions

In summary, a water-soluble fluorescent probe $\text{C}-\text{GGH}$ was successfully used for recognition of $\text{Cu}^{2+}$ and $\text{CN}^-$ based on the displacement strategy. The probe $\text{C}-\text{GGH}$ displayed high selectivity and sensitivity for copper ions in 100% aqueous media.
aqueous solution. The *in situ* formed C-GGH-Cu\(^{2+}\) can effectively respond to CN\(^-\) accompanied by the fluorescence recovery of the probe system. The probe C-GGH-Cu\(^{2+}\) allowed detection of CN\(^-\) in aqueous solution with a LOD of 0.017 \(\mu\text{mol/L}\), which is much lower than the maximum contaminant level (1.9 \(\mu\text{mol/L}\)) for cyanide in drinking water set by the WHO. And the probe C-GGH-Cu\(^{2+}\) exhibited high selectivity for CN\(^-\) over other common anions. The proposed method was also successfully applied to detect the contents of CN\(^-\) in a cyanide-containing gold leach waste solution, which implies its great potential for the practical applications.
