Efficient oxygen evolution electrocatalysis in acid by a perovskite with face-sharing IrO$_6$ octahedral dimers

Lan Yang$^{1,2}$, Guangtao Yu$^3$, Xuan Ai$^1$, Wensheng Yan$^4$, Hengli Duan$^4$, Wei Chen$^3$, Xiaotian Li$^2$, Ting Wang$^3$, Chenghui Zhang$^3$, Xuri Huang$^3$, Jie-Sheng Chen$^5$ & Xiaoxin Zou$^1$

The widespread use of proton exchange membrane water electrolysis requires the development of more efficient electrocatalysts containing reduced amounts of expensive iridium for the oxygen evolution reaction (OER). Here we present the identification of 6H-phase SrIrO$_3$ perovskite (6H-SrIrO$_3$) as a highly active electrocatalyst with good structural and catalytic stability for OER in acid. 6H-SrIrO$_3$ contains 27.1 wt% less iridium than IrO$_2$, but its iridium mass activity is about 7 times higher than IrO$_2$, a benchmark electrocatalyst for the acidic OER. 6H-SrIrO$_3$ is the most active catalytic material for OER among the iridium-based oxides reported recently, based on its highest iridium mass activity. Theoretical calculations indicate that the existence of face-sharing octahedral dimers is mainly responsible for the superior activity of 6H-SrIrO$_3$ thanks to the weakened surface Ir-O binding that facilitates the potential-determining step involved in the OER (i.e., O$^* + \text{H}_2\text{O} \rightarrow \text{HOO}^* + \text{H}^+ + e^-$).
The oxygen evolution reaction (OER) is the primary reaction that occurs at the anode in many electrochemical energy conversion processes, such as water splitting, CO$_2$ reduction, N$_2$ fixation, etc. Due to its multi-proton/electron-coupled kinetics, the OER is a quite sluggish half-reaction, and often has a crucial role in the overall efficiency of these electrochemical processes. Therefore, over the past several years, considerable effort has been devoted to the search and synthesis of efficient electrocatalysts that can significantly lower the kinetic barriers for OER. Whereas a large number of oxygen evolution electrocatalysts based on a wide range of transition metals work well under alkaline conditions, only the few of the recently developed electrocatalysts are found to be effective for OER in acidic media. Despite the difficulties, there are strong demands for the OER in acidic pH regime. For instance, proton exchange membrane (PEM) water electrolysis is an attractive and advanced route for sustainable hydrogen production, especially when coupled with some renewable energy systems. PEM water electrolysis offers many advantages, such as high current densities, ultrahigh gas purities, low ohmic losses and good compactness. But this technique requires corrosion-resistant, structurally stable, more active oxygen evolution electrocatalysts containing reduced iridium amount.

To the best of our knowledge, an iridium-based compound (or an unusual perovskite oxide) with face-sharing IrO$_6$ octahedral subunits has never been reported to effectively electrocatalyze the oxygen evolution reaction (OER) among the iridium-based oxide catalysts reported recently. OER in acid. In addition, 6H-SrIrO$_3$ has never been studied as a catalyst in any chemical reactions.

**Results**

**Crystal structure and electrical conductivity of 6H-SrIrO$_3$.** 6H-SrIrO$_3$ is the thermodynamically stable polymorph of SrIrO$_3$, which adopts a monoclinic distortion structure of the hexagonal form of perovskite BaTiO$_3$ (Fig. 1a). It consists of alternating face-sharing IrO$_6$ octahedral dimers and corner-sharing, isolated IrO$_6$ octahedra along the c axis (Fig. 1b). Correspondingly, there are two types of Ir atoms in 6H-SrIrO$_3$. One is in the face-sharing IrO$_6$ octahedral dimers, and the other is in the corner-sharing, isolated IrO$_6$ octahedra (Fig. 1c). It is remarkable that there is Ir–Ir metallic bonding in face-sharing IrO$_6$ octahedra, as revealed by the very short Ir(I)–Ir(I) distance (2.796 Å). This can be further supported by the electron location function (ELF) and the correlative ELF values with a range of 0.4 to 0.5 distribute between the two neighboring Ir atoms in face-sharing IrO$_6$ dimers, indicating that Ir–Ir bond is metallic in character. (See details about ELF in Methods). Besides Ir–Ir metallic bonding, there are obviously weaker Ir–O bonds in the face-sharing IrO$_6$ octahedral dimers in comparison with those in the corner-sharing, isolated IrO$_6$ octahedra. As shown in Fig. 1c...

Synthesis and electrochemical properties for OER in acid of 6H-SrIrO$_3$. Encouraged by the unique crystal structure of 6H-SrIrO$_3$, we synthesized this material and attempted to explore its potential electrocatalytic activity for OER in acid. The observed powder X-ray diffraction (XRD) pattern is almost in agreement with the fitting plot (Fig. 2a), revealing that the material is composed of high purity 6H-SrIrO$_3$. The refinement results are listed in Supplementary Table 1. Scanning electron microscopy (SEM) images (Fig. 2b and Supplementary Figure 4) show that the material has micron-sized, plate-like particles with a dominant thickness distribution of 30–60 nm. Additionally, chemical mapping and energy dispersive X-ray spectroscopy (EDS) show that the Sr and Ir elements are homogeneously distributed over the material, with a Sr:Ir atomic ratio of ca. 1:1 (Supplementary Figure 5). X-ray photoelectron spectroscopy (XPS) result further reveals a Sr:Ir atomic ratio of ca. 1:1 for 6H-SrIrO$_3$. In the high resolution transmission electron microscopy (HRTEM) images (Fig. 2c and Supplementary Figure 6), three sets of lattice fringes are shown, giving interplanar distances of 0.283, 0.279, and 0.283 nm corresponding to the (130), (200), and (310) crystallographic planes of 6H-SrIrO$_3$, respectively. The observed angles between these crystallographic planes match well with the theoretical values. These results further suggest that the exposed facet of micron-sized 6H-SrIrO$_3$ plates is (001). The exposure of this facet is also confirmed by the fast Fourier transform image (Fig. 2c, inset). Furthermore, high-angle annular dark field (HAADF) STEM image (Supplementary Figure 7) of the edge of a 6H-SrIrO$_3$ particle again reveals that the 6H-SrIrO$_3$ is highly crystalline.

Before the electrocatalytic studies, we first tested the chemical stability of 6H-SrIrO$_3$ in strongly acidic media (0.5 M H$_2$SO$_4$). XRD and TEM results reveal that 6H-SrIrO$_3$ retains its crystal structure well, even after its exposure in 0.5 M H$_2$SO$_4$ over 48 days (Supplementary Figure 8). In addition, after such a long time testing, there is no detectable leached Ir species and only ~1.3% of total Sr content leached in the acidic solution. These results suggest that 6H-SrIrO$_3$ has excellent chemical stability in acid.

Next, we evaluated the electrocatalytic properties of 6H-SrIrO$_3$ toward OER in acidic media (0.5 M H$_2$SO$_4$). For comparative purpose, we also synthesized IrO$_2$ nanoparticles with a particle size of 10–20 nm (see structural characterizations in Supplementary Figure 9) and studied their catalytic activity for OER. As shown in Fig. 3a, both 6H-SrIrO$_3$ and IrO$_2$ exhibit remarkable electrocatalytic activity toward OER, and the former is more active than the latter. For example, at 1.525 V, the electrocatalytic activity of 6H-SrIrO$_3$ (measured by the current densities per the geometric area) is almost four times higher than that of IrO$_2$. Additionally, 6H-SrIrO$_3$ produces a current density of 10 mA cm$^{-2}$ at an overpotential ($\eta$) of 248 mV, whereas IrO$_2$ gives the same current density at a higher overpotential (300 mV). The results also reveal that 6H-SrIrO$_3$ is among...
the most active Ir-based oxide electrocatalysts for OER in acid (see Supplementary Table 2), although there might be the differences in protocols, such as catalyst loading, use of binder and electrolyte, employed in their electrocatalytic tests. For example, some Pb-, Bi-, or Y-containing, Ir-based pyroclore compounds usually give a current density of 10 mA cm$^{-2}$ at overpotentials higher than 340 mV$^{19-22}$, and Ir–W bimetallic oxide catalysts with an optimal composition require an over-potential of 370 mV for the acidic OER$^{22}$. Moreover, a perovskite-type La$_2$LiIrO$_6$ catalyst can produce a current density of 10 mA cm$^{-2}$ at an overpotential of ca. 300 mV$^{17}$, but this material suffers from the serious surface reconstruction, resulting in the generation of IrO$_2$ nanoparticles, during electrocatalysis.

Besides exhibiting good catalytic activity per geometric area, 6H-SrIrO$_3$ also shows good mass activity (normalized by the mass of iridium) for the acidic OER. As shown in Fig. 3b, 6H-SrIrO$_3$ gives the highest mass activity for OER in acid among the iridium-based oxide electrocatalysts reported recently$^{15,16,18-22}$. The mass activity of 6H-SrIrO$_3$ is about seven times as high as that of IrO$_2$, and is 2.2–5.8 times higher than those of Ir-based pyroclore compounds. The mass activity of 6H-SrIrO$_3$ is even around twenty times higher than the Ir–W bimetallic oxide catalyst. Moreover, it is worth noting that the superior catalytic activity of 6H-SrIrO$_3$ does not correlate with its surface area. The surface area (obtained with N$_2$ adsorption method) of 6H-SrIrO$_3$ is typically lower by more than an order of magnitude in

Scale bars, 5 nm
Comparison of electrocatalytic properties for OER between 6H-SrIrO₃ and 3C-SrIrO₃. In order to further assess the catalytic properties of 6H-SrIrO₃, we synthesized 3C-phase SrIrO₃ perovskite (3C-SrIrO₃) as a reference material for comparative studies. 3C-SrIrO₃ adopts a well-known pseudo-cubic structure, in which all the IrO₆ octahedra are corner-shared (see its crystal structure in Supplementary Figure 11)²⁹. Additionally, the thin films of 3C-SrIrO₃ were recently demonstrated to give the best intrinsic catalytic activity for OER in acid³⁰, due to the in situ generation of amorphous IrOₓ on the surface by serious strontium leaching during electrocatalysis.

The experimental procedures are almost the same for the synthesis of 6H-SrIrO₃ and 3C-SrIrO₃ (see experimental details in Methods). In order to explore the reasons why the addition of more acidic condition in the synthesis can favor the formation of metastable 3C-SrIrO₃ over 6H-SrIrO₃, we first compared the Ir 4f XPS spectra of IrO₂, 6H-SrIrO₃ and 3C-SrIrO₃ (Supplementary Figure 12a). The results reveal that the Ir 4f⁵/₂ and Ir 4f⁷/₂ XPS peaks for 3C-SrIrO₃ appear at the higher binding energies compared with IrO₂ and 6H-SrIrO₃. This demonstrates that the average oxidation state of iridium for 3C-SrIrO₃ is higher than +⁴.³⁰ The higher average oxidation state of iridium are believed to be favorable for the formation of 3C-SrIrO₃. This argument is mainly based on recent studies, in which low-valent heteroatom doping (e.g., Co, Mg, Zn, Zn, etc.) can lead to the increase in the oxidation state of iridium and the stabilization of 3C-SrIrO₃.²⁸,³¹,³² In view of the difference in synthetic systems between our work and the previous studies²⁸,³¹,³², we attempted to synthesize 3C-phase SrIrO₃ by low-valent heteroatom doping (cobalt as dopants used in this work) with the experimental procedures that were used for the synthesis of 6H-SrIrO₃ (see experimental details in Methods). The results show that in this case, the formation of the 3C-phase is indeed preferable, and the resulting material also has a higher oxidation state of iridium (Supplementary Figure 12b). Next, we compared the thermogravimetric (TG) and differential thermal analysis (DTA) in air of the precursors of 6H-SrIrO₃ and 3C-SrIrO₃. As shown in Supplementary Figure 13a, the organic components in the precursors are oxidatively decomposed in air at elevated temperature (ca. 500 °C), and this process is highly exothermic. The presence of more acidic condition (i.e., the precursor for the synthesis of 3C-SrIrO₃) is also found to result in more heat released at elevated temperature. The more released heat in the synthesis should favor the generation of high-valent iridium species. This is confirmed by the XPS results (Supplementary Figure 13b), which show that the sample obtained by calcining the precursor of 6H-SrIrO₃ at 500 °C contains zero-valent and four-valent Ir species, whereas the sample obtained by calcining the precursor of 3C-SrIrO₃ at 500 °C contains four-valent and five-valent Ir species. Overall, the presence of more acidic condition favors the formation of 3C-SrIrO₃ by facilitating the generation of the more oxidized iridium species.

The 3C-SrIrO₃ material we synthesize contains of micron-sized particles with a small surface area comparable with that of 6H-SrIrO₃ (Supplementary Figures 14, 15 and Table 2). The 3C-SrIrO₃ material has a Sr:Ir atomic ratio of 0.82:1 and a certain amount of IrOₓ on the surface. The Sr deficiency for 3C-SrIrO₃ is because the acid treatment is necessary for the removal of the SrCO₃ impurities during the material synthesis, and simultaneously, the acid treatment also results in some strontium leached from 3C-SrIrO₃. This result is also in agreement with the previous study showing the easy strontium leaching of 3C-SrIrO₃ in acid¹⁶.

The electrocatalytic result (Supplementary Figure 16) reveals that 3C-SrIrO₃ affords a current density of 10 mA cm⁻²geo at an overpotential (η) of ~270 mV, which is similar to that (270–290 mV) required by the thin films of 3C-SrIrO₃ reported previously¹⁶. Obviously, 6H-SrIrO₃ has a higher catalytic activity than 3C-SrIrO₃ because the former needs a smaller overpotential of ~248 mV to deliver a current density of 10 mA cm⁻²geo. The superior catalytic activity of 6H-SrIrO₃ is further supported by the result that the former exhibits two times mass activity as high as the later (Fig. 3b).

Moreover, both 6H-SrIrO₃ and 3C-SrIrO₃ exhibit good catalytic stability for OER in acid, as shown in Fig. 3c. However, after 30 h-long electrocatalysis test, only ~1% of total Sr content (0.9–1.5 Sr layers of 6H-SrIrO₃) is detected in the acid solution in the presence of 6H-SrIrO₃, whereas ~24% of total Sr content is deviated from the stoichiometry of 3C-SrIrO₃ due to the Sr leaching during electrocatalysis (Fig. 3d). Considering that 3C-SrIrO₃ has been a Sr-deficient material with an 18% deviation before the electrocatalysis, the 3C-SrIrO₃ material after electrocatalysis has a total strontium deficiency up to 42%. The result is also consistent with the 30–50% of total Sr content leaching for the thin films of 3C-SrIrO₃ as oxygen evolution catalysts in acid¹⁶. Additionally, HRTEM and X-ray photoelectron spectroscopy (XPS) results show that 6H-SrIrO₃ has good structural stability and keeps high crystallinity (Fig. 3e and Supplementary Figure 17), but 3C-SrIrO₃ takes place obvious surface amorphourization during electrocatalysis (Fig. 3f). This is further supported by the high-angle annular dark field (HAADF) STEM image (Supplementary Figure 20), which shows that there is not secondary, amorphous IrOₓ phase generated on the 6H-SrIrO₃ surface after OER. The N₂ isotherm data of 6H-SrIrO₃ (Supplementary Figure 18) reveal that there are not micropores formed after OER. Moreover, the comparison of the 6H-SrIrO₃’s CV curves before and after OER (Supplementary Figure 19) shows that the CV shape of 6H-SrIrO₃ after OER is not exactly same as that before OER, but does not change a lot. This suggests that 6H-SrIrO₃ might undergo a weak surface reconstruction during OER probably thanks to the slight Sr leaching during OER. It should be pointed out that while the better structural stability of 6H-SrIrO₃ than 3C-SrIrO₃ has been unambiguously confirmed, the possibility of a very thin amorphous IrOₓ layer (or a tiny amount of IrO₃ clusters) on the 6H-SrIrO₃ surface cannot be completely ruled out at current stage.

The better structural stability of 6H-SrIrO₃ in comparison with 3C-SrIrO₃ can be explained by the comparison of their O K-edge X-ray absorption spectra (Supplementary Figure 21). The comparison reveals that there is stronger Ir 5d-O 2p hybridization or stronger Ir-O covalence for 3C-SrIrO₃. The stronger covalence results in the easier structural loss of the perovskite phase or surface amorphourization during electrocatalysis, as suggested by the recent studies on perovskite electrocatalysts ³³.

In order to further assess the stability of 6H-SrIrO₃, we compared the Ir leaching during OER in the presence of 6H-SrIrO₃ and IrO₂. We used inductively coupled plasma atomic emission spectroscopy (ICP-OES) to detect the Ir species in the electrolyte at a current density of 10 mA cm⁻²geo with 6H-SrIrO₃ or IrO₂ as the electrocatalyst. The result (Supplementary Figure 22) reveals that a tiny amount of leached
Ir species are detected in the electrolytes for both 6H-SrIrO₃ and IrO₂ as the electrocatalysts, but the amount of leached Ir species in the presence of 6H-SrIrO₃ as the electrocatalyst is obviously lower than that in the presence of IrO₂ as the electrocatalyst. This result further demonstrates that 6H-SrIrO₃ is a stable electrocatalyst for OER in acid.

In order to determine the Faradaic efficiency during the OER, we compared the amount of O₂ produced from the OER in the presence of 6H-SrIrO₃ with the theoretically expected O₂ amount that can be generated from the OER. The result (Supplementary Figure 23) reveals that the detected O₂ amount is very close to the expected value during the OER, further demonstrating the about 100% Faradaic efficiency given by 6H-SrIrO₃.

Discussion

We performed density functional theory (DFT) computations in order to get a better understanding of the electrocatalytic activity for OER of 6H-SrIrO₃. We constructed the correlative theoretical models in view of the above experimental results, including the [001] facet of 6H-SrIrO₃ as the main exposed one and a small amount of surface strontium leached during electrocatalysis. We cleaved the optimized 6H-SrIrO₃ bulk structure through its (001) plane to obtain two representative surfaces (Fig. 4a–d). The surface-I exposes the Ir atoms in the face-sharing octahedral dimers (Fig. 4a, b), while the surface-II exposes the Ir atoms in the isolated, corner-sharing IrO₆ octahedra (Fig. 4c, d). On the basis of these surface models, we investigated the electrocatalytic activity for OER of 6H-SrIrO₃ according to the approach proposed by Rossmeisl et al.³⁴,³⁵ In this approach, the OER is suggested to include the four elementary reaction steps and each step involves one proton/one electron-coupled transfer process, as shown below:

\[
\begin{align*}
\text{H}_2\text{O}^+ & \rightarrow \text{HO}^+ + \text{H}^+ + e^- \quad (1) \\
\text{HO}^+ & \rightarrow \text{O}^+ + \text{H}^+ + e^- \quad (2) \\
\text{O}^+ + \text{H}_2\text{O} & \rightarrow \text{HOO}^+ + \text{H}^+ + e^- \quad (3) \\
\text{HOO}^+ & \rightarrow * + \text{O}_2 + \text{H}^+ + e^- \quad (4)
\end{align*}
\]

where * and X⁺ (X = HO, O, or HOO) represent a surface active site and an adsorbed X intermediate on the surface, respectively. As shown in Fig. 4e and f, all of the four elementary reaction steps involved in the OER on both surface-I and surface-II are found to move uphill in free energy when no potential is applied (\(U = 0\) V). An additional potential has to be applied to make every step go downhill in free energy, and the minimum additional potentials are determined to be 1.69 and 1.80 V for the surface-I and surface-II, respectively. Considering the equilibrium potential of the OER (\(U = 1.23\) V), the minimum theoretical overpotentials (\(\eta\)) are calculated to be 0.46 and 0.57 V for the surface-I and surface-II, respectively. These results further demonstrate that the surface-I, comprising the Ir atoms in the face-sharing octahedral dimers, has better catalytic activity for OER than the surface-II with the Ir atoms in the isolated, corner-sharing IrO₆ octahedra. For comparison, we also explore the OER activities on the (110) surface of IrO₂ and (010) surface of 3C-SrIrO₃, and both the sampled surfaces have the similar structural feature to the surface-II, as illustrated in Supplementary Figures 24 and 25. Our computed overpotentials are 0.59 and 0.56 V for IrO₂ and 3C-SrIrO₃, respectively, both of which are lower than that in the presence of IrO₂ as the electrocatalyst.

![Fig. 4](https://example.com/fig4) Theoretical understanding of electrocatalytic activity for OER of 6H-SrIrO₃. a Side and b top views of the surface-I of 6H-SrIrO₃; c Side and d top views of the surface-II of 6H-SrIrO₃; e free-energy diagrams of four elementary reaction steps for the OER on the surface-I and f surface-II of 6H-SrIrO₃ at the different applied potentials. The optimized structures of HO, O, and HOO adsorptions on the surface-I and surface-II are also shown in e and f.
comparable to that of the surface-II (0.57 V) and larger than that of surface-I (0.46 V). It is worth mentioning that our computed overpotential on the (110) surface of IrO2 is also close to the previously reported one.14 The above calculations imply that the existence of face-sharing octahedral dimers (the main structural feature of surface-I) is mainly responsible for the superior OER activity of 6H-SrIrO3, as observed in the above experimental results.

From the Fig. 4e and f, we can also find that the potential-determining step for both surface-I and surface-II is the third elementary reaction step involved in the OER (i.e., $O^+ + HOO^+ \rightarrow HOO^+ + H^++ + e^-$) because the maximum Gibbs free-energy difference is between $\Delta G_{HOO^+}$ and $\Delta G_{SrO}$. The facilitated potential-determining step involved in the OER for the surface-I, with respect to the surface-II, can be attributed to the relatively weak $O^+$ binding energy of 1.848 eV, while the surface-II binds $O^+$ more strongly ($\Delta E_{O^+} = 1.711$ eV).

When DFT calculations have provided some useful insights into the catalytic active sites and the activity trend for the Ir-based materials from the theoretical computations is consistent with that from experiments, there are still some differences between the thermodynamic overpotentials obtained by DFT and the experimental ones. This difference might be caused by multiple factors. First, all the computations are based on thermodynamic considerations. Other important electrocatalytic processes, such as mass and charge transport, cannot be involved in the DFT calculations. Second, the distribution and concentration of active sites on the real material surface are generally very complex, but this complexity cannot be adequately reflected by DFT calculations. Third, at current stage, DFT calculations are not capable of this complexity cannot be adequately re

In summary, 6H-SrIrO3 has been identified as a highly efficient, low-iridium oxygen evolution electrocatalyst that can work well in acidic media. 6H-SrIrO3 is an unusual perovskite oxide electrocatalyst with face-sharing IrO6 octahedral dimers. The unique face-sharing IrO6 octahedral subunits of 6H-SrIrO3 are proven to be important for its remarkable catalytic activity and structural stability. These good properties also make 6H-SrIrO3 a promising electrocatalyst for proton exchange membrane (PEM) water electrolysis. The findings in this work might help spark a kind of creativity in the rational design/synthesis of high-performance electrocatalysts for the acidic OER.

**Methodology**

**Chemicals and reagents.** Potassium hexachloroiridate(IV) (K2IrCl6, 99.99%) was purchased from Aladdin. Strontium nitrate (Sr(NO3)2), citric acid monohydrate (C6H8O7·H2O), ethylene glycol, hydrochloric acid (HCl) and sulfuric acid (H2SO4) were purchased from Beijing Chemical Factory. Cobalt nitrate hexahydrate (Co(NO3)2·6H2O) was purchased from Shanghai Xilong Chemical Factory. Nanof® perfluorinated resin solution (3 wt% in mixture of lower aliphatic alcohols and water containing 45% water) was purchased from Sigma-Aldrich. All the chemicals and reagents were used without further purification. Highly purified water (>18 MΩ cm resistivity) was provided by a PALL PURELAB Plus system.

**Materials synthesis.** For the synthesis of 6H-SrIrO3, Sr(NO3)2 (280 mg) and citric acid (280 mg) were mixed with 5 mL deionized H2O to form the solution 1, and K2IrCl6 (80 mg) was mixed with 4 mL ethylene glycol to form the solution 2. The solution 1 was then stirred into the solution 2 dropwise. The resulting mixture was dried at 150 °C for 12 h to obtain a brown solid product as the precursor, followed by calcination in air at 200 °C (6 h), 300 °C (6 h), 500 °C (3 h), and 700 °C (6 h) in succession. The heating rate was 1.7 °C min$^{-1}$. The obtained solid product containing SrIrO3 and SrCO3 was treated with 1 M HCl for 6 h to remove the SrCO3 impurities, giving the 6H-SrIrO3 material. The sequence of synthesis steps was refined through trials and errors.

In order to further assess the stability of 6H-SrIrO3 in 1 M HCl solution, we dispersed the as-obtained 6H-SrIrO3 powders in 1 M HCl solution for 2 days, and then used ICP-OES to detect the Sr and Ir ions in the solution. The result shows that there is no detectable leached Sr and Ir species in the solution, demonstrating the good stability of 6H-SrIrO3 in 1 M HCl solution.

For the synthesis of 3C-SrIrO3, the experimental procedures are almost the same as these for the synthesis of 6H-SrIrO3, except the amount of citric acid (840 mg) that was used to form the solution 1.

For the synthesis of Co-doped 3C-SrIrO3, as a control sample, the experimental procedures are almost the same as these for the synthesis of 6H-SrIrO3. The only difference was that a certain amount of cobalt nitrate hexahydrate (14.5 mg) was added to form the solution 2. In the resulting sample, labeled as Co-doped 3C-SrIrO3, the Co/atomic ratio is about 14.

In order to synthesize the SrOx phases (6H-SrIrO3 and 3C-SrIrO3) without IrO2, as the secondary phase, an excessive amount of strontium (Sr/atomic ratio $\approx$ 8.1) was used during the synthesis in this work. The use of the excessive amount of strontium resulted in the formation of strontium carbones (SrCO3) as the impurities (please see Supplementary Figure 26). The acid treatment with 1 M HCl was employed to remove the SrCO3 impurities.

For the synthesis of 3C-SrIrO3, the experimental procedures are almost the same as these for the synthesis of 6H-SrIrO3. The only difference was that Sr(NO3)2 was not involved in the synthesis. Supplementary Figure 27 presents XRD patterns of the IrO2 samples obtained by calcining the precursor at 300, 500, and 700 °C.

**Characterizations.** Powder X-ray diffraction patterns (PXRD) of the samples were collected with an X-ray diffractometer (RIGAKU, Japan, model D/MAX2550 V/PC) with a scan speed of 1° min$^{-1}$ within the diffraction angle range from 10 to 100. The charging for the PXD for the FWHM fitting was performed with a high-resolution X-ray analysis system (GSAS) program. The scanning electron microscope (SEM) images were obtained with a JEOL JSM 7600F electron microscope. The transmission electron microscope (TEM) images were obtained with a Philips-FEI Tecnai G2S-Twin microscope equipped with a field emission gun operating at 200 kV. The related plasma atomic spectroscopy measurements were performed on a Perkin-Elmer Optima 3300DV ICP spectrometer. The X-ray photo-electron spectroscopy (XPS) was performed on an ESCALAB 250X-ray photoelectron spectrometer with a monochromatic X-ray source (Al Kα 1486.6 eV). The O K-edge X-ray absorption near-edge (XANES) spectra were measured using a high-resolution transmission electron microscope (HRTEM) equipped with an aberration-corrected STEM with the model of FEI Titan Cubed Themis G2 300, whose accelerating voltage and electron current were set at 200 kV and around 40 pA, respectively. (Note that because 6H-SrIrO3 is very sensitive to the electron beams, high-angle annular dark field STEM images must be obtained at the lowest electron current of 40 pA.)

**Electrochemical measurements.** All the electrochemical measurements were performed with a three-electrode system by using a CHI instrument (Model 650E). The electrolyte was 0.5 M H2SO4 and was bubbled with O2 gas during the electrochemical measurements. A carbon rod was used as the counter electrode, and a saturated calomel electrode (SCE) was used as the reference electrode. The saturated calomel electrode was calibrated by the reversible hydrogen electrode (RHE), giving their conversion equation: $E_{SCE-RHE} = E_{SCE} + 0.241 V$. The scan rate was 0.5 mV s$^{-1}$ when linear sweep voltammetry (LSV) was used. The data in this work was compensated by 85% iR drop. The geometric surface area of the electrode was used to normalize the current density.

For the preparation of working electrodes, the powdered catalyst (7 mg), including 6H-SrIrO3, 3C-SrIrO3, and IrO2, was dispersed in a mixture comprising isopropanol (100 μL) and Naflon solution (10 μL, 5 wt% in mixture of lower aliphatic alcohols and water). 1 μL of the resulting mixture was then drop-casted onto a glassy carbon electrode with a diameter of 3 mm for drying. The working electrode had a catalyst loading of ca. 0.90 mg cm$^{-2}$. A series of cyclic voltammetry (CV) measurements were performed first at various scan rates (10, 25, 50, 75 and 100 mV s$^{-1}$) in the potential window between 0.83 and 0.93 V vs. RHE. Then, a linear plot was obtained by establishing the relationship between the difference of the anodic and cathodic currents ($i_a - i_c$) at 0.88 V vs. RHE and the scan rate. The double-layer capacitance ($C_d$) is one half of the slope value of the fitting line. The ECAS can be obtained by dividing $C_d$ by a specific capacitance ($C_s$). A $C_s$ value of 0.035 mF cm$^{-2}$ was suggested in the previously reported work.

The reference electrode (i.e., saturated calomel electrode, SCE) was calibrated by the reversible hydrogen electrode (RHE) in 0.5 M H2SO4. Two Pt electrodes were first cleaned by cyclic in 0.5 M H2SO4 between −2 and 2 V for 2 h, and then used as the working electrode and the counter electrode, respectively. During the calibration, the electrolyte was saturated by H2. A series of controlled-potential chronoamperometric curves were carried out around the possible zero current potential (the interconversion between the hydrogen oxidation and hydrogen...
evolution reaction) with a dwell time of 5 min. The result showed that the potential of zero net current was found at ~0.241 V vs. the SCE electrode. And thus, the potentials, measured against SCE, were converted into the potentials vs. RHE by using the equation $E_{\text{RHE}} = E_{\text{SCE}} + 0.241 \text{ V}$.

**Computation details.** The generalized gradient approximation (GGA) with the Perdew–Burke–Ernzerhof exchange-correlation functional\(^ {16,37}\) (including a semi-empirical van der Waals (vdW) correction)\(^ {24,25}\) was employed for the density functional treatment (DFT). The projector-augmented plane potentials, measured against SCE, were converted into the potentials vs. RHE by using the equation $E_{\text{RHE}} = E_{\text{SCE}} + 0.241 \text{ V}$.
