Abstract

AKARI (formerly ASTRO-F) is an infrared space telescope designed for an all-sky survey at 10–180 μm, and deep pointed surveys of selected areas at 2–180 μm. The deep pointed surveys with AKARI will significantly advance our understanding of galaxy evolution, the structure formation of the universe, the nature of buried AGNs, and the cosmic infrared background. We describe here the important characteristics of the AKARI mission, the orbit, and attitude control system, and investigate the optimum survey area based on the updated pre-flight sensitivities of AKARI, taking into account the cirrus confusion noise as well as the surface density of bright stars. The North Ecliptic Pole is concluded to be the best area for 2–26 μm deep surveys, while the low-cirrus noise regions around the South Ecliptic Pole are worth considering for 50–180 μm pointed surveys to high sensitivities limited by the galaxy confusion noise. Current observational plans concerning these pointed surveys are described in detail. Comparing these surveys with deep surveys using the Spitzer Space Telescope, the AKARI deep surveys are particularly unique in respect of their continuous wavelength coverage over the 2–26 μm range in broad-band deep imaging, and their slitless spectroscopy mode over the same wavelength range.

Key words: galaxies: evolution — galaxies: statistics — infrared: galaxies — space vehicles: instruments

1. Introduction

How did galaxies form and evolve? How did clusters of galaxies and the large-scale structure of the universe form and evolve? How do Active Galactic Nuclei (AGNs) link together with Ultraluminous Infrared Galaxies (ULIRGs) in their birth and evolution? What is the nature of the sources contributing to the Cosmic Infrared Background (CIRB)? In order to answer these important questions of modern astronomy we need statistically significant numbers of sources based on large-area surveys to uniform depths covering significant cosmological volumes. Such surveys should be made in many wavebands, since multi-wavelength spectral energy distributions (SEDs) as well as photometric redshifts are useful to identify the types and ages of the detected galaxies.

Naturally, there is a trade-off between the area and the depth of any survey, with a greater required depth resulting in a narrower survey due to the finite observation time. For example, at wavelengths shorter than 2 μm, towards two blank fields, the Hubble Space Telescope (HST) has produced excellent images with unprecedented sensitivity and angular resolution (Hubble Deep Fields: HDF), but they were limited to relatively small areas (HDF-N, 5.3arcmin², Williams et al. 1996 and HDF-S, 0.7 arcmin², Gardner et al. 2000; Williams et al. 2000). Recently, thanks to the Advanced Camera for Surveys onboard the HST, very large deep survey programs, such as the Great Observatories Origins Deep
Table 1. Overview of the planned AKARI extragalactic deep surveys.

| Name       | Field center (J2000) RA | Dec. | Field size and shape | Imaging bands and depth* |
|------------|-------------------------|------|----------------------|-------------------------|
| NEP-Deep   | 17h55m24s00 +66d37m32s00 | 0.5 deg² circular | all IRC, FIS |
| NEP-Wide   | 18h00m00s00 +66d36m00s00 | 6.2 deg² circular | all IRC, FIS |
| SEP low-cirrus | 4h44m00s00 -53d20m00s00 | 15 deg² fan-shape | S9W, L18W, all FIS |

* IRC: InfraRed Camera, FIS: Far-Infrared Surveyor, S9W and L18W are names of IRC bands, cf. subsection 2.2 and tables 3 and 6.

Survey (GOODS, 320 arcmin², Giavalisco et al. 2004) and the Galaxy Evolution from Morphology and SEDs survey (GEMS, 795 arcmin², Rix et al. 2004), have also been performed. A 1.5 deg² survey program is now on-going (COSMOS project).

Longer infrared wavelengths beyond 2 µm are undoubtedly very important. The stellar mass of a galaxy is a fundamental property of galaxies, and is well traced by near-infrared (1–2 µm) light. Since ground-based telescopes are not sensitive enough to detect stellar light beyond 2 µm, space-borne telescopes are essential to study the galaxy stellar mass at high redshift. Mid-infrared wavelengths are also important because they are sensitive to dusty star-forming galaxies, which are characterized by the polycyclic aromatic hydrocarbon (PAH) features as well as the hot dust continuum. This fact had previously been recognized by the first all-sky survey in the mid- and far-infrared with the Infrared Astronomical Satellite (IRAS, Neugebauer et al. 1984). After launching the Infrared Space Observatory (ISO, Kessler et al. 1996), which executed many infrared surveys covering a wide range in both depth and area at 7, 15, 90, and 170 µm, various mid- to far-infrared SEDs of starburst galaxies as well as AGNs (Genzel, Cesarsky 2000 and references therein) have been revealed and investigated in great detail. The ISO surveys and their follow-up spectroscopic observations have demonstrated the importance of the mid- to far-infrared wavelengths in studying the evolution of galaxies (HDF-S: Franceschini et al. 2003, FIRBACK Marano: Patris et al. 2003, ELAIS-S1/S2: Pozzi et al. 2004, Lockman Hole: Oyabu et al. 2005).

In 2003 August, NASA launched an advanced space infrared observatory, the Spitzer Space Telescope (formerly SIRTF, Werner et al. 2004), offering the capability of deep imaging from 3–160 µm and spectroscopy from 5–38 µm. In 2006 February, JAXA (Japan Aerospace eXploration Agency) launched a complementary infrared astronomy satellite, AKARI (formerly known as ASTRO-F²). AKARI will observe at near- to far-infrared wavelengths, like Spitzer telescope. It should be emphasized that AKARI is primarily a surveyor mission, though it has an additional role as an observatory with unique capabilities complementary to Spitzer telescope. A detailed comparison of these two missions is given in subsection 6.2. It is expected that AKARI will also provide an invaluable database for planning observations with Herschel Space Observatory (Pilbratt 2003).

In this paper, we describe three planned major extragalactic surveys with AKARI:

- A deep 2–26 µm survey at the North Ecliptic Pole (NEP), covering a 0.5 deg² area, to a 5 σ flux limit of 10–30 µJy at 11–18 µm (NEP-Deep in table 1).
- A wide, shallow 2–26 µm survey at the NEP, over a 6.2 deg² area, to a 5 σ flux limit of 60–130 µJy at 11–18 µm (NEP-Wide in table 1). The survey region is a circular area surrounding the NEP-Deep field, and in total 450 pointing observations are required.
- A deep 50–180 µm survey towards a low-cirrus region near the South Ecliptic Pole (SEP), covering 15 deg², down to the confusion limit due to unresolved galaxies (SEP low-cirrus in table 1).

The locations of the fields are summarized in table 1. In section 2 we present the AKARI mission, and detail its observing modes. We then describe the key science objectives of the AKARI deep surveys in section 3. In section 4 we discuss the various constraints on the survey characteristics, such as the visibility, confusion due to infrared cirrus and saturation from bright stars. Section 5 details the observing plan. Section 6 compares these surveys with other infrared surveys conducted with ISO and Spitzer telescope. In section 7 we review the current status of our ground-based preemptive observations. A summary is given in section 8. Throughout this paper we assume a flat concordance cosmology of ΩM = 0.3, ΩΛ = 0.7 and H₀ = 72 km s⁻¹ Mpc⁻¹.

2. The AKARI Mission Outline

AKARI will be a second-generation infrared sky survey mission after IRAS with much improved sensitivity, spatial resolution, and wider wavelength coverage. During the expected mission life of more than 500 days, AKARI will make an all-sky survey in 6 wavebands in the mid- to far-infrared region since IRAS, and the first ever all-sky survey at 100–180 µm. In addition to the all-sky survey, deep imaging and spectroscopic observations in the pointing mode will also be carried out in many wavebands covering 2–180 µm. The observation strategy in this mode was discussed in Pearson et al. (2001) based on the preliminary mission specifications. This paper describes deep extragalactic surveys based on the updated pre-flight specifications of the mission. The expected results of the deep pointed surveys will appear in an updated version of the above paper based concerning the in-flight sensitivities (C. P. Pearson et al. 2006, in preparation).

AKARI is equipped with a 68.5-cm cooled (approximately to 6 K) Ritchey–Chérétien type telescope and two focal-plane instruments covering the 2–180 µm wavelength range. Details

² ASTRO-F was successfully launched on 2006 February 21, and has been re-named AKARI.
of the AKARI mission and satellite system are described in Murakami (2004), and details on the current performance of the focal-plane instruments are described in Kawada et al. (2004) and Onaka et al. (2004).

2.1. AKARI Orbit and Observation Modes

The orbit of AKARI is a sun-synchronous polar orbit at an altitude of 750 km and an inclination of $98.4^\circ$. The orbital period is approximately 100 min. In figure 1, the AKARI spacecraft attitude is shown schematically. In the all-sky survey mode, the spacecraft rotates uniformly around the axis directed toward the Sun once every orbital revolution, resulting in a continuous scan of the sky on one orbit. In this configuration, the entire sky can be covered in half a year. In attitude operation for pointed observations (figure 1 right), due to limitations imposed to prevent earthshine from illuminating the telescope baffle, the duration of any single pointed observation is limited to 10 min. The pointing direction can be freely chosen in the telescope orbital plane given by the survey mode attitude. However, it is restricted to within $\pm1^\circ$ to the direction perpendicular to the orbital plane. The attitude control system provides an additional capability to slightly change the pointing direction defining the following attitude modes: step-scan, slow-scan, and micro-scan. The slow-scan is a uniform scan with a much slower scan speed (less than $30''$ per second) than that of the all-sky survey, and is an option for pointed observations with AKARI. Hence, the duration of this observing mode is also limited to 10 min. The slow-scan survey is especially useful for covering a larger sky area than that obtainable by pointing toward the fixed direction in the sky to much better sensitivities than those of the all-sky survey. One should note that the overheads in the pointing attitude mode are significant: approximately 20 min is required for maneuvering and stabilization. Hence, the number of pointing observations in one orbit is restricted to three or less (see table 2).

2.2. Scientific Instruments

AKARI incorporates two focal-plane instruments covering the infrared wavelength range from 2 to 180 $\mu$m. The first focal plane instrument is the Far-Infrared Surveyor (FIS, Kawada et al. 2004, cf. table 3), which will primarily survey the entire sky simultaneously in four far-infrared bands from 50 to 180 $\mu$m with approximately diffraction-limited spatial resolutions ($30''$–$60''$, Jeong et al. 2003). Each waveband is equipped with corresponding far-infrared imaging arrays, denoted as follows: N60, WIDE-S, WIDE-L, and N160, all of which are operated simultaneously. The second focal-plane instrument is the InfraRed Camera (IRC, Onaka et al. 2004), which is primarily designed to take deep images of selected regions of sky by pointed observations from 2 to 26 $\mu$m. The IRC (cf. tables 3 and 4) comprises of three channels: NIR (2–5 $\mu$m), MIR-S (5–12 $\mu$m), and MIR-L (12–26 $\mu$m). These three channels can be operated simultaneously. The waveband characteristics for broad-band imaging are summarized in table 3 and figure 2. Each IRC channel is equipped with 3 broad-band imaging bands, which have to be selected by rotating a filter wheel. Both focal-plane instruments are equipped with spectroscopic elements of moderate or low resolution; the FIS is equipped with a Fourier-Transform Spectrometer (FTS) covering 50–180 $\mu$m using the WIDE-S and WIDE-L detector arrays, while the IRC is equipped with low-dispersion grisms (and a prism in the NIR channel), which enable slitless spectroscopy over the field-of-view (FOV) of each channel with spectral resolutions of 20–50 at 2–26 $\mu$m (table 4). The IRC also has a capability for slit spectroscopy. Figure 3 shows the FOVs configuration projected onto the

---

3 We hereafter call this function of the attitude control system “offset control” which allows the telescope to be directed out of the nominal orbital plane up to $\pm1^\circ$.

* Sensitivity for one scan. Surveys with at least two scans (all-sky survey) or four scans (SEP low-cirrus region survey) are planned.
† In the case of the astronomical observation template (AOT) for deep imaging with no filter change and no dithers at the ecliptic poles. The net exposure times in this AOT are 459 s per pointing for the NIR, and 513 s per pointing for the MIR-S/MIR-L channels, respectively. Photometric apertures are determined so that the signal-to-noise ratio for the source is maximized with the expected point-spread function at each waveband (typical aperture radius is 1–2 pixels).
‡ NA: not available in the observing mode shown here.

sky. Note that the NIR and the MIR-S channels observe the same sky simultaneously, while the FOV of the MIR-L channel is offset by approximately 20′ from the NIR and the MIR-S channels. During pointing observations, all focal-plane instruments are operated simultaneously, although the target is acquired through a selected FOV of either the NIR/MIR-S, MIR-L, or FIS. Hence, a parallel-mode observation, i.e. observation with channels which do not observe the same field of view in the sky, is always executed as long as this does not have any impact on the data rate, or does not induce heat dissipation to the AKARI cryostat, which would shorten the mission life. The pre-flight sensitivities estimated from the current laboratory experiments of the telescope and the focal plane instruments at low temperatures are given in tables 3 and 4. The IRC sensitivity is given for its single-filter astronomical observation template (AOT), in which no filter change is made during a single pointed observation, such that each IRC channel observes the target with a single filter. There are also two-filter or three-filter AOTs as well as an AOT dedicated for spectroscopy. The FIS broad-band sensitivity in the pointing mode is not available, since only the FTS will be used in the pointing observation mode. The FIS sensitivity in the slow-scan attitude mode is shown, since the slow-scan survey is useful to observe larger areas within the limited time of a single pointed observation.
2.3. Mission Phases and Observation Programs

Observations with AKARI can be divided into the following phases:

- **PV phase** \([L(launch) + 1–L + 2\) months\]: observations for performance verification of the whole system.
- **Phase 1** \((L + 2–L + 8\) months\): primarily for the all-sky survey. However, pointed observations toward fields close to the ecliptic poles are planned for orbits passing through the South Atlantic Anomaly (SAA).
- **Phase 2** \([L + 8–L + 18\) months (boil-off of liquid He)]\): supplemental all-sky survey observations for areas not sufficiently covered in Phase 1, and pointed observations in any region on the sky.
- **Phase 3** (after boil-off of liquid He): pointed observations with the IRC-NIR channel, which will continue to function even after the boiling-off of the liquid He. The duration of this phase is uncertain, and is limited by the life of the mechanical coolers.

During the AKARI mission phases mentioned above, the following observation programs are planned:

- **Large-area Survey (LS)**: the all-sky survey, the primary objective of the AKARI mission, as well as large-area Spitzer/Legacy surveys in the pointing mode over two dedicated fields near the ecliptic poles: the NEP (subsection 5.2) and the Large Magellanic Cloud (LMC). The outline of the LS programs are described in Matsuhara et al. (2005).
Table 4. Specifications of IRC spectroscopic channels.

| Band | Wavelength coverage (µm) | Spectral resolution (λ/dλ)* | Flux limit (continuum)† (per pixel, 5σ, mJy) |
|------|--------------------------|----------------------------|------------------------------------------|
| NP   | 1.7–5.5                  | 22                        | 0.02                                     |
| SG1  | 5.5–8.3                  | 47                        | 1.0                                      |
| SG2  | 7.4–13                   | 34                        | 3.2                                      |
| LG2  | 17.7–25                  | 27                        | 6.7                                      |

*λ is the center wavelength, and dλ is the wavelength resolution corresponding to the width in FWHM of the point spread function.
† In the case of one pointing observation at the ecliptic poles with the AOT for the “slitless spectroscopic mode”, where the source spectra are dispersed in the imaging area of the detector array.

- Mission Programs (MP): an organized program of pointed observations planned by the AKARI science working groups (AKARI team plus collaborators within the international astronomical community). The targets are spread over large areas, but cannot be included in the NEP and LMC surveys.
- Open-time Program (OP): a program of pointed observations open to the Japanese, Korean, and ESA communities. 30% of the total pointed observation opportunities in both Phases 2 and 3 will be allocated to OP.
- Director’s Time: Observing time allocated to the Project Manager, including any “Target of Opportunity” time. Less than 5% of the total observation is considered so far.
- Calibration Time: For the long-term maintenance and performance verification for each instrument, calibration observations will be made at regular periods.

3. Key Scientific Objectives

Here, we describe the key scientific objectives of the AKARI deep pointed observation extragalactic surveys, and also discuss the optimal survey area and depth.

3.1. Mass Assembly and Structure Evolution

The total stellar mass of a galaxy is well traced by the near-infrared luminosity at 1–2 µm, where the effects of star formation are small compared to optical wavelengths. The evolution of the stellar mass function of a galaxy provides a basic piece of information for modern cosmology. Moreover, the galaxy’s stellar mass can be used as a tool to reveal the evolution of the large-scale structure of the universe, if a sufficient number of galaxies are sampled over a large enough cosmic volume. Since the spectroscopic determination of the redshift of galaxies in such a large sample is extremely time and effort consuming, the “photo-z” technique, a method for the determination of redshifts based on multi-wavelength data, has been widely used (see Hyper-z: Bolzonella et al. 2000, Baysian method: Benitez 2000, ANN-z: Collister, Lahav 2004, HDF-N: Dickinson et al. 2003, K20 survey: Fontana et al. 2004 for examples). Since ground-based telescopes are not sensitive enough to detect stellar light beyond 2 µm, the photo-z technique has thus far been based on the 0.4 µm break and the Lyman break. On the other hand, space-borne telescopes, such as Spitzer telescope and AKARI, can observe longward of 2 µm and can thus execute a systematic study of the galaxy stellar mass at high redshifts. Furthermore, there is another redshift estimator in the rest-frame 1.6 µm, where the...
Fig. 6. $5\sigma$ sensitivities in $\mu$Jy for the IRC instrument in the pointing mode (NEP-Deep and NEP-Wide surveys, see section 5) and the FIS instrument in the all-sky survey mode as well as in the slow-scan mode. Also shown for reference are the assumed spectral energy distributions of a giant elliptical galaxy [rest-frame absolute $K = -26$ mag (in Vega)] and dusty ERO spectral energy distributions at redshifts of 1.44 and 3 modeled on the archetypical ERO HR10. The source confusion due to galaxies have been included from the recently updated evolutionary models of Pearson (2005). About BLAST, confer subsection 7.3.

H$^-$ opacity minimum of the stellar atmosphere (Sawicki 2002) exists. The 4 Spitzer/IRAC wavebands are specially designed to determine the photometric redshift by using this bump. The near-infrared and shorter mid-infrared filter bands of IRC (see table 3) continuously cover the 2–10 $\mu$m wavelength range, and hence a systematic study of the galaxy mass at various redshifts is also possible. Figure 4 shows the tracks of typical normal galaxies for $z = 0$–4 on a two-color diagram for the IRC wavebands. For determining the mass function in each redshift bin, a mass sensitivity to well below $10^{11} M_\odot$ (i.e. characteristic stellar mass $M_*$ of the Schechter function, see Dickinson et al. 2003) is required. As shown in figure 5, 10 pointing observations in the N3 and N4 bands satisfy this requirement out to $z = 4$. In this plot, the galaxy formation epoch $z_{\text{form}} = 20$ is assumed to demonstrate the high sensitivity to the stellar mass, even at high redshifts.

Here, we discuss the requirement for the survey volume. We require statistically significant numbers of galaxies detectable with AKARI at each redshift bin. If the source of the uncertainty is solely the Poisson error, one could simply request $\geq 100$ sources per redshift bin with 10% accuracy. However, for relatively small survey volumes, observational estimates of the number density of the galaxies suffer from the cosmic variance — the field-to-field variation due to the large-scale structure. For example, in the case of a 0.5 deg$^2$ area, the comoving volume for $\Delta z = 0.2$ intervals at $z = 2$–3 is $1.1 \times 10^6$ Mpc$^3$, corresponding to a cube of side length of 100 Mpc. According to Somerville et al. (2004), the uncertainty due to the cosmic variance for strongly clustered populations, such as Extremely Red Objects (EROs) is estimated to be 30–40%, while for less clustered populations it is around 15–20% (for Lyman Break Galaxies: LBGs). The cosmic variance shows a rather weak dependence on the survey volume, $V$: $V^{\gamma/6}$, where $\gamma$ is the index of the two-point correlation function; therefore, a factor of two reduction of the variance requires an order-of-magnitude larger volume, which cannot be easily obtained by the on-going space infrared telescopes. It should be noted, however, that Peacock and Dodds (1994) described the power spectra obtained by optical large-area surveys as well as the IRAS survey, which gives only 3–4% cosmic variances for 0.5 deg$^2$ area with $\Delta z = 0.2$ interval. In conclusion, at $z \geq 1$ a 0.5 deg$^2$ area is our minimum requirement to avoid serious effects due to cosmic variance, while for $z \leq 1$, more than 5 deg$^2$ area is recommended.

The survey area and depth requirements to obtain the desired scientific objectives described in this subsection are summarized as follows:

- Survey depth: the sensitivity for the stellar mass of a galaxy, $< 10^{11} M_\odot$ out to $z = 4$. Approximately 10 pointing observations are required for the 2–10 $\mu$m wavebands.
- Survey area: 0.1 deg$^2$ is not sufficient to overcome the cosmic variance, however, a 0.5–1 deg$^2$ area is reasonable at $z = 1$–4 if 10–30% cosmic variance effect is acceptable.
3.2. Dusty Star-Formation History of the Universe

In the past few years, considerable progress has been made in understanding the star-formation rate (SFR) of high-$z$ galaxies using the Lyman drop-out technique to identify galaxies at $z = 3–5$ (Steidel et al. 1996; Ouchi et al. 2004). Well over 2000 Lyman-break systems have now been observed at $z > 3$. These are ultraviolet (UV)-bright, actively star-forming galaxies with blue spectra and SFRs of a few to $\sim 50 M_\odot$ yr$^{-1}$. Moreover, thanks to the commissioning of very deep large-area surveys with narrow-band filters on 8-m class telescopes, more than twenty Ly$\alpha$-emitting galaxies (LAEs) at $z > 5$ have been identified (Taniguchi et al. 2003; Shimasaku et al. 2004; Ouchi et al. 2005), providing us with the first insight into the star-formation history of the universe beyond $z = 5$. Typical SFRs of $z = 5–6$ LAEs are 5–10 $M_\odot$ yr$^{-1}$, which however should be considered as a lower limit, since the blue half of the Ly$\alpha$ emission may be absorbed by H$\alpha$ gas and dust.

---

**Fig. 7.** Predicted fluxes of ULIRGs as a function of the redshift for the IRC-NIR and IRC-MIR-S bands. The SED variation is determined from the observed SED of sub-mm galaxies at $z = 2–3$ (Takagi, Pearson 2005). The luminosity is assumed to be $3 \times 10^{12} L_\odot$. The thick solid and dashed lines indicate the expected fluxes from Arp 220 and M 82. The horizontal lines indicate the flux limits of the NEP survey with the IRC (dashed, for NEP-Wide; solid, for NEP-Deep).
grains within the galaxy, itself, and by the intergalactic H I gas.

The popular Madau plot (Madau et al. 1996) implied that the SFR of the universe peaked at $z = 1–2$, although the SFR derived from the rest-frame optical/UV light has serious uncertainties in correcting of the dust extinction. However, the stellar mass of a galaxy derived from an SED fitting including the $K$-band does not suffer so critically from the extinction correction, and it has been revealed that stellar mass density of the universe as a function of redshift shows a rapid increase in the stellar mass density at $z = 1–2$, based on deep and wide $K_s$ band surveys (Caputi et al. 2004, 2005). Furthermore, galaxies selected from optical and near infrared photometry with $BzK = (z' - K)_{AB} - (B - z')_{AB} > -0.2$ have been found to show active SFRs of $> 100 \, M_\odot \, yr^{-1}$ at $z > 1.4$ (Daddi et al. 2004). Therefore, it is very important to understand the star-formation history of the universe not only at $z > 4$, but also at $z = 1–2$.

It has been revealed that a significant portion of the energy emitted in the early universe came not only from UV-selected galaxies, but also from very luminous galaxies in the far-infrared region, which are hidden at optical wavelengths because of obscuration from interstellar dust grains. Recent

Fig. 8. Same as figure 7, but for the IRC-MIR-L and the FIS bands.
submillimeter deep surveys with the SCUBA instrument on the JCMT have shown the existence of numerous such sources, showing that the sub-mm galaxies represent an important component of the cosmic star formation at high redshifts. For example, from the follow-up optical spectroscopy with multi-object spectrographs on 10-m class telescopes, Chapman et al. (2003, 2005) have reported a median redshift of 2.3 for their sample of sub-mm galaxies with VLA identifications.

Since the sub-mm galaxies are very faint at optical wavelengths (UV in their rest frame) due to extinction by dust in the systems, themselves, mid- and far-infrared observations with space infrared telescopes, such as Spitzer and AKARI, are critical to unveil their true nature. Such infrared observations will give unique information on their infrared SEDs, which is an important clue to obtain information on the mass-to-light ratio, the overall dust opacity, and to infer the hidden star-formation rate of these galaxies.

From these considerations, we propose to concentrate on the dusty star-formation history at \( z = 1 - 3 \) with AKARI, and generate statistically meaningful numbers of samples (order of 100–1000) in each redshift bin. Figure 6 shows the expected flux limits for the AKARI wavebands as well as the SED of a hyper-luminous \( (L_{\text{IR}} = 10^{13} L_\odot) \) ERO at \( z = 3 \). A quantitative discussion on the expected number of sources in the far infrared was given in Jeong et al. (2004), and its revision, including the near- and mid-infrared source counts, can be found in C. P. Pearson et al. (2006, in preparation). Figures 7 and 8 show predicted fluxes of ULIRGs as a function of redshift for the IRC and FIS wavebands used for the proposed survey toward the ecliptic poles. Fluxes for various ULIRG SEDs with an infrared luminosity of \( 3 \times 10^{12} L_\odot \) (Takagi, Pearson 2005) are shown. Note that if there are AGN contributions, the ULIRGs should be brighter than that expected from this model. Hence, in order to detect ULIRGs at \( z = 2 - 3 \) in the mid-infrared, 8–10 pointings per filter, i.e. the depth proposed for the NEP-Deep survey, is sufficient. It should also be noted that the FIS slow-scan survey can potentially detect the far-infrared emission of the \( z \approx 2 \) mid-infrared sources in the NEP-Deep field (figure 8).

Figure 9 shows a comparison of the comoving volume per unit redshift interval for Spitzer/GOODS (160 arcmin\(^2\) for CDF-S, Giavalisco et al. 2004), Spitzer/SWIRE (50 deg\(^2\), Lonsdale et al. 2004), Spitzer/FLS, and for the proposed AKARI NEP surveys. As discussed in subsection 3.1, a 0.5deg\(^2\) survey provides the sufficient cosmic volume for \( z \geq 1 \).

The survey area and depth requirements to obtain the desired scientific objectives described in this subsection are summarized as follows:

- **Survey depth:** the sensitivity to detect ULIRGs at high redshift, for example, \( L_{\text{IR}} = 10^{13} L_\odot \) out to \( z = 3 \). In particular, the 11–24 \( \mu \)m wavebands are important, and approximately 10 pointing observations are required in each band.
- **Survey area:** 0.1 deg\(^2\) is not sufficient to overcome the cosmic variance, however, a 0.5–1 deg\(^2\) area is reasonable for \( z = 1 - 3 \); if 10–30% cosmic variance can be acceptable. Below \( z \approx 1 \) a 5–10deg\(^2\) area is preferable.

### 3.3. Unveiling the Nature of the Cosmic Infrared Background

Our knowledge of the Cosmic InfraRed Background (CIRB) at both near- and far-infrared wavelengths has been drastically increased by observations with COBE (Hauser, Dwek 2001; Lagache et al. 1999; Wright 2004) and the Japanese IRTS mission (Matsumoto et al. 2005). In the near-infrared, the observed 2 \( \mu \)m brightness of CIRB is more than a factor of two larger than that estimated by ultra-deep galaxy counts based on large ground-based telescopes (Totani et al. 2001; Matsumoto et al. 2005), suggesting the existence of a contribution from a new population, such as the first stars (Kashlinsky 2005 and references therein). From the IRTS results, Matsumoto et al. (2005) found a signature of a break at 1–2 \( \mu \)m in the SED of the CIRB, and the existence of a bump in the power spectrum of the spatial fluctuation of the CIRB. The IRC onboard AKARI has a spectroscopic capability in the near infrared to \( \geq 2 \mu \)m. Moreover, for this study, the IRC is very powerful because of its higher spatial resolution than those of COBE and IRTS as well as the high point-source sensitivity, which will enable us to subtract any foreground point-like sources (stars and galaxies). Hence, we will be able to investigate the small-scale spatial fluctuations of the residual background. With IRTS, an appreciable spatial correlation at the 1°–2° scale has been reported; therefore, at least a survey scale of 2°–4° is required to obtain good statistical samples of such correlation signals. Supplemental data at various ecliptic latitudes are also necessary to subtract the contribution of the zodiacal light.

In the far-infrared, not only the brightness of the CIRB, but also its spatial fluctuations, have been studied by observations with ISO (Lagache, Puget 2000; Matsuura et al. 2000). However, the source confusion limit is more serious than in the near-to-mid infrared due to the larger diffraction-limited beam size, inhibiting the detection of high-redshift sources.
Fig. 10. Angular power spectrum $P(k)$ of the CIRB fluctuation in the far-infrared, where $k$ is the angular frequency. Results of the ISO/FIRBACK 170 $\mu$m survey in ELAIS N2 (Puget, Lagache 2001), ISO 90 $\mu$m survey in Lockman Hole (Matsuhara et al. 2000): $N_{HI} < 10^{20}$ cm$^{-2}$, and recent preliminary analysis of Spitzer/SWIRE 160 $\mu$m survey (Grossan, Smoot 2005), are also shown. Shot noise (thin dashed lines) is estimated for randomly distributed background galaxies fainter than 10 and 50 mJy at 90 and 160 $\mu$m, respectively. The data at 160 (170) $\mu$m show better agreement with the galaxy clustering model (dotted, Perrotta et al. 2003) than the shot noise case. For a comparison, the cirrus power spectra for $N_{HI} = 5 \times 10^{20}$ cm$^{-2}$ (in the low-cirrus region near the SEP) and $2 \times 10^{20}$ cm$^{-2}$ are also shown by dash-dotted lines. The AKARI sensitivities (thick dashed lines) calculated by assuming a white-noise spectrum corrected for the spectra of the point-spread function are far below the expected background fluctuation power.

On the other hand, the fluctuation power of the surface brightness of the sky, after excluding the bright point sources, contains information on the sources located at relatively high redshift. Hence, the fluctuation study is a very powerful tool to understand the nature of the sources responsible for the CIRB. Figure 10 shows the angular power spectra of the surface brightness fluctuations in the far-infrared, observed with ISO and Spitzer telescopes. These power spectra are calculated from the images where $S \geq 50$ mJy sources are removed, and are consistent with the shot (Poisson) noise due to $S < 50$ mJy sources. Moreover, the fluctuation power is consistent with the view of strong evolution in the galaxy counts at 50–200 mJy, which can be interpreted as the emergence of a huge number of ultra-luminous or hyper-luminous infrared galaxies at $z \sim 1$ (Pearson 2001; Takeuchi et al. 2001).

Not only the Poisson noise arising from the discrete nature of the galaxies, but also the angular correlation (clustering) of the galaxies, are expected to contribute to the power of the surface brightness fluctuations (Peebles 1980). The observed fluctuation power, however, shows no evidence for any contribution from galaxy clustering. Thus, the major scientific goal of the fluctuation studies with AKARI and Spitzer photometries is to confirm the existence of the fluctuation power due to clustering, and to estimate the redshift of the galaxies responsible for the clustering. For this purpose one should perhaps examine the cross-correlation of multi-color images in order to isolate the fluctuation power due to sources over some redshift range (say, $z \sim 1$ or $z \sim 2$). The signal-to-noise ratio of the images should be high enough to obtain the fluctuation power due to $z \sim 2$ ULIRGs ($S \sim 10$ mJy). Clearly, the AKARI all-sky survey is not adequate, since the flux limit is higher than the source confusion limit, and thus the slow-scan mode observation is mandatory (see tables 3 and 5). Figure 10 also shows the expected contribution of the detector noise in the slow-scan observation mode. Regarding the required area for the survey, one should also take into account of the field-to-field variation of the clustering signal (i.e. cosmic variance). As we have shown in the previous subsection, a survey area of order 10$\text{deg}^2$ is required to investigate the clustering due to $z \sim 1$ galaxies. The low-frequency noise due to the galactic infrared cirrus (cirrus noise) should be also minimized and is discussed in subsection 4.2. Moreover, the survey area should be contiguous, in order to confirm the existence of the cirrus noise at a few degrees scale, and to judge whether the cirrus noise will not be a problem at higher spatial frequencies.

The survey area and depth requirements to obtain the desired scientific objectives described in this subsection are summarized as follows:

- **Survey depth**: to study the cosmic near-infrared background fluctuations, the survey area should be a contiguous, 2$\text{deg}^2$–4$\text{deg}^2$ wide, circular or square shape. The sensitivity requirement is easily achieved with the exposure time of a single pointing observation. Good stability of the detector array is a key issue to obtain a reliable signal of the background fluctuations at low spatial frequencies.
- **Survey area**: to study the cosmic far-infrared background fluctuations, the signal-to-noise ratio of the images should be high enough to obtain the fluctuation power due to $z \sim 2$ ULIRGs ($S \sim 10$ mJy at 90–140 $\mu$m), and hence requires the slow-scan observation mode. A survey area of order 10$\text{deg}^2$ is required to investigate clustering due to $z \sim 1$ galaxies.

### 3.4. **Statistical Study of Buried AGNs**

Not only the cosmic star-formation history, but also the birth and evolution of Super-Massive Black Holes (SMBHs) are major science goals of modern astronomy. Moreover, the birth
and evolution of SMBHs are closely related to the evolution of host galaxies, as indicated by the tight correlation between the mass of SMBHs and the velocity dispersion of the bulge component of host galaxies (e.g. Meritt, Ferrarese 2001) in the local universe. Furthermore, the results from recent hard X-ray surveys have revealed that most of the accretion onto the SMBHs is obscured by dust (Ueda et al. 2003), thus prohibiting a diagnostic study by optical lines (“buried AGNs”). In such buried AGNs, most of the AGN luminosity is absorbed by dust and re-radiated in the mid to far-infrared. Thus, in order to unveil the nature of such buried AGNs, infrared observations with AKARI will play a key role. Moreover, to discriminate between the hot dust emission powered by AGNs and the warm dust emission powered by star formation, multi-color data at optical to far-infrared wavelengths is particularly useful. This will also enable us to understand the AGN contribution to the CIRB, especially at far-infrared wavelengths.

As described in subsection 3.2, the proposed NEP survey will provide a huge number of ULIRGs or Hyper-luminous infrared galaxies (HLIRGs) out to z = 3, and these samples will provide a unique database to investigate the contribution of the buried AGNs as the energy source for the ULIRGs. One should note that such studies will be more effective when observing time is allocated to XMM/Newton hard X-ray imaging of the NEP AKARI deep field.

Another diagnostic tool to investigate the energy sources of ULIRGs is the dust features in the thermal infrared. Since an energy source for buried AGN is, by definition, concentrated at the center of the dust cloud, its presence is traced by the carbon dust absorption feature at 3.4 µm and the 10–20 µm silicate dust features. So far 6–11 µm spectra of many ULIRGs with ISO (Rigopoulou et al. 1999) and ground-based L-band spectra (Imanishi, Dudley 2000) have been obtained. However, the limited wavelength coverage made it very difficult to determine whether the spectra were dominated by strong 7.7 µm PAH emission features (starburst-powered) or a strong 9.7 µm absorption feature of silicate dust implying the presence of a buried AGN.

The AKARI/IRC incorporates slitless spectroscopic functions at 2–26 µm with a spectral resolving power of 30–90, suitable to study relatively broad spectral features. Therefore, we will perform an unbiased spectroscopic survey by using the slitless spectroscopic mode in order to provide numerous SED samples of various galaxy types, including the serendipitous detection of buried AGN candidates. Moreover, it is noted that studies with the 3.3 µm PAH feature of local starburst galaxies as well as with the 3.4 µm feature of local AGNs are impossible with Spitzer/IRS, due to a lack of wavelength coverage below 5 µm.

The survey area and depth requirements to obtain the desired scientific objective described in this subsection are summarized as follows:

- The survey depth and area requirements for the imaging surveys are already stated in the summary of subsection 3.2. The buried AGN population is an important subset of the entire galaxy sample. A detailed discussion will be given in a separate paper by C. P. Pearson et al. (2006, in preparation).

- The survey depth and area requirement for a spectroscopic survey, good sensitivity for the mid-infrared dust features, is a key issue in order to generate a sample of unbiased mid-infrared SEDs of galaxies in sufficient numbers. This will also be discussed in a separate paper.

4. Optimization of the Location of the Survey Fields

In this section, we describe the best location of the survey area for an extragalactic deep survey with AKARI. In short, we first examined the visibility constraint of the AKARI spacecraft, which led us to conclude that the ecliptic pole regions are almost a unique choice; we then checked if the survey will suffer from confusion noise due to the galactic infrared cirrus, and also investigated the density of bright sources (mostly stars in the Galaxy), which may cause serious saturation of the near-infrared detectors.

4.1. Visibility Constraint of AKARI

According to the attitude control scenario described in section 2, we checked the sky visibility constraint for deep surveys that require a significantly large number of pointed observations. For simplicity, we assumed a rectangle survey area of uniform depth at an ecliptic latitude β, satisfying the following equation:

$$N_c N_s N_{ptf} \leq \frac{10 N_c + 120}{\Delta \lambda_0 \cos \beta},$$

where $N_c$, $N_s$, and $N_{ptf}$ are the number of FOVs in the cross-scan direction, the number of FOVs in the scan direction, and the number of pointed observations per FOV, respectively. $\Delta \lambda_0 = 41$ is the longitudinal separation between successive orbits at the ecliptic plane. This equation gives the minimum β at which we could perform a survey with a total number of pointed observations, $N_c N_s N_{ptf}$, and is shown in figure 11.

For example, 1 deg² coverage with 30 pointings per FOV requires $N_c N_s N_{ptf} \approx 1000$. Clearly such a required number of pointing opportunities can only be allowed in regions very close to the ecliptic poles ($\beta \geq 89^\circ$) unless the survey area is a long strip or a thin donut. Such geometries do not satisfy the requirement from the scientific objectives described in section 3. Hence, the deep survey field must be chosen at the ecliptic polar regions.

4.2. Confusion Due to the Infrared Cirrus Emission

An important sensitivity limitation arises due to the spatial fluctuation of the infrared cirrus. Helou and Beichman (1990) have assumed that the fluctuation power is proportional to $\overline{B}_v$ for all wavelengths, where $\overline{B}_v$ is the mean brightness of the infrared cirrus. They have expressed the cirrus confusion noise by

$$\sigma(\lambda)_{1\text{mJy}} = 0.73 \left( \frac{\lambda}{100 \mu m} \right)^{2.5} \left( \frac{D}{0.7 \text{m}} \right)^{-2.5} \left( \frac{\overline{B}_v}{1\text{MJysr}^{-1}} \right)^{1.5}.$$  \hspace{1cm} (2)

Thus, the cirrus confusion noise will depend not only on the variation of the surface brightness of the background structure, but also on the resolution of the telescope ($\lambda/D$), resulting
in less noise at shorter wavelengths. Kiss et al. (2001) have analyzed 40 sky regions with the ISOPHOT instrument on ISO, concluding that the cirrus noise was consistent to within a factor of 2 according to the formulation of Helou and Beichman (1990).

Figure 12 shows the IRAS 100 µm map (Schlegel et al. 1998) near the ecliptic poles. Unfortunately, as shown in the figure, the ecliptic poles are not optimal areas for the local minimum of the infrared cirrus: 2–3 MJy sr$^{-1}$. Applying equation (2) to the AKARI FIS/IRC wavebands and assuming a range of mean brightness for the infrared cirrus at 100 µm ($B_{100}$) with the infrared cirrus SED of Dwek et al. (1997), we obtain the results for the cirrus confusion noise in table 5. Unless a relatively bright cirrus region ($B_{100} \geq 5$ MJy sr$^{-1}$) is observed, the cirrus confusion is not problematic for the IRC bands. It is noteworthy that, based on recent Spitzer observations at 24 µm in a bright cirrus region in Draco ($N_{HI} = 4–14 \times 10^{20}$ cm$^{-2}$), Dole et al. (2004) reported a rather weak effect, leading to a completeness degradation of only 15%.

However, the quantities of cirrus noise toward the ecliptic poles are appreciable for the FIS bands (especially longer wavelength channels). Hence, we should carefully choose any deep field for FIS imaging, especially for the studies of CIRB fluctuations. One should also take into account any angular frequency dependence of the fluctuation power spectrum of the cirrus: $P(k) \propto k^{-3}$ (Gautier et al. 1992; Kiss et al. 2001; Jeong et al. 2005), where $k$ is the angular frequency. Fluctuations at large angular scales (order of a degree) are likely to be dominated by cirrus noise, even though the point source detection (i.e. at high angular frequency) is not affected. Hence, a low-cirrus region is required, especially for the CIRB study in the far-infrared. The optimum area for such far-infrared deep
surveys is the low-cirrus region in the south or in the ELAIS N1 field ($B_{100} \lesssim 0.5 \text{ MJy sr}^{-1}$, corresponding to a hydrogen nuclei column density of $5 \times 10^{19} \text{ cm}^{-2}$), as shown in figure 12. Figure 10 shows the expected cirrus power spectra toward the low-cirrus region near the SEP, compared with the shot noise due to the unresolved galaxies. The advantage of the low-cirrus region near the SEP can be clearly seen.

4.3. Bright Stars

Bright stars in our Galaxy as well as the Magellanic clouds should be avoided for extragalactic deep surveys. Not only the saturated pixel due to the bright stars, but also the adjacent pixels may not be useful for deep imaging, because such pixels are affected by an increased photon noise. $K \lesssim 12 \text{ mag}$ corresponds to the saturation limit of the N2 band imaging of the IRC. However, since the FOV of the IRC is as wide as $10' \times 10'$, it is difficult to find fields without any bright stars in the ecliptic polar regions. In figure 13 the density distributions of bright 2MASS stars ($K \lesssim 12 \text{ mag}$) are shown with the AKARI visibility contours. At the NEP approximately 5 such stars exist per FOV of the IRC. Below $K \simeq 15 \text{ mag}$ extragalactic sources begin to dominate the source counts, and the photon noise due to the stars is not appreciable. By using the star count model of the Galaxy (Nakajima et al. 2000), we estimated approximately on average 50 stars per FOV down to $K \sim 15 \text{ mag}$. When considering the current best estimate for the in-flight point spread function of the IRC-NIR channel (approximately 10 pixels per source in the 70% energy circle), this means approximately only 0.3% of the pixels will suffer from saturation, or the increased photon noise due to stars. In the case of the SEP, as shown in figure 13, the surface density of the galactic stars is about twice larger than that at the NEP, since it is close to the LMC. In conclusion, the surface density of the galactic stars is non-negligible, but still within acceptable limits to perform extragalactic surveys. Thus, for the near- and mid-infrared deep surveys with AKARI, we selected the field near the NEP simply because the star density is a factor of two smaller at the NEP; moreover, we could not allocate so many pointed observations for extragalactic surveys near the SEP because of the existence of another large-area survey with AKARI: the LMC survey.

The bright stars can cause serious damage to the optical pre-survey images. Hence, the field position was chosen to avoid saturation of the CCDs of the Suprime-Cam instrument by bright ($V \leq 10 \text{ mag}$) stars (see section 7).

5. Observation Plan

5.1. Proposed Area for the Deep Pointings Surveys

From the above discussion, regarding the IRC deep survey field, the NEP is the best candidate because approximately 1000 pointing observations can only be realized within a few degrees from the NEP (see figure 11), and there are no other serious limitations. There is an option to move the NEP-Wide survey field to the ELAIS N1 field, one of the Spitzer/SWIRE fields. However, the ecliptic latitude of the ELAIS N1 is not high enough to be observable throughout the year, and thus it is hard to generate a circular or nearly rectangular map, which is one of the key requirements to study the cosmic near-infrared background fluctuations (see subsection 3.3). In contrast, the SEP is not so good for the IRC extragalactic deep survey due to its proximity to the LMC; moreover, there exists a large-area survey program toward the LMC, which makes it difficult to allocate a large number of pointed observations for any extragalactic survey. Thus, for the near- and mid-infrared deep extragalactic surveys we conclude that the NEP is the best target field.

Regarding far-infrared deep surveys, the NEP is acceptable, since the cirrus confusion limit is approximately the same or below the galaxy confusion limit, considering a mean cirrus

| Band  | $\lambda_c$ (\(\mu\)m) | Galaxy confusion (5\(\sigma\) $\mu$Jy) | Cirrus confusion (5\(\sigma\) $\mu$Jy) for $B_{100}$ |
|-------|------------------------|---------------------------------|---------------------------------|
|       |                        | 40 beam/source                  | 20 beam/source                  | 0.5 MJy sr$^{-1}$ | 3 MJy sr$^{-1}$ | 10 MJy sr$^{-1}$ |
| N2    | 2.43                   | < 1                             | < 1                             | < 1               | < 1              | < 1              |
| N3    | 3.16                   | < 1                             | < 1                             | < 1               | < 1              | < 1              |
| N4    | 4.14                   | < 1                             | < 1                             | < 1               | < 1              | < 1              |

* The cirrus noise is calculated assuming the model of Helou and Beichman (1990).
Fig. 13. Bright \( K < 12 \) 2MASS source density around the NEP region (left) and the SEP region (right). AKARI visibility contours (solid lines) are shown for 250, 200, 150, 100, and 50 (in Phase 1 plus 2) away from the pole. Gradient corresponds to 130 (darkest), 160, 190, 220, 260, 290, 320, 350, 380, and 410 stars per square degree.

brightness (at IRAS 100 \( \mu \)m) of \( \bar{B}_{100} = 1–2 \text{MJy sr}^{-1} \) and \( \bar{B}^{3}_{100} \), dependence of the fluctuation power spectrum (Gautier et al. 1992, see table 5). However, an extremely-low cirrus region is preferable, since the major scientific goal, measurement of the CIRB fluctuations over degree scales, will be hampered by the \( k^{-3} \) dependence of the infrared cirrus emission, where \( k \) is the angular frequency. As shown in figure 12, alternative candidate fields are the ELAIS N1 field near the NEP and the low-cirrus region near the SEP at \( \beta = -74^\circ \), where \( \bar{B}_{100} \) is as low as 0.2 MJy sr\(^{-1}\) (Schlegel et al. 1998). The advantage of the ELAIS N1 field near the NEP is that there are numerous multi-wavelength data sets already available, including the Spitzer data. However, pointed observations for the NEP survey (with the IRC) severely conflicts with those for the ELAIS N1 fields, and a large-area survey (more than \( 10^\text{deg}^2 \)) is not realistic. On the other hand, pointing opportunities for the SEP low-cirrus region do not conflict with those for the LMC survey (i.e. the locations are different in ecliptic longitude), thus we conclude that the SEP low-cirrus region is the best target field for far infrared deep slow-scan surveys. In table 1 we summarize an overview of the currently planned deep surveys.

5.2. The NEP Survey

In this subsection we describe the details of the current observation plan for the NEP survey with AKARI in its pointing attitude mode. In order to satisfy the scientific requirements (section 3), the survey area should be observed to a suitable depth for the detection of statistically meaningful samples of extragalactic sources (\( \gg 10^3 \)) out to \( z = 4 \) in the near-infrared, and to \( z = 3 \) in the mid-infrared. Moreover, the survey area should be large enough so that the obtained sample does not suffer from serious uncertainty due to cosmic variance, and the geometry of the area should be a circle or a square, i.e. a strip or ring should be avoided.

Currently the following two blank-field surveys are planned:

- **NEP-Deep**: deep (28 pointing observations per FOV) survey over approximately \( 0.5^\text{deg}^2 \).
- **NEP-Wide**: wide and shallow (2 pointings per FOV) survey of approximately \( 6^\text{deg}^2 \). The survey region is a circular area surrounding the NEP-Deep field.

For the former, the one-filter AOT will be used (8–10 pointing observations per filter and per FOV), while for the latter, the three-filter AOT will be used. Therefore, data will be obtained in all 9 IRC wavebands. The locations of the survey fields are shown in figure 14. The total number of pointed observations amounts to 954. During Phase 1 and the first six months of Phase 2, approximately 2.6 pointing opportunities per day using mainly the orbits passing the SAA will be allocated for the survey. The pointing directions are primarily determined by the requirements from the IRC observations: the FIS will be operated in the FTS mode (probably in low spectral resolution mode of approximately \( 1 \text{cm}^{-1} \)) in parallel, in order to obtain the 50–180 \( \mu \)m SED of the diffuse emission. Although the FTS mode is not sensitive enough to obtain the spectrum of each extragalactic source, these FTS observations toward the NEP are useful to study of the CIRB as well as galactic interstellar matter, by using several hundred pointing opportunities in this parallel mode.

5.2.1. The deep survey “NEP-Deep”

The survey area of NEP-Deep is a circular area whose center is slightly offset from the NEP, in order to cover the deep pre-survey field, which has been already surveyed at optical wavelengths with Subaru/Suprime-Cam (see section 7). The survey field is observable for many orbits during the mission, when the offset control is applied. This will be important if we are to cover the field with all IRC channels efficiently. This reasoning is explained as follows: first, as shown in figure 3

5.2.2. The wide survey “NEP-Wide”

The survey area of NEP-Wide is a strip-like area surrounding the NEP-Deep field. The entire area is observed by AKARI in its pointing attitude mode, which can provide an excellent coverage in the near-infrared. The survey area is divided into two parts: the north and south regions, each covering an area of approximately \( 3^\text{deg}^2 \). The northern region is observed in the one-filter AOT (28 pointing observations per filter and per FOV), while the southern region is observed in the three-filter AOT (2 pointings per FOV). The total number of pointed observations amounts to 582. The survey is divided into two phases: Phase 1 (approximately 3 months) and Phase 2 (approximately 1 year). During Phase 1, the survey is divided into two segments: Segment 1 (approximately 1 month) and Segment 2 (approximately 2 months). During Phase 2, the survey is divided into two segments: Segment 3 (approximately 3 months) and Segment 4 (approximately 9 months). The pointing directions are primarily determined by the requirements from the IRC observations: the FIS will be operated in the FTS mode (probably in low spectral resolution mode of approximately \( 1 \text{cm}^{-1} \)) in parallel, in order to obtain the 50–180 \( \mu \)m SED of the diffuse emission. Although the FTS mode is not sensitive enough to obtain the spectrum of each extragalactic source, these FTS observations toward the NEP are useful to study of the CIRB as well as galactic interstellar matter, by using several hundred pointing opportunities in this parallel mode.
Fig. 14. Survey area planned for the NEP survey in the pointing mode, consisting of a circular area (NEP-Deep, smaller one surrounding the rectangle) with 28 pointings per FOV and a larger circular area (NEP-Wide, centered at the NEP) with 2 pointings per FOV. Also shown are the optical deep survey field with Subaru/Suprime-Cam (rectangle area) as well as the location of ROSAT X-ray clusters (red diamonds, Gioia et al. 2003), ROSAT galaxies, AGNs, planetary nebulae (blue crosses), and high-z radio sources (circles, Brinkmann et al. 1997).

The FOV of the MIR-L channel is offset from those of the NIR and MIR-S channels by approximately 20', thus one pointing observation provides a NIR/MIR-S image and a MIR-L image separately on the sky. Secondly, since the FOV configuration rotates 180° in approximately 6 months, another pointing observation after 6 months enables us to obtain corresponding images in the complementary channel. Thus, two 10' × 10' fields separated by approximately 20' have been covered with all IRC channels. Therefore, allocation of the same number of pointed observations in both Phase 1 and Phase 2 (first 6 months) is a mandatory requirement for the NEP-Deep survey. Since the 0.5 deg² corresponds to 18 independent FOVs, 28 pointings per FOV result in 504 pointed observations in total with just one half of them being executed in Phase 1. Table 6 summarizes the expected flux limits for the NEP survey.

5.2.2. The shallow-wide survey “NEP-Wide”

The survey region of NEP-Wide is selected to surround the NEP-Deep field, but is a circular area whose center coincides with the NEP. Unlike NEP-Deep, the offset control is not actively used, but the pointing directions are regularly placed (i.e. FOVs are primary ordered in the in-scan direction, then the sky coverage is expanded in the cross-scan direction as the scan path rotates) so that the every portion of the survey field is covered with a uniform depth of 2 pointings per FOV in three-filter mode (AOT-03). In this manner, the survey field will be covered by both the NIR/MIR-S and the MIR-L over one year (Phase 1 plus the first six months of Phase 2). We currently plan to allocate 450 pointed observations in total, resulting in 225 independent FOVs, corresponding to approximately 6.2 deg².

Table 6. IRC and FIS flux limits expected for the NEP survey.

| Band (IRC) | λ_c (µm) | NEP-Deep* (5σ, µJy) | NEP-Wide† (5σ, µJy) |
|------------|----------|----------------------|---------------------|
| N2         | 2.43     | 2.8                  | 12                  |
| N3         | 3.16     | 1.2                  | 5.5                 |
| N4         | 4.14     | 2.3                  | 11                  |
| S7         | 7.3      | 10                   | 49                  |
| S9W        | 9.1      | 9                    | 39                  |
| S11        | 10.7     | 12                   | 56                  |
| L15        | 15.7     | 22                   | 100                 |
| L18W       | 18.3     | 31                   | 130                 |
| L24        | 23.0     | 57                   | 270                 |

| Band (FIS) | λ_c (µm) | Slow-scan‡ (5σ, mJy) | All-sky survey§ (5σ, mJy) |
|------------|----------|----------------------|---------------------------|
| N60        | 65       | 35                   | 100                        |
| WIDE-S     | 90       | 7                    | 20                         |
| WIDE-L     | 140      | 4.5                  | 40                         |
| N160       | 160      | 9                    | 70                         |

* AOT-00 (single filter per pointing). Net exposure times: 4000–5000 s per filter.
† AOT-03 (3 filters per pointing). Net exposure times: 200–230 s per filter.
‡ Assumes four slow-scans with a speed of 15'' s⁻¹ at each sky position.
§ Achieved by integrating the all-sky survey data of all overlapping scans toward the NEP-Wide field.
5.3 Near the SEP Survey “SEP low-cirrus”

Here, we describe the details of the current observing plan toward the low-cirrus region near the SEP using the FIS slow-scan mode. The target area is shown in figure 15. Since the major science goal of this survey is to perform a study of the CIRB fluctuations on degree scales or larger, contiguous mapping in an area over at least 15 deg$^2$ is planned. Considering the visibility of the low cirrus region at $\beta \simeq 74^\circ$, a daily allocation of 3–4 pointing opportunities is mandatory to create such a contiguous map. In figure 15, an example of the footprints of the FIS FOV are also shown as boxes; in this scenario, at each pointing observation, the FIS FOV makes a round trip (240 s forward-scan, then 240 s backward, with 15'' s$^{-1}$ scan rate) along the nominal survey path, resulting in an $8' \times 1'$ strip map. Using 270 pointing opportunities over the 90 d when the low-cirrus region is visible (this corresponds to 3 pointing opportunities per day), 3 (along the scan) $\times$ 90 (cross-scan, with 4' steps) mosaics of the $8' \times 1'$ strip maps corresponds to an approximately 15deg$^2$ fan-shape area.

Figure 16 compares the depths and areal coverage for various slow-scan rates for a fixed number (270) of pointed observations. The expected sensitivities of the WIDE-L and N160 bands reach below the galaxy confusion limit, even in the case of the fastest scan rate (30'' s$^{-1}$), and hence the adoption of a faster scan rate is adequate in order to expand the survey area. It is also worth noting that the all-sky sensitivity does not reach the confusion limit, even if we take into account the large number of overlapping scans expected near the ecliptic poles.

6. Uniqueness of the Surveys

We discuss the uniqueness of the AKARI deep surveys compared to other contemporary surveys carried out with previous and ongoing missions.
690 H. Matsuhara et al. [Vol. 58,

Fig. 16. Depth and areal coverage for various slow-scan surveys with the FIS bands. At each point on this plot, 270 pointing observations are assumed. The resulting areal coverage varies according to the scan-speed: 8°, 15°, and 30° s⁻¹. For a comparison, the dashed and solid curves show the all-sky survey sensitivities by simply taking into account the number of overlapping scans at any given point on the sky. The horizontal dashed lines are the galaxy confusion limit for a 69 cm telescope estimated based on the recent Spitzer results.

6.1. Infrared Space Observatory

The Infrared Space Observatory (ISO, Kessler et al. 1996) launched in 1995 November was equipped with a 60 cm cooled telescope and had the capability for near- and mid-infrared imaging: ISOCAM, a 3' × 3' field of view camera with 32 × 32 pixels. Most of the deep ISOCAM surveys utilized two broad-band filters: LW2 at 6.7 μm and LW3 at 15 μm. In particular, the ISOCAM 15 μm surveys covered a wide range in both sensitivity and spatial area: 0.013 deg² with
100 µJy, 0.3−0.4deg$^2$ with 0.5−0.8 mJy, and 13deg$^2$ with 1 mJy (Genzel, Cesarsky 2000 and references therein), resulting in the discovery of a strongly evolving population of galaxies below 1 mJy. This evolving population can be interpreted as the presence of luminous, ultra-luminous, and hyper-luminous infrared galaxies at $z \sim 1$ (Pearson 2001; Takeuchi et al. 2001). These infrared galaxies may be the main contributors to the cosmic infrared background radiation (Takeuchi et al. 2001; Chary, Elbaz 2001). However, the area of the ISOCAM surveys was not large enough to provide sufficient samples of these galaxies when separated into several redshift bins, and the surveys were made solely with the 15 µm band. Hence, our understanding of on the star-formation history around $z \sim 1$ is still rather limited.

Thanks to the innovation of detector technology, the sensitivity in the near- and mid-infrared regions of AKARI and Spitzer telescope has been improved by an order of magnitude over that of ISOCAM onboard ISO, although the telescope aperture has not increased very much in tandem.

6.2. Spitzer Space Telescope

In 2003 August, NASA successfully launched an advanced space infrared observatory, Spitzer (Werner et al. 2004). Spitzer telescope is an 85 cm diameter cooled telescope with three focal-plane instruments: IRAC, MIPS, and IRS. The IRAC instrument covers the near- to mid-infrared wavelengths in 4 bands at 3.6, 4.5, 5.8, and 8.0 µm (Fazio et al. 2004), while the MIPS instrument covers the mid- to far-infrared wavelengths in 3 bands at 24, 70, and 160 µm (Rieke et al. 2004). The IRS instrument (Houck et al. 2004) is a low resolving power of 20–50. Spitzer telescope has already completed various wide-area surveys, partly for its Legacy science projects (SWIRE, GOODS) and partly for the guaranteed time observations. Data products from the first look survey (FLS) and the Legacy projects have already been released to the world, and numerous scientific results have already appeared in the literature. Therefore, we should take into account the success of Spitzer telescope in designing the AKARI surveys. Besides the major uniqueness as an all-sky surveyor, AKARI also has several unique characteristics in the pointing mode compared to Spitzer telescope:

- The 2−26 µm imaging FOV (approximately $10' \times 10'$) is four-times larger in area than IRAC.
- Continuous wavelength coverage from 2 to 26 µm, especially in three wavebands (S11, L15, and L18W) are available in the 8−24 µm gap of the Spitzer bands.
- 2.5−5 µm slit spectroscopic capability with moderate resolving power of 140.
- 2−26 µm slitless spectroscopic capability with low resolving power of 20−50.
- Four wavebands at 50−180 µm where Spitzer/MIPS has two bands.

Here, we describe the uniqueness of imaging capability in more detail.

(1) FOV of IRC: The large FOV of the IRC compensates for the lower sensitivity per unit observing time. Hence, the IRC has a similar survey speed to that of Spitzer telescope. However, AKARI has to carry out the all-sky survey, and its mission lifetime is shorter than that of Spitzer telescope. Hence, in general Spitzer telescope as a mission is superior to make deep as well as wide-area surveys (of order 10$^5$ square degrees). Note that the IRC-NIR channel can work even in Phase 3 after Helium boil-off. Thus, for example, with 10 pointing observations per day over a year in Phase 3, a 50 deg$^2$ area to the depth of NEP-Wide can be surveyed at 2−5 µm.

(2) Continuous wavelength coverage from 2−26 µm: the IRC wavelength coverage over the 8−24 µm gap of the Spitzer bands (see figure 2) is extremely useful to estimate the redshift and to unveil the nature of $z = 1−3$ galaxies: star-forming galaxies are characterized by the PAH features at rest-frame 3.3, 6.2, and 7.7 µm and silicate absorption at 10 µm (“silicate-break”, see Takagi, Pearson 2005), while AGNs with dusty tori are characterized by a rather featureless hot dust continuum, occasionally with absorption features of silicate or carbon dust grains.SED fitting to the sources will break any degeneracy in the starburst-AGN phenomenon. Moreover, 11–18 µm surveys, which are much deeper and wider than those with ISO, are one of the most unique capabilities of AKARI. Although Spitzer/IRS has a 16 µm peak-up camera, it covers only 1.2 arcmin$^2$ FOV. Hence, the IRC can perform surveys with a 100-times faster mapping speed.

(3) Four wavebands at 50−180 µm: in the far-infrared Spitzer/MIPS has 70 µm and 160 µm bands, while AKARI/FIS has 4 wavebands. Such multi-color information provided by AKARI/FIS is useful to solve the redshift–temperature degeneracy in interpreting the far-infrared SED, since the peak of the dust emission resides in the far-infrared. This is also true for studies of the CIRB fluctuations; by cross-correlating the faint detected sources or fluctuation images at shorter wavelengths (WIDE-S and N60) and the fluctuation images at longer wavelengths (WIDE-L and N160), we can investigate the typical redshift of the sources contributing to the CIRB fluctuations.

By utilizing these unique capabilities, the ecliptic pole surveys with AKARI will reveal the dusty star-formation history of the universe, break the degeneracy in the starburst–AGN phenomenon, and unveil the origin of CIRB. Regarding the mid-infrared deep survey with AKARI, one might ask why we do not plan to observe the Spitzer/Legacy or FLS fields with solely S11, L15, and L18W. The answer is quite simple: for deep surveys in the pointing mode, except for regions toward the ecliptic poles, we cannot provide a sufficient number of pointing opportunities to achieve the depth required for the detection of $z = 2−3$ objects, as described in section 4.

It is, however, worthwhile to consider collaborative surveys with Spitzer telescope toward the NEP as well as the SEP low-cirrus regions. For the former, if IRAC 4 band and MIPS 24 µm imaging were carried out, the AKARI/IRC could then concentrate on imaging with 10−20 µm bands and the slitless spectroscopy. In the case of the latter survey, besides the FIS slow-scan surveys, we cannot undertake $\sim 10$ deg$^2$ IRC surveys because of the relatively low visibility of the field. Thus, IRAC and MIPS shallow, but wide-area imaging will greatly increase the scientific value of the SEP low-cirrus region survey.
7. Coordinated Multi-Wavelength Pre-Surveys

To perform our scientific goals, multi-wavelength data in the AKARI deep survey fields at both ecliptic poles are essential in many respects. First of all, the higher spatial resolution of ground-based large telescopes enables us to obtain accurate source positions, which are vital for follow-up with optical/near-infrared spectroscopy. Second, high spatial resolution near-infrared images can give us an opportunity to classify the galaxy type based on the optical (in rest frame) morphology of the source. Third, multi-color optical/near-infrared photometric data are useful to estimate the photometric redshift of the counterparts of the AKARI sources by identifying the LBGs (Steidel et al. 1996; Ouchi et al. 2004), or the 0.4 μm break in their SEDs (such as EROs, Pozzetti, Mannucci 2000; Mannucci et al. 2002; Caputi et al. 2004; Fontana et al. 2004). These techniques are very useful to check and confirm the photometric redshifts estimated from the SEDs using the AKARI wavebands, by using the 1.6 μm bump as well as the silicate/PAH features. We have already obtained preparatory images at the optical/near-infrared bands toward the AKARI survey fields, and here we briefly introduce the current status for future reference.

7.1. NEP Pre-Surveys

In 2003 June, we observed the NEP-Deep region with the Subaru/Suprime-Cam, where the 3σ limiting magnitudes (AB) reach down to B = 28.4, V = 27, R = 27.4, i′ = 27, and z′ = 26.2 over 918 arcmin². This has been followed by a successive observation in 2004 July with V and a narrow band filter (NB711). Further near-infrared (J and Ks) images have been taken with KPNO-2-m/FLAMINGOS to a limiting magnitude (Vega) of Ks ≈ 20 mag also in 2004 June. Together with the near-infrared images, we can identify candidate active star-forming galaxies at z > 1.4 by using the BzK technique (Daddi et al. 2004). A comparison of these BzK samples with ULIRGs found by the proposed AKARI deep survey will provide a unique database for studying star-formation history of the universe. Furthermore, a larger area of approximately 2 deg² has been observed with CFHT/Megacam at optical (g′, r′, i′, and z′) wavelengths to a 5σ limiting magnitude (AB) of 26 mag in the g′, r′, and i′ bands and 24 mag in the z′ band. This survey covers a part of the NEP-Wide area, and will also be useful for identifying candidate clusters of galaxies. We also plan to obtain a deep U-band images to search for the Lyman-break population at z ≤ 3.

7.2. SEP Pre-Surveys

To identify the far-infrared sources detected in the FIS slow-scan survey toward the SEP low-cirrus region, optical observations are underway. In 2004 we obtained R-band images over about half of the FIS survey field area to R = 25 mag by using the ESO 2 m and the CTIO 4 m telescopes. Surveys at other wavebands are also under consideration.

7.3. Surveys at Other Wavelengths

Deep radio images are very useful to identify luminous starburst galaxies. At the NEP, there is an existing 20 cm VLA observation by Kollgaard et al. (1994) to a limiting flux density of 200 μJy over 29.3 deg². However, this survey seems to be too shallow to identify the mid-infrared sources expected from the deep surveys with AKARI/IRC. For the area centered at the NEP we have already taken 21 cm radio images to a limiting flux of 50 μJy by using the WSRT in the Netherlands. A deeper VLA proposal is under consideration.

Submillimeter data are mandatory to study the star-formation history of the universe hidden by the dust, since the submillimeter flux (far-infrared in rest frame) is a direct measure of the infrared bolometric luminosity originating from dust warmed by the stellar light. The SCUBA camera on the JCMT is no longer available for guest observers, and thus allocation of the telescope time of the JCMT to the NEP field is very difficult until commissioning of the SCUBA-2 camera. The Balloon-borne Large Area Submillimeter Telescope (BLAST) is a promising candidate to obtain submillimeter data for the NEP field. BLAST is a 2-m aperture balloon-borne telescope incorporating 250, 350, and 500 μm imagers with 6.5 × 13’’ FOV (PI: Dr. Mark Devlin, University of Pennsylvania). Long-duration (~ 10 days) flights at the South Pole and Alaska have been commissioned from 2005 summer, which will allow 1 deg² deep surveys to be made. We are planning a coordinated multi-band survey toward the NEP with AKARI and BLAST. With this coordinated survey, we will obtain optical identifications of BLAST sources with multi-band data in a similar manner to that of the SCUBA galaxies with Spitzer/MIPS 24 μm fluxes (Egami et al. 2004; Ivison et al. 2004).

UV and X-ray data are also very important. One of the most promising methods for selecting 1.5 < z < 2.5 galaxies is the Lyman break technique, which requires near-UV observations. Moreover, far-UV fluxes at ~ 1500 Å are one of the key diagnostics for star formation, while the infrared data from AKARI tell us about the amount of starlight extinted by the dust. We should seek deep pointing observations with the Galaxy Evolution Explorer (GALEX), which was launched in 2003 April. X-ray data are also important in two respects: the X-ray emission from the hot intergalactic medium is useful to search for cluster candidates, and deep X-ray images are necessary to identify buried AGNs which may be strong mid-infrared emitters in the AKARI deep images. The ROSAT source catalogues have already been released (Henry et al. 2001; Gioia et al. 2003), and hard X-ray imaging with XMM-Newton Observatory is under consideration.

8. Summary

The AKARI observational strategy and the details of the observational plans for the coordinated deep pointing surveys toward the ecliptic poles are described. We have reviewed the scientific goals and requirements for the surveys, as well as the technical constraints of the AKARI spacecraft and effects of the foreground astronomical sources. We conclude that the NEP is the best location for the AKARI extragalactic 2–26 μm deep survey, while the low-cirrus regions near the SEP is optimum for the 50–180 μm slow-scan surveys.

The ELAIS-N1 field, one of the Spitzer/SWIRE fields, cannot be selected as a wide, shallow survey field, since its ecliptic latitude is not high enough to generate a circular, or nearly rectangular, map.

The technical details of the blank-field surveys are as follows:

- **NEP-Deep 2–26 μm survey**: a deep (28 pointing observations per FOV) survey of approximately 0.5 deg² with three filters per each IRC channel, resulting in 504 pointing observations in total (a half is in Phase 1).
- **NEP-Wide 2–26 μm survey**: a wide but shallow (2 pointings per FOV) survey of approximately 6.2 deg² with three filters per each IRC channel. The survey region is a circular area surrounding the NEP-Deep field. In total 450 pointing observations are required.
- **SEP low-cirrus region survey**: at 50–180 μm: 15–20 deg² fan-shape area toward the very low cirrus (B(100) as low as 0.2 MJy sr⁻¹) region using the FIS slow-scan mode with a redundancy of at least two. In total, 270 pointing observations are required.

In the same target field of the above-mentioned imaging surveys, we are also investigating the technical feasibility of IRC’s unique slitless spectroscopic capability, in order to construct an unbiased sample of near to far-infrared SED templates for various kinds of galaxies at z < 1. This will be further described in a separate paper (Y. Ohyama et al. in preparation). Multiwavelength ground-based surveys are also ongoing, and optical images and catalogs will be published soon (T. Wada et al. in preparation).

We would like to thank all AKARI team members for their support in this project. We also thank Dr. David Hughes for discussion on possible collaboration between BLAST and AKARI, Dr. Takamitsu Miyaji for his effort on the X-ray observation plan, and Dr. Patrick Henry for information on the ROSAT clusters toward the NEP. This work is partly supported by the Japan Society for the Promotion of Science (JSPS) grant (grant number 15204013 and 16204013). CPP acknowledges support from JSPS while in Japan.
