Abstract—This paper considers particle propagation in a cylindrical molecular communication channel, e.g. a simplified model of a blood vessel. Emitted particles are influenced by diffusion, flow, and a vertical force induced e.g. by gravity or magnetism. The dynamics of the diffusion process are modeled by multi-dimensional transfer functions in a spatio-temporal frequency domain. Realistic boundary conditions are incorporated by the design of a feedback loop. The result is a discrete-time semi-analytical model for the particle concentration in the channel. The model is validated by comparison to particle-based simulations. These numerical experiments reveal that the particle concentration of the proposed semi-analytical model and the particle-based model are in excellent agreement. The analytical form of the proposed solution provides several benefits and the particle-based model are in excellent agreement. The model is validated by comparison to particle-based simulations. These numerical experiments reveal that the particle concentration of the proposed semi-analytical model and the particle-based model are in excellent agreement. The analytical form of the proposed solution provides several benefits and the particle-based model are in excellent agreement.

I. INTRODUCTION

The application of communication engineering principles to biotechnological problems has prompted a large interest and has motivated the investigation of the transport of molecules as carriers of information, see [1] for a review of recent literature.

The transport of molecules, or more generally particles, differs fundamentally from the propagation of electromagnetic waves and therefore requires new theoretical models for system design and analysis [1]. Though negligible at macro-scale, the transport by diffusion becomes relevant at nanoscale. However, diffusion can be slow and thus relying only on diffusion might be limited to small distances such as in intracellular communication. In fact, in biotechnology, active transport mechanisms induced by an external force, fluid flow, or a combination thereof are well established [2]. In particular, magnetic forces are attractive because the magnetization of biological particles is often negligible and special purpose magnetic nanoparticles can be engineered and tailored to an application by adapting their size and composition [3]. In this way, magnetic nanoparticles can be selectively detected and externally steered in a preferred direction by a magnetic field. Furthermore, magnetic nanoparticles can be made biocompatible by suitable coating to avoid reactions with undesired reactants and allow for specific binding to others [3].

Motivated by the concept of using magnetic nanoparticles for molecular communication proposed in [4], [5] and the practicality of studying blood vessels [6]–[8], here we consider particle transport subject to horizontal fluid flow, diffusion, and a vertical magnetic force in a cylinder model of a blood vessel. For simplicity, we assume a uniform axial flow, which is a typical model known as plug flow [9]. Although blood vessels may have a complicated shape, modeling them as cylinders is well-accepted [2]. To study the distribution of particles along a segment of the vessel wall, a line receiver model is considered.

When neglecting diffusion, the particle trajectory in a cylinder due to fluid flow and magnetic force can be accurately modeled even for more complicated flow patterns [10]. However, modeling diffusion, flow, and particle drift by magnetic force in a cylinder is analytically demanding due to the non-symmetry of the problem. Therefore, usually finite element numerical simulation is employed to study this type of system, e.g., in drug-targeting [11], [12]. However, numerical solutions lead to algorithms with typically long run-times and low flexibility due to changing channel parameters.

A different modeling technique is the application of functional transformations, which are based on the modal expansion of an initial boundary value problem [13], [14]. This technique has been already applied successfully, e.g. in the field of sound synthesis and circuit modeling, see [15], [16] for further references. This kind of modeling technique offers several benefits: It leads to semi-analytical models in terms of a state-space description which provide insights into the diffusion process. Furthermore, these models allow the adaptation of their boundary behavior using feedback techniques [15], [17].

This paper proposes a semi-analytical model for a diffusive cylindrical molecular communication channel in the presence of a magnetic force and flow. The model leads to a low run-time simulation algorithm, which provides several benefits compared to purely numerical models. The derivation of the model follows the mathematically more detailed description in [18], where particle diffusion under the influence of a magnetic force in a circular disk is simulated. Our results might be useful for studying molecular communication in, e.g. blood vessels, flow reactors or microfluidic channels. It is also applicable to the study of diffusion with horizontal slurry flow in tubes where particles sediment due to gravity [19], Chapter 13.

The paper is structured as follows: In Section II a physical description of the scenario under study is presented. In Section III a semi-analytical model for the diffusive cylindrical channel is derived and a simulation algorithm is proposed. The
variables in the system are normalized. Introducing a reference vessel. Information carrying nano particles are emitted into the validity of the model is shown in Section IV by simulation, the mapping $a$ terms of partial differential equations (PDEs) is established, the particle flux is denoted by vector $\mathbf{d}$, is mounted. As an example generalization, for probing the at a point on the vessel wall where a receiver nanomachine is obtained. For modeling the reception, the particle concentration is desired causing a constant uniform drift velocity $u$, see [4] for details. For modeling the reception, the particle concentration is desired at a point on the vessel wall where a receiver nanomachine is mounted. As an example generalization, for probing the dynamics of the particle concentration over an extended axial distance, a line receiver of length $d'$ is considered. The particle concentration over time in the receiver is denoted by $p'_{r,z}(x', y', t')$ (the $z'$-index indicates the position in $z'$-direction), the particle flux is denoted by vector $\mathbf{d}'$.

A. Normalization

Before the physical description of the scenario in Fig. 1 in terms of partial differential equations (PDEs) is established, the variables in the system are normalized. Introducing a reference time $\tau = \frac{r}{a'}$ and a reference length $\lambda = a'$ in terms of the radius $a'$ of the cylinder and the diffusion coefficient $D'$ leads to the following normalization

$$
(x,y,z) = \left(\frac{x'}{\lambda}, \frac{y'}{\lambda}, \frac{z'}{\lambda}\right), \quad \mathbf{i} = \mathbf{u'} \cdot \frac{\lambda^2 \tau}{\lambda}, \quad p = p' \cdot \frac{\lambda^3}{\lambda}, \quad a = a' \frac{\lambda}{\lambda},
$$

$$
D = D' \cdot \frac{r}{\lambda^2}, \quad v_z = v'_z \cdot \frac{\tau}{\lambda}, \quad u = u' \cdot \frac{\tau}{\lambda}, \quad t = t' \cdot \frac{\tau}{\tau}. \tag{2}
$$

In the following, concentrations and fluxes in the cylindrical geometry are formulated in polar coordinates, using the mapping $x = r \cos(\varphi)$ and $y = r \sin(\varphi)$, particularly $y_0 = r_0 \sin(\varphi_0)$. With this normalization and substitution a normalized dimensionless physical model is considered in the following sections.

B. Physical Model

Due to the geometry of the problem, the average concentration in a line receiver, $p_{r,z}$, following a point release, can be expressed as

$$
p_{r,z}(r, \varphi, t) = p_{xy}(r, \varphi, t) \cdot p_{d,z}(t). \tag{3}
$$

Here, $p_{d,z}$ is the accumulated concentration in the line segment for a one-dimensional drift-diffusion process in $z$-direction. It is obtained by integration [1, Eq. (23)]

$$
p_{d,z}(t) = \int_{z-\frac{d}{2}}^{z+\frac{d}{2}} \frac{1}{\sqrt{4\pi t}} \exp\left(-\frac{(\tilde{z}-v_z t)^2}{4t}\right) \, d\tilde{z}. \tag{4}
$$

Furthermore, $p_{xy}$ is the concentration of a diffusion process in a circular cross-section of a cylinder. Its calculation is the main task in the following sections. We note that a similar separation as in (3) also holds for the flux $i$.

The particle concentration $p_{xy}$ in the circular disk $\varphi \in [0, 2\pi)$, $r \in [0, a]$ under the influence of the vertical drift velocity $u$ is given by the following PDE

$$
\frac{\partial}{\partial t} p_{xy}(r, \varphi, t) = -\text{div} \, i_{xy}(r, \varphi, t) \quad r \leq a, t > 0 \tag{5a}
$$

$$
i_{xy}(r, \varphi, t) = -\text{grad} \, p_{xy}(r, \varphi, t) - e_y u p_{xy}(r, \varphi, t) \tag{5b}
$$

$$
i_r(r, \varphi, t) = \frac{1}{r} \delta(r-r_0) \delta(\varphi-\varphi_0) \quad t = 0, \tag{5c}
$$

$$
p_{xy}(r, \varphi, t) = \frac{1}{r_0} \delta(r-r_0) \delta(\varphi-\varphi_0) \quad t = 0, \tag{5d}
$$

with the unit vector in $y$-direction $e_y$, the delta impulse $\delta(\cdot)$ and gradient $\text{grad}$ and divergence $\text{div}$ in cylindrical coordinates. The emission of particles is described by the initial condition [5d] and the zero flux at $r = a$ by the boundary condition [5c].

C. Transformation of Variables

The presence of the drift term in [5b] highly scales the complexity of a direct solution of the system (5a), (5b). Therefore, the problem is transformed into an auxiliary problem with the auxiliary particle concentration $q_{xy}$ by application of the substitution $p_{xy}(r, \varphi, t) = q_{xy}(r, \varphi, t) \exp\left(-\frac{u}{2}(y-y_0) - \frac{v_z}{2} t\right)$, see also [20]

$$
\frac{\partial}{\partial t} q_{xy}(r, \varphi, t) = -\text{div} \, i_{xy}(r, \varphi, t) \quad r \leq a, t > 0 \tag{6a}
$$

$$
i_{xy}(r, \varphi, t) = -\text{grad} \, q_{xy}(r, \varphi, t) \tag{6b}
$$

$$
i_r(r, \varphi, t) = \frac{u}{2} \sin \varphi \cdot q_{xy}(r, \varphi, t) \quad r = a \tag{6c}
$$

$$
q_{xy}(r, \varphi, t) = \frac{1}{r_0} \delta(r-r_0) \delta(\varphi-\varphi_0) \quad t = 0. \tag{6d}
$$

The main task in the following sections is to derive a semi-analytical model for the auxiliary concentration $q_{xy}$ with the non-trivial boundary condition [6c]. In the end, this result is used to obtain a semi-analytical simulation model for the desired concentration [3] at the receiver.
D. Vector Formulation

Before the transfer function model for the considered diffusion process is constructed in Section III, the auxiliary PDE in (6a), (6b), the boundary conditions (6c), and the initial conditions (6d) are rearranged into a unified vector form according to \[15\]. The reformulation of the PDE in (6a), (6b), in terms of a matrix valued spatial differential operator \( L \) defined on the circular disk \( x = [r, \varphi] \) with \( r \in [0, a] \) and \( \varphi \in [-\pi, \pi] \) leads to

\[
\left[ \frac{\partial}{\partial t} C - L \right] y(x, t) = 0, \quad L = A + \nabla I, \tag{7}
\]

with a mass matrix \( C \), a matrix of damping parameters \( A \), and the identity matrix \( I \). The involved block matrices and operators are defined as

\[
A = \begin{bmatrix} 0 & -I \\ 0 & 0 \end{bmatrix}, \quad C = \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix}, \quad \nabla = \begin{bmatrix} -\text{grad} & 0 \\ 0 & -\text{div} \end{bmatrix}. \tag{8}
\]

Vector \( y \) contains the independent variables of the system: the auxiliary particle concentration and the flux in \( r- \) and \( \varphi- \) direction

\[
y(x, t) = \begin{bmatrix} q_{xy}(x, t) \\ i_{xy}(x, t) \end{bmatrix}^T,
\]

\[
i_{xy}(x, t) = [i_x(x, t) \ i_\varphi(x, t)]^T,
\]

where \((\cdot)^T\) denotes the transposed. According to the dimensions of \( i_{xy} \) and \( q_{xy} \) in (9), the matrices and vectors in (8) have sizes \( 3 \times 3 \) and \( 3 \times 1 \), respectively. The initial conditions for the auxiliary particle concentration \( q_{xy} \) in (6d) are rearranged similar to the vector of variables in (9)

\[
y_0(x) = \begin{bmatrix} q_{xy}(x, 0) \\ 0 \end{bmatrix}^T. \tag{10}
\]

In addition to the desired boundary behavior (6c), a second boundary condition is defined

\[
i_\varphi(a, \varphi, t) = \phi(\varphi, t), \tag{11}
\]

with a general boundary excitation \( \phi \). The second set of conditions (11) is used to design a general transfer function model for the diffusion process in Section III-A. The derived model serves as a blueprint for a diffusion process, where different kinds of boundary conditions can be incorporated. In Section III-B the desired boundary behavior (6c) is realized by a modification of the blueprint model.

E. Laplace Transformation

Applying the Laplace transform to the PDE in (7) and (10) leads to

\[
sC - L \mathbf{Y}(x, s) = \mathbf{C}y_0(x), \tag{12}
\]

where \( \mathbf{Y} \) is the frequency domain equivalent of the vector of variables \( y \) in (9). The complex frequency is denoted by \( s \). The frequency domain representation of the PDE in (12) and the boundary conditions (6c), (11) are the basis for the subsequent transformations.

III. SEMI-ANALYTICAL

In this section, a transfer function model for the circular diffusion process is derived. First, a model for the process described by the PDE in (12) with the second set of boundary conditions in (11) is established using a modal expansion of the spatial differential operator \( L \) into eigenfunctions \[13\], \[14\]. Then, this model is formulated as a state-space description and is forced to fulfill the boundary conditions in (6c) by the design of a feedback loop \[17\].

A. Transfer Function Model

To derive a transfer function for the given 2-D diffusion process (12), the spatial differential operator \( L \) is expanded into eigenfunctions \( \tilde{K} \) (see Section III-A3) based on the Sturm-Liouville theory \[14\].

1) Sturm-Liouville Transformation: For the transformation of space variables, a Sturm-Liouville transformation is defined in terms of the integral transform \[14\]

\[
T \{ \mathbf{Y}(x, s) \} = \tilde{Y}_n(\mu, s) = \int_0^a \int_0^{2\pi} \tilde{K}^n(x, \mu) \mathbf{C}Y(x, s) \, r \, dr \, d\varphi, \tag{13}
\]

with the eigenfunctions \( \tilde{K}_n \). The inverse transformation is a generalized Fourier series with the eigenfunctions \( K_n \) and the scaling factor \( \tilde{N}_{\mu,n} \)

\[
T^{-1} \{ \tilde{Y}_n(\mu, s) \} = \mathbf{Y}(x, s) = \sum_{n=-\infty}^{\infty} \sum_{\mu=0}^{\infty} \frac{1}{\tilde{N}_{\mu,n}} \tilde{Y}_n(\mu, s) K_n(x, \mu), \tag{14}
\]

where \( \tilde{Y}_n(\mu, s) \) is a scalar representation of the vector of variables in (9) in the temporal and spatial transform domain. Index \( \mu \in \mathbb{Z} \) is the index of a spatial frequency variable \( s_{\mu,n} \) for which (7) has nontrivial solutions \[14\], \[15\].

Both sets of eigenfunctions \( K_n \) and \( \tilde{K}_n \) are determined from problem-specific eigenvalue problems \[15\]. The index \( n \in \mathbb{Z} \) is here already introduced because of the Bessel-nature of the eigenfunctions, cf. Section III-A3.

2) Transform Domain Representation: Applying the forward transform (13) to the PDE (12) and exploiting the properties of the eigenfunctions (see \[14\], \[15\]) leads to

\[
s\tilde{Y}_n(\mu, s) - s_{\mu,n} \tilde{Y}_n(\mu, s) = \bar{y}_n(\mu) + \Phi_n(\mu, s), \tag{15}
\]

with the transform domain representation of the initial conditions \( \bar{y}_n(\mu) \) from (10) and the transformed boundary term \( \Phi_n(\mu, s) \) given by

\[
\bar{y}_n(\mu) = \int_0^{2\pi} \int_0^a J_n(k_{\mu,n}r) e^{-jn\varphi} q_{xy}(x, 0) \, r \, dr \, d\varphi, \tag{16}
\]

\[
\Phi_n(\mu, s) = -\int_0^{2\pi} a J_n(k_{\mu,n}\alpha) e^{-jn\varphi} \Phi(\varphi, s) \, d\varphi, \tag{17}
\]

with the \( n \)-th order Bessel functions of the first kind \( J_n \) and \( \Phi \) is the frequency domain equivalent of the boundary excitation \( \phi \) in (11). The values \( s_{\mu,n} = -k_{\mu,n}^2 \) represent the spatial eigenfrequencies of the diffusion process. Solving (15) for the
transformed vector of variables leads to a representation in terms of a multidimensional transfer function
\[ Y_n(\mu, s) = \frac{1}{s - s_{\mu, n}} \left( \tilde{y}_n(\mu) + \Phi_n(\mu, s) \right), \quad \Re(s_{\mu, n}) < 0. \] (18)

3) Eigenfunctions and Eigenfrequencies: The eigenfunctions for the forward and inverse transformation are derived by solving a dedicated eigenvalue problem \([14]\). Its derivation is skipped here for brevity but it is described for similar problems in \([15, 21]\). The eigenfunctions in \([13, 14]\) are obtained as
\[
K_n(x, \mu) = \begin{bmatrix}
J_n(k_{\mu,n}r) \\
-J_{\mu,n}J_n(k_{\mu,n}r) \\
-\frac{1}{2}(jn)J_n(k_{\mu,n}r)
\end{bmatrix} e^{jn\varphi},
\]
\[
\tilde{K}_n(x, \mu) = \begin{bmatrix}
J_n(k_{\mu,n}r) \\
J_{\mu,n}J_n(k_{\mu,n}r) \\
J_n(k_{\mu,n}r)
\end{bmatrix} e^{jn\varphi},
\] (19)
where \(J'(x) = \partial/\partial x J(x)\). The eigenfrequencies \(s_{\mu, n}\) of the diffusion process are calculated by the evaluation of boundary conditions similar to \([11]\), i.e., from the real-valued zeros of \(J_n'(k_{\mu,n}a) = 0\).

Due to the bi-orthogonality of the eigenfunctions, the scaling factor \(N_{\mu, n}\) is calculated by evaluation of the integral \([14]\)
\[
N_{\mu, n} = \int_0^{2\pi} \int_0^a \tilde{K}_n^T(x, \mu) C K_n(x, \mu) r \, dr \, d\varphi.
\] (20)

4) State-Space Description: Grouping all elements of the matrices and vectors in \([15]\) in the range of \(n, \mu\) into vectors gives a state equation in the continuous frequency domain
\[
sY(s) = AY(s) + \hat{y}_i + \hat{\Phi}(s),
\] (21)
with the matrices and vectors
\[
Y(s) = \left[ \ldots, Y_n(\mu, s), \ldots \right]^T, \quad \hat{y}_i = \left[ \ldots, \hat{y}_n(\mu), \ldots \right]^T,
\]
\[
\Phi(s) = \left[ \ldots, \Phi_n(\mu, s), \ldots \right]^T, \quad A = \text{diag} \left( \ldots, s_{\mu,n}, \ldots \right).
\] (22, 23)
The diagonal matrix \(A\) contains the eigenvalues \(s_{\mu,n}\) of the system on its main diagonal. The reformulation of the inverse transformation in \([14]\) leads to an output equation for the state-space description,
\[
Y(x, s) = C(x) Y(s),
\] (24)
where
\[
C(x) = \begin{bmatrix}
C_1^T(x) \\
\vdots \\
C_N^T(x)
\end{bmatrix} = \begin{bmatrix}
K_1(x, \mu) \\
\vdots \\
K_N(x, \mu)
\end{bmatrix}.
\] (25)
Here, \(K_{m,n}\) is the \(m\)-th element of eigenfunction \(K_n\) in \([19]\). The complete state-space description based on state equation \([21]\) and output equation \([24]\) is shown in Fig. 2 (switch open). The matrices and vectors in \([21, 24]\) are theoretically of infinite size (see range of \(n, \mu\) in \([14]\)), and therefore they have to be interpreted in an operator sense. For numerical evaluation, the sums in \([14]\) have to be truncated so that the matrices become finite and computable.

This state-space model was obtained for the boundary conditions in \([11]\) and includes the yet undetermined general boundary term \(\Phi(s)\). Setting this term to zero corresponds to the scenario of particle diffusion in a cylinder with zero flux at the boundary \([22]\) p. 378\). In the next section, the boundary terms are used to realize the desired boundary behavior \([6c]\).

B. Feedback Loop

In this section, a feedback loop is designed to adjust the boundary behavior of the state-space model from Section III-A to \([14]\) so that it fulfills the boundary conditions in \([6c]\) \([15, 17, 23]\).

1) Feedback Matrix: The state-space model in \([21, 24]\) is designed with the general boundary term \(\Phi_n(\mu, s)\). Now, the excitations \(\phi\) are replaced by the desired ones \(\hat{\phi}\). The goal is an expression for \(\Phi_n(\mu, s)\) in terms of the state vector \(Y(s)\) of the state-space description. A feedback matrix for the system is constructed according to the concepts described in \([15]\). The starting point is the general transformed boundary term \([17]\). Inserting the desired boundary conditions \([6c]\) into the general term \(\Phi(\mu, s)\) in \([11]\) (in the frequency domain) leads to
\[
I_r(a, \varphi, s) = \Phi(\varphi, s) = \frac{u}{2} \sin \varphi \cdot Y_1(a, \varphi, s).
\] (26)

This representation is inserted into the transformed boundary term \([17]\). Exploiting the output equation \([24, 26]\) leads to
\[
\Phi_n(\mu, s) = -a J_n(k_{\mu,n}a) \int_0^{2\pi} e^{-jn\varphi} \frac{u}{2} \sin \varphi c_n^*(a, \varphi) Y(s) d\varphi.
\] (27)
The integration over \(\varphi\) and considering \([25, 19, 14]\) leads to
\[
\Phi_n(\mu, s) = -\hat{b}_n(\mu) \frac{u}{2} \sum_{m=\infty}^{\infty} \sum_{n=0}^{\infty} J_m(k_{\mu,n}a) f(m, n) Y_m(\mu, s),
\] (28)
with the coefficients \(\hat{b}_n(\mu) = a J_n(k_{\mu,n}a)\) and a function \(f\) defined in terms of Kronecker delta functions and the imaginary unit \(j\)
\[
f(m, n) = \pi j \left( \delta_{m,n-1} - \delta_{m,n+1} \right).
\] (29)

Sorting the sums in \([28]\) into vectors leads to an expression for the transformed boundary term realizing the realistic boundary conditions in terms of the state vector
\[
\Phi(s) = -BK Y(s),
\] (30)
with the feedback matrix \(BK\)
\[
BK = \begin{bmatrix}
\hat{b}_n k_n^T \\
\vdots \\
\hat{b}_n k_n^T
\end{bmatrix}, \quad \hat{b}_n = \begin{bmatrix}
\hat{b}_n(\mu) \\
\vdots \\
\hat{b}_n(\mu)
\end{bmatrix}, \quad K_n = \begin{bmatrix}
k_n^T \\
\vdots \\
k_n^T
\end{bmatrix}.
\] (31)
The system shown in Fig. 2 with open switch realizes the A
The modification of the state matrix (6c) (switch closed) according to (30), (33).

(6a), (6b) in the frequency domain with a generalized boundary term C. Simulation Algorithm
the auxiliary concentration into variables (9), the modified state-space description has to be transformed into the discrete-time domain.

Applying an inverse Laplace transform to state equation (33) with the sampling interval T affects only step 9. Also, to incorporate time-varying u, the algorithm is constructed in step 5. With that matrix, the modified state matrix \( \mathbf{A}_c \) is computed in step 6. In step 7, the auxiliary concentration \( q_{xy} \) is computed with \( 25 \), \( 26 \) with a \( for\)-loop over time. Finally, the auxiliary concentration is transformed into the receiver concentration \( p_{r,z} \) in steps 8,9.

The algorithm assumes fixed parameters (\( u, v_z, \) etc.), but variable parameters can be easily incorporated and not all steps have to be repeated. Changing e.g. the velocity \( u \), the algorithm stays the same for steps 1-3, a change of the horizontal flow \( v_z \) affects only step 9. Also, to incorporate time-varying parameters, e.g. for a time-varying velocity \( u \), steps 5,6 have to be moved inside the \( for\)-loop in step 7. This can affect the runtime of the algorithm.

IV. Verification and Analysis
In this section, simulation results for the semi-analytical model described in Section III are presented. The model outcome is compared to particle-based simulations [1]. Furthermore, the proposed semi-analytical model is analyzed in view of runtime and accuracy. Also, the benefits of a semi-analytical model over purely numerical models are discussed.

### Table I

| Algorithm step | Equations |
|----------------|-----------|
| 1. Choose index range \( N, M \) | \[ (25), (26) \] |
| 2. Compute \( M \) zeros of \( J_n(L, \mu, \nu) = 0 \) | \[ (35), (36) \] |
| 3. Compute state and output matrices \( \mathbf{A}, \mathbf{C} \) | \[ (29), (31), (32) \] |
| 4. Choose desired boundary behavior | \[ (6c) \] |
| 5. Compute feedback matrix \( \mathbf{BK} \) | \[ (30), (31) \] |
| 6. Compute modified state matrix \( \mathbf{A}_c \) | \[ (33) \] |
| 7. for \( k = 1 : \text{simulationDuration} \) | compute auxiliary concentration \( q_{xy} \) \[ (35), (36) \] |
| 8. Transformation of variables \( q_{xy} \rightarrow p_{xy} \) | \[ (37) \] |
| 9. Compute receiver concentration \( p_{r,z} \rightarrow p_{r,z} \) | \[ (38) \] |

Third, the concentration in the cylindrical slice has to be recombined with the discrete-time equivalent of the concentration in a line segment [4] to obtain a solution for the complete cylinder

\[ p_{r,z}(x, k) = p_{r,y}(x, k) \cdot p_{r,z}(x, k), \]  \[ (38) \]  

where the concentration \( p_{xy}(x, k) \) can be calculated at any point of the system geometry by evaluation of \( 25 \), \( 26 \), \( 27 \).
Concentration

\( p(x, t) = \sum_{\mu=1}^{M} Q_{\mu} e^{-Q_{\mu}^2 t} \phi_{x}(r, \theta) \)

Bi. Particle-Based Verification

In the particle-based method, the injection of particles into the system is performed at time \( t \), where the number of terms, \( Q \), is fixed to \( N = 20 \) and the range of \( \mu \) is varied as \( M = 70, 20, 10, 5 \). The circle markers represent the channel boundary, which is reflected back into the channel. For measuring the concentration along the receiver, we consider a normalized cuboid of size \( 0.05 \times 0.05 \times 10 \) approximating the line receiver in Fig. 1. An estimate of the accumulated concentration is obtained by counting the number of observed particles within the cuboid and dividing by the surface area \((0.05)^2\) and the number of released particles \( N_{\text{TX}} \). For \( N_{\text{TX}} = 10^3 \), results are averaged 100 times.

The concentration along the receiver is then simulated with the proposed model (38) at the bottom of the cylinder. The left plot shows the blue line in Fig. 3 and represents the channel boundary, which is reflected back into the channel. The right plot in Fig. 4 shows the receiver concentration at \( t = 75 \) s. The results in Fig. 4 reveal a trade-off between runtime and accuracy. This shows the flexibility of the proposed model: If the exact concentrations are needed, the number of terms, \( Q \), can be chosen large at the cost of runtime. On the other hand, to study the rough behavior of a channel for different parameter sets, the number of terms can be reduced to run many simulations in a short time. The plot on the right-hand side of Fig. 4 shows that the accuracy also depends on the velocity \( u \) and, for a given \( Q \), decreases for increasing \( u \).

C. Algorithm Analysis

The runtime \( t_Q \) of the algorithm is \( t_{2870} = 125 \) s for simulating a normalized duration of \( t_{\text{dur}} = 0.5 \) starting at \( t = 0 \). For \( Q = 820 \) the semi-analytical model still agrees very well with the results of the particle-based model. The runtime decreases to \( t_{2870} = 4.5 \) s. A further reduction of the number of terms leads to visible deviations, but the runtime drops to \( t_{210} = 0.9 \) s, \( t_{210} = 0.5 \) s. For comparison, the runtime of the particle-based simulation is approx. \( t_p \approx 30 \) min to simulate a normalized duration \( t_{\text{dur}} = 0.5 \). The results in Fig. 4 reveal a trade-off between runtime and accuracy. This shows the flexibility of the proposed model: If the exact concentrations are needed, the number of terms, \( Q \), can be chosen large at the cost of runtime. On the other hand, to study the rough behavior of a channel for different parameter sets, the number of terms can be reduced to run many simulations in a short time. The plot on the right-hand side of Fig. 4 shows that the accuracy also depends on the velocity \( u \) and, for a given \( Q \), decreases for increasing \( u \).

D. Benefits of the Semi-Analytical Model

The proposed semi-analytical state-space model (see Section III) offers many advantages over purely numerical models. In particular, the semi-analytical description of the diffusion process allows to compute the channel impulse response in an analytical manner. Hence, solutions in the form of (35) can be related to parameters relevant for communication system design (e.g. inter-symbol interference) more directly than solutions for purely numerical models. Additionally, the complexity of the model can be reduced by using a semi-analytical approach.
simulation algorithm is flexible (varying \(M, N\)), and can be adjusted to the simulation purpose (see Section IV-C). Knowing the eigenvalues \(s_{p,n}\) of the diffusion process provides insight into the behavior, e.g. damping or asymptotic behavior. As the output variable \(y\) in (35) also contains the fluxes \(i\), they can be obtained without any additional effort.

The formulation of the solution in terms of a space-state representation in Section III-A with the general boundary term \(\Phi(s)\) can be extended to different kinds of boundary conditions. In this paper, the techniques from Section III-B are used to realize the boundary conditions (55). By the same technique also other types of boundary behavior can be realized, e.g. semi-permeable membranes or non-reflective cell walls [15]. The incorporation of different boundary conditions can be seen as an extension of the general space-state description, so the computation of the general model (Steps 1-3 in Table I) remains the same. This allows the simulation of complex diffusive systems/channels in a semi-analytical manner by separating the general model from the desired boundary behavior.

Also, the interconnection of several semi-analytical models for larger biochemical structures is possible by the techniques shown in Section III-B [23]. E.g. several cylindrical models can be used to model a cascade of blood vessels, or several spherical models can realize complex interacting cell structures.

V. CONCLUSION AND FUTURE WORK

In this paper, we presented a semi-analytical model for the diffusion of particles influenced by a vertical force and horizontal uniform drift in a cylindrical shape modeling e.g. the transport of information carrying magnetic nano-particles within a blood vessel under the influence of a magnetic field. The semi-analytical model is based on a modal expansion of spatial differential operators, and is useful e.g., for studying the signal strength of the channel impulse response. After the design of a general model for the diffusion process, the boundary behavior of the system is adjusted by a feedback loop. The validity of the model is verified by comparisons to particle-based simulation results. An analysis of the algorithm reveals several benefits (e.g. in runtime and flexibility) compared to purely numerical models.

Future work might investigate extensions to non-uniform laminar flow, more complex receiver models, and different geometries. Based on the time-variant source signals in [21], the excitation of the model by realistic time- and space-variant source signals will be considered.
