ABSTRACT
The Oxford Dartmouth Thirty Degree Survey (ODTS) is a deep, wide, multi-band imaging survey designed to cover a total of 30 square degrees in $BV Ri'Z$, with a subset of $U$ and $K$ band data, in four separate fields of 5-10 deg$^2$ centred at 00:18:24 +34:52, 09:09:45 +40:50, 13:40:00 +02:30 and 16:39:30 +45:24. Observations have been made using the Wide Field Camera on the 2.5-m Isaac Newton Telescope in La Palma to average limiting depths ($5\sigma$ Vega, aperture magnitudes) of $U=24.8$, $B=25.6$, $V=25.0$, $R=24.6$, and $i'=23.5$, with observations taken in ideal conditions reaching the target depths of $U=25.3$, $B=26.2$, $V=25.7$, $R=25.4$, and $i'=24.6$. The INT $Z$ band data was found to be severely effected by fringing and, consequently, is now being obtained at the MDM observatory in Arizona. A complementary $K$-band survey has also been carried out at MDM, reaching an average depth of $K_{5\sigma} \approx 18.5$. At present, approximately 23 deg$^2$ of the ODTS have been observed, with 3.5 deg$^2$ of the K band survey completed. This paper details the survey goals, field selection, observation strategy and data reduction procedure, focusing on the photometric calibration and catalogue construction. Preliminary photometric redshifts have been obtained for a subsample of the objects with $R \leq 23$. These results are presented alongside a brief description of the photometric redshift determination technique used. The median redshift of the survey is estimated to be $z \approx 0.7$ from a combination of the ODTS photometric redshifts and comparison with the redshift distributions of other surveys. Finally, galaxy number counts for the ODTS are presented which are found to be in excellent agreement with previous studies.

Key words: cosmology: surveys - catalogues - galaxies: general - cosmology: observations - large-scale structure of the Universe.

1 INTRODUCTION
Understanding the origin and evolution of galaxies and large scale structure within the Universe remains one of the most challenging areas in modern cosmology. With the completion of 2 Degree Field Galaxy Redshift Survey (2dFGRS, Colless 2001) and the imminent conclusion of the Sloan Digital Sky Survey (SDSS, Stoughton, Lupton & Bernardi 2002), we are witnessing the emergence of an accurate and detailed model of structure in the nearby Universe. However, to gain insight into the evolution of the Universe out to higher redshifts requires the advent of deep surveys, with substantial areal coverage to ensure large number statistics and avoid cosmic variance. A number of such surveys have been initiated in recent years, each with individual goals but all hoping to shed light on the structure and formation of the high redshift Universe. For example, the ESO Imaging Survey (EIS, Nonino 1999) is a 24 deg$^2$ moderately deep 1 band survey ($\mu_{AB} \approx 23.7$) with additional limited coverage in B, V and the infrared. A sub-area of the EIS
(0.25 deg$^2$) is covered in UBVRI to $I_{5000 AB} \approx 24.7$ forming the EIS-Deep survey (Arnouts 2001). The Canada-France Deep Fields Survey (CFDF, McCracken et al. 2001), consists of 4 deep fields totalling 1 deg$^2$, all covered in V and I ($I_{5000 AB} \approx 25.5$), with additional U and B coverage. Also ongoing are the Combo-17 survey (Wolf et al. 2003), where fields totalling 0.25 deg$^2$ have been observed through 17 medium-band filters to a limiting magnitude of $R_{5000 AB} = 26.2$, and the NOAO Deep Field Survey (NDWFS, Jannuzi et al. 2002) which will cover 24 deg$^2$ in BRIJH and K to $R_{5000 AB} = 26$. Here we describe the Oxford-Dartmouth Thirty Degree Survey (ODTS) which aims to provide multi band observations, to allow for the determination of photometric redshifts, to depths comparable with the deepest wide field surveys to date and over a wider area. The Wide Field Camera (WFC) on the Isaac Newton Telescope (INT) on La Palma has been used to observe 23 deg$^2$ (out of the total 30 deg$^2$) of $BVR$ ($R_{5000 AB} \approx 25.6$ assuming 1'' seeing) and $i'$ imaging, with a subset of $U$ band data. The $Z$ band data, although initially planned for observation at the INT, are now currently being acquired using the 2.4m Hiltner Telescope at the MDM observatory, Kitt Peak (see section 3.1). Also, a K-Band survey, designed to run in parallel with and be complementary to the optical ODTS, is currently being carried out using the 1.3m McGraw-Hill Telescope at MDM, to a depth of K$\approx$18.5 (Olding 2002). In addition, deep radio data have been obtained from the VLA, covering a total of 2 square degrees of the ODTS to a 5σ flux density limit of 100 micro-Jy at 1.4GHz with a resolution of 1.5'', and with deeper 1.4 GHz data and lower frequency (e.g. 74MHz and 330MHz) radio data over some fraction of the area. Part of the ODTS data also overlaps with the Texas-Oxford One Thousand (TOOT) redshift survey of radio sources (Hill & Rawlings 2003), allowing us to obtain spectroscopic redshift measurements for a number of sources in the ODTS.

The ODTS was initially designed with the following goals:

1. **Clustering of Bright Lyman Break Galaxies (LBGs)** (Allen et al, submitted): Lyman Break Galaxies exhibit a break in their spectra short wards of the Lyman limit, 912Å in the rest frame. For LBGs at high redshift, z=3 and 4, this results in a $U$ and $B$ band drop out thus permitting the detection of Lyman Break candidates using the ODTS multi band data. Due to the extent of the ODTS, the clustering of LBGs can be studied over a much larger area than previously available, thus minimising the effects of cosmic variance.

2. **Clustering Properties of Faint Galaxies** (MacDonald et al, in prep.): Previous surveys have lacked the combination of both depth and width required to explore the large scale clustering and evolution of faint galaxies as a function of magnitude, colour and redshift. The size of the ODTS potentially allows the measurement of the angular correlation function up to degree scales.

3. **Clustering of Extremely Red Objects (EROs)** (Olding 2002): Matching the ODTS $R$ band data with the MDM K-band data will allow for the selection of a large number of EROs, the criteria being an $R - K > 5$, over a relatively large area. The ODTS can be used to estimate their space density and photometric redshifts will allow for clustering and evolution to be analysed.

4. **Detection of High Redshift ($x > 5$) Quasars**: Extremely high redshift QSOs are rare but known to exist, as confirmed by the SDSS (Anderson 2001). Uncertainties still surround issues such as the shape of their luminosity function at the faint end and their evolution at high redshift. Colour selection methods, via the $(V-i)$ vs $(i-Z)$ colour-colour relation, will allow for the selection of faint QSO’s at $z > 5$.

5. **High Redshift Galaxy Clusters**: Combining information about

---

**Figure 1.** The system response, determined from the filter transmission curves and the CCD response, for the full set of ODTS filters ($UBVRI'Z$).

The cluster colour-magnitude relation (Gladders & Yee 2000) with photometric redshifts and a search for spatial over-densities, clusters with $0.2 < z < 1.2$ can be selected from the ODTS. The aim is to use this sample to investigate the cluster colour-magnitude relation as a function of redshift and cluster mass (Hammell et al, in prep.).

This paper summarises the ODTS and presents a full description and characterisation of the survey data, structured as follows. Section 2 discusses the survey design, specifically the criteria adopted for the field selection, the filter set used, and the observation strategy. Section 3 outlines the basic data reduction process. Section 4 describes the photometry and source extraction, and section 5 outlines the astrometry. Section 6 details the photometric calibration for each band and section 7 outlines the algorithm used to generate the final matched catalogue. In section 8 a brief summary of the photometric redshift determination is given and in section 9 galaxy number counts are presented and compared with previous studies. Finally, a summary is given in Section 10.

---

### 2 THE OXFORD-DARTMOUTH THIRTY DEGREE SURVEY DESIGN

The ODTS was initiated in August 1998, and was designed to make use of the Wide Field Camera located at the prime focus of the 2.5m Isaac Newton Telescope on La Palma. It is a deep-wide survey facilitating 6 filters per field; namely RGO $U$, Kitt Peak $R$, Harris V, Harris or Sloan $R$, Sloan $i'$ and RGO $Z$, the system response for which are provided in Figure 1. Six filters were selected to allow for the determination of photometric redshifts for objects in the survey. In particular, the Kitt Peak $R$ and Sloan-Gunn $i'$ filters were adopted, as opposed to their Johnson-Cousins counterparts, because they have higher throughput and simpler, more box-like transmission curves which are better for photometric redshift determination and allow for cleaner colour-colour selection of objects with sensitive spectral features, such as LBGs. In addition the $i'$ filter is less susceptible to fringing caused by sky emission lines (see section 3.1). Initially the Sloan-Gunn $i'$ filter was not available at the INT, so observations were made using the Harris $R$ filter which...
has a long red tail, and so suffers from noticeable fringing. However, the $i'$ filter became available at the beginning of the Virgo field (see table 1) observations and, consequently, was adopted for this field only. Initially, the ODTs was designed to cover $\sim 30$ deg$^2$ to estimated depths (2'' aperture Vega magnitudes) of $B = 26.2$, $V = 25.7$, $R = 25.4$ and $i' = 24.6$ and $Z = 22.0$, assuming a 5σ detection threshold and the median INT seeing of 1", with an additional sub area of $\approx 5$ deg$^2$ in $U(\approx 25.3)$ assuming ideal (seeing $< 0.7''$) conditions. The initial Vega and AB magnitude limits for the survey are given in table 2.

### 2.1 Field Selection

Initially the Andromeda, Hercules and Lynx fields were chosen from a number of potential fields primarily for their observability during the first few allocated INT runs; their centres are shown in table 1. The Virgo field was added at a later date to optimise year round observability and provide a field visible from the Southern hemisphere. In addition, the selected fields had to have low extinction, overlap with existing (multi-wavelength) datasets and have a lack of bright stars, nearby galaxies and bright, large clusters. The mean extinction, $E(B - V)$, in each field was determined from the DIRBE corrected IRAS 100 µm maps of Schlegel, Finkbeiner & Davis (1998) and was found to be $< 0.06$ in Andromeda and $< 0.02$ in the remaining fields. The large (4') pixel scale of the IRAS maps provides little information about the small scale distribution of the Galactic dust, and therefore making extinction corrections using 4' cells, as opposed to individual galaxy corrections, could imprint a low level spurious clustering pattern. This potential bias combined with the low galactic extinction values meant no extinction corrections for galactic dust were applied.

| Field     | $\alpha$(J2000) | $\delta$(J2000) | $l$ | $b$ |
|-----------|----------------|----------------|-----|-----|
| Andromeda | 00 18 24       | +34 52 00      | 115 | -27 |
| Lynx      | 09 09 45       | +40 50 00      | 181 | +42 |
| Hercules  | 16 39 30       | +45 24 00      | 70  | +41 |
| Virgo     | 13 40 00       | +02 30 00      | 330 | +62 |

| Filter | Exposure Time | 5σ Limiting depths using 2'' Aperture AB Magnitudes | Vega Magnitudes |
|--------|----------------|---------------------------------------------------|-----------------|
| $U$    | 6 x 1200s      | 26.1                                               | 25.3            |
| $B$    | 3 x 900s       | 26.1                                               | 26.2            |
| $V$    | 3 x 1000s      | 25.7                                               | 25.7            |
| $R$    | 3 x 1200s      | 25.6                                               | 25.4            |
| $i'$   | 3 x 1100s      | 25.0                                               | 24.6            |
| $Z$    | 1 x 600s       | 22.4                                               | 21.9            |

Table 2. The exposure times and expected detection limits (5σ aperture Vega and AB magnitudes) for the various pass bands used for the ODTs. With the exception of the $U$ and $Z$ images, each pointing is segregated into three separate exposures with 5'' offsets of the telescope.

2.2 Observations

Observations were made over 63 nights between August 1998 and March 2003, during which time several nights were lost due in part to instrument problems, but mostly due to bad weather conditions. The data were obtained using the WFC which is a mosaic of four 4096 x 2048 pixel CCD chips, each chip covering of $22.8'' \times 11.4''$ ($\approx 0.29$ degt$^2$ per WFC pointing) with a pixel scale of 0.33'' per pixel. At the beginning and end of each night bias, dark and twilight flat-field frames were acquired. Landolt standard star frames were also observed several times throughout each night (see section 4.1). On the whole, data were taken when conditions were either photometric or light cirrus was present, with variable seeing across the fields. Assuming the median INT seeing of 1", the 5σ detections shown in table 2 implied a total of 3.7 hours per pointing were required to obtain the multi band data ($BV Ri'$), resulting in a survey speed of $\sim 1.2$ degt$^2$ per night (not including the $U$ data). The median seeing values actually obtained for each field in each band are presented in table 3 alongside the median depth reached in each band in each field. There are no values for the $Z$ band data at present because the fringing proved too severe (see section 3.1). Figure 2 illustrates how the $R$ band depths vary across the Andromeda field (fully reduced data only) and figure 3 shows the corresponding cumulative distribution of fraction of total area versus depth in $R$.

In order to cover each of the ODTs fields efficiently with the WFC focal plane geometry, a tiling pattern involving using the camera in two rotational positions, $180^\circ$ apart, was employed. The fields were covered by a diagonal grid, with the rotation alternating with each row. Each grid element, representing one pointing of the INT WFC, was assigned a unique ODTs identification number. Figure 4 illustrates how the $R$ band depths vary across the Andromeda field (fully reduced data only) and figure 3 shows the corresponding cumulative distribution of fraction of total area versus depth in $R$.

| Filter | Andromeda Seeing / Depth | Lynx Seeing / Depth | Hercules Seeing / Depth |
|--------|--------------------------|---------------------|-------------------------|
| $U$    | 1.00/24.8                | n/a                 | n/a                     |
| $B$    | 1.31/25.3                | 1.46/25.61          | 1.24/25.8               |
| $V$    | 1.24/24.8                | 1.23/25.2           | 1.66/24.9               |
| $R$    | 1.13/24.3                | 1.36/24.7           | 1.32/24.7               |
| $i'$   | 1.10/23.4                | 1.55/23.7           | 1.64/23.5               |

Table 3. Median seeing and median depths reached (Vega magnitudes) for the reduced field data, where the depth of each frame has been determined from the turn over in number counts.

| Field | Area in Square Degrees - Observed/Reduced |
|-------|------------------------------------------|
| $U$   | 3.77/0.16/1.16, 6.96/2.31                |
| $B$   | 4.06/1.33, 7.83/1.77                     |
| $V$   | 4.06/1.75, 7.83/1.78                     |
| $R$   | 4.06/1.50, 7.83/1.79                     |
| $i'$  | 3.77/0.16/1.16                          |

Table 4. Current areas of observed and reduced multi-band ($UBV Ri'$) data for the 4 ODTs fields.
Figure 2. A grey-scale image of the reduced $R$ band Andromeda data (totalling 2.78 square degrees), demonstrating how the depths reached vary across the field. Frame depths vary from 24.3 to 25.2 magnitudes where the lighter the shade, the greater the depth. Variable conditions and individual chip response differences lead to slight changes of depth within each pointing as expected. It should be noted that there are small gaps ($\approx 1'$) present between the WFC chips.

Figure 3. The cumulative distribution of the fraction of area (totalling 2.78 square degrees) versus $R$ depth reached for the reduced Andromeda data. Frame depths vary from 24.3 to 25.2.

Observations for the optical (INT) portion of the ODTS were completed in March 2003 with approximately 23 deg$^2$ of the survey observed in $BVRi'$, although the data reduction is still ongoing. The $U$ data, taken in the best observing conditions, currently cover $\sim 1$ deg$^2$ in the Andromeda field. The total coverage of the fully reduced data is summarised in table 4.

3 DATA REDUCTION

3.1 Preprocessing

Standard IRAF$^1$ data reduction routines were implemented to remove the instrumental signature. Bias subtraction was made using the chip over-scan regions and master bias frames. The dark current was found to be negligible. Small non-linearities were known to exist in the WFC chips, the corrections for which were determined by the Cambridge Astronomical Survey Unit$^2$ and were applied appropriate to the time of observation.

Corrections for variations in the pixel to pixel sensitivity and vignetting caused within the optics were made by dividing frames

---

$^1$ IRAF is distributed by the NOAO, which is operated by the Association of Universities for Research in Astronomy, Inc. under cooperative agreement with the National Science Foundation.

$^2$ The values of the linearity corrections used, along with other information about the INT WFC, are available on the CASU website - http://www.ast.cam.ac.uk/~wfcsur/index.php.
The Oxford-Dartmouth Thirty Degree Survey I: Observations and Calibration

Figure 4. The (a) 0h Andromeda, (b) 9h Lynx, (c) 16h Hercules and (d) 13h Virgo fields divided into diagonal grids, where each numbered grid element represents one WFC pointing. The 4 individual chips of the WFC can be seen and in the bottom left corner of diagram (c) two of the WFC pointings are outlined in black for clarity, and the chip numbers have been marked. Coloured coded bars illustrate the coverage of each sub-field to date.

by the appropriate master flat field, created by median combining the object frames, or the twilight flat frames in the case of those bands subject to fringing. On comparison of the $B$ and $V$ band twilight flats with the deep sky flats obtained from the $B$ and $V$ object frames, it was found that no illumination correction was necessary.

The $R$, $i'$ and $Z$ band images were found to suffer from fringing caused by the multiple reflection and interference of the night-sky emission lines within the CCD. Unfortunately de-fringing is far from trivial as the relative intensities of the emission lines are dependent on the atmospheric conditions, thus fringing is a time varying effect. To de-fringe the data the bias corrected, flat-fielded $R$, $i'$ and $Z$ target frames from each night were median combined. This resulted in master fringe frames for each band, containing the residual sky fringe pattern. For each image, the master fringe frame was subtracted, scaling the fringe level of the master fringe frame to that of the fringing in the images. This effectively removes the dominant zeroth order fringing component, an example of which can be seen in figure 5.

For the WFC images, fringing effects were found to be $\sim 0.5\%$ of the sky level for the $R$ band, $\sim 3\%$ for $i'$ and $\sim 6\%$.
4 PHOTOMETRY

Initially, photometric zeropoints were estimated for each frame in every band for each observing run using the standard star data acquired (see section 4.1). Using these zeropoints, SExtractor (Bertin & Arnouts 1996) was then used to perform the photometry. After source catalogues had been created for each image (see section 4.2), accurate photometric zeropoints were determined across the V band by comparing objects in overlap regions (see section 6.1), and adjusting their zeropoints relative to a chosen calibrator chip. Finally, the other bands were adjusted relative to the V band data by comparing the colours of the stars in the ODTS images with those obtained using the Pickles (1998) library of stellar spectra, and applying zeropoint corrections needed to match these data sets (see section 6.2).

4.1 Initial Photometric Calibration using Standard Stars

Extracting source counts from the data at this stage will result in a measure of the instrumental magnitude which must be converted to the apparent magnitude. In order to perform this flux calibration, short exposures of various fields containing several standard stars, calibrated by Landolt (1992), were observed through the same filters as that night’s target fields. Landolt fields SA92, SA95, SA101 and SA104 covered the ODTS fields well, with several standard stars falling in each frame. For each observing run, at least two of these standard fields were observed and were chosen to span a large airmass range, enabling us to monitor photometric quality throughout the night, and allowing for the subsequent estimation of extinction and colour terms.

As the survey progressed, the large number of non-photometric nights and the substantial overheads associated with multiple-band observations of standard stars prompted the use of an alternative procedure to establish the multi-band photometry for each survey run (see section 6.1). With this method, it is only the zeropointing of the V band calibrator chip that is of importance, as the zeropoints of the rest of the V band data are determined by overlap matching (see section 6.1) and the other bands are then corrected relative to the V band, via stellar locus fitting (see section 6.2). Data for the Andromeda V band calibrator frame and the corresponding standard star observations were obtained during photometric conditions, and the zeropoint was determined in the usual fashion. The uncertainty on the zeropoint of the V band calibrator frame was found to be 0.07 magnitudes.

4.2 Object Extraction using SExtractor

SExtractor (Bertin & Arnouts 1996), an automated package, was used to perform the image analysis and source extraction. It is designed for the detection of faint objects in wide-field surveys and so is particularly suited to the ODTS data. It also has the additional advantages of speed, a de-blending algorithm and a neural network star-galaxy classifier. Due to the aforementioned problems with the background subtraction, all images were background subtracted prior to SExtractor object detection and the background subtraction algorithm used by SExtractor was switched off.

Convolving the data with a Gaussian filter of full width half maximum (FWHM) close to the seeing is known to optimise detections and reduce noise levels during the source extraction. Hence, a Gaussian filter described by a $3 \times 3$ matrix with an FWHM of $1.5 - 6.1$ pixels ($= 0.5'' - 2''$) depending on the seeing, was utilised which had proved, after initial tests, the most effective at faint source extraction. Objects meeting the extraction criteria of having 8 connected pixels with flux $> 0.4\sigma$ above the local background level were analysed. This corresponded to a minimum of $> 1.3\sigma$ per object detection (Booth 2001), however in practise only $> 5\sigma$ detections are included in the final catalogues.

Within SExtractor, the intensity profile of each source was automatically examined in order to ascertain whether it was a single source or a merged object, where the latter initiates the de-blending
procedure within SExtractor. Simulations suggest that photometric errors for objects de-blended by SExtractor are < 0.2 magnitudes and in most cases are < 0.1 magnitudes. Astrometric errors due to de-blending are typically < 0.4 pixels (0.1") (Bertin & Arnouts 1996).

On occasion, the comparatively low detection threshold used resulted in spurious detections in the wings of both bright and extended objects where the local background noise level was relatively high. Hence the 'cleaning' procedure was implemented within SExtractor whereby the contribution to the background from bright/extended objects is estimated by fitting them with appropriate Gaussian profiles. Local object intensities remaining above the detection threshold when the adjusted local background was subtracted were accepted into the final catalogue. These spurious detections typically accounted for 10 – 20% of all detections and those few which remained after cleaning were dealt with during the image masking process detailed in section 4.4.

SExtractor was used to calculate aperture and isophotal corrected magnitudes for every source. Aperture magnitudes were obtained by integrating the flux within a fixed aperture and subtracting the contribution from the sky background, its value estimated within an annulus outside the aperture. For the ODTS, an aperture size of diameter 10 pixels (3.33") was used for all bands. Isophotal corrected magnitudes were also computed whereby the flux within a specified isophote, set at 2.5× the local background level, was integrated. To retrieve flux existing outside the limiting isophote, a Gaussian profile was then fit to the intensity distribution of the object and an estimation of the omitted flux made and subtracted. All extracted magnitudes have an associated rms error calculated within SExtractor. This random error increases with faintness, but remains small to the limiting depths of the ODTS compared with the various calibration uncertainties (see section 6.3).

Aperture magnitudes, although consistent, will tend to underestimate the actual magnitude of an extended object due to the flux lost outside the aperture. Simulations suggest that this is negligible for seeing-limited objects fainter than \( R \approx 18.5 \) in the ODTS data (Olding 2002). Isophotal corrected magnitudes work well for the brighter more extended objects but become unstable at the faint end as they involve assumptions about the shapes of objects which become highly uncertain at faint magnitudes. In general the isophotal corrected magnitudes were found to be less self-consistent than the aperture magnitudes, ascertained by comparing the spread of the ODTS stellar data around the main sequence and the scatter in the difference in magnitudes for common objects found in the overlap regions.

Ultimately catalogues containing both aperture and isophotal corrected source magnitudes for each frame at each pointing in every band were archived, but aperture magnitudes were used in the final calibrations performed in section 6, as they give much more consistent colours. Archiving both magnitudes allows the user to choose the magnitude regime most appropriate for their work.

### 4.3 Star/Galaxy Separation

During the source extraction, SExtractor classifies each object as a star or galaxy reflected in the value of the stellarity index parameter. A trained neural network was employed to determine the stellarity index for each object dependent on the seeing, peak intensity and a measurement of the isophotal area (see Bertin & Arnouts (1996) for details). The seeing for each pointing was obtained by taking the median FWHM of all bright, unsaturated objects in the image, identified from their profiles as stars. The stellarity index has a value between 0 and 1, where 0 represents a galaxy, 1 a star and intermediate values, by design, give an indication of the uncertainty of the classification. Bertin & Arnouts (1996) claim an algorithm success rate of \( \approx 95\% \) to \( R \approx 22 \) when the seeing is \( \approx 0.9'' \), however the seeing varies quite dramatically across the ODTS fields. Figure 6 depicts the behaviour of the stellarity index as a function of magnitude for each band in the Andromeda field. As expected, at faint magnitudes the stellarity index tends towards 0.5 as the distinction between stars and galaxies becomes less pronounced due to object profiles becoming seeing dominated. At very bright magnitudes, the index tends to drop due to saturation effects. From figure 6, it is apparent that the classifier begins to break down at magnitudes of \( B > 22.5, V > 22, R > 21.5 \) and \( I > 21.5 \). However, it should be noted that the depths to which the classifier is successful is a strong function of seeing and therefore varies between pointings. All objects with a stellarity index > 0.9 were considered to be stars.

### Image Masking

False detections caused by the presence of asteroid and satellite trails, excessive vignetting, low-level fringing, diffraction spikes,
and halos around bright stars had to be removed from, or flagged in, the final catalogues. For each image a mask was created manually which identified all the contaminated image areas. The method employed consisted of drawing either rectangular or circular shaped holes around the spurious structures in the data frame, where objects appearing within the holes were then flagged appropriately, allowing for subsequent rejection. An example of an image and its mask can be seen in figure 7.

The effective area of the survey was consequently reduced and the final areas for each band in each field after masking are shown in table 5.

5 ASTROMETRY

The conversion of the source pixel position to right ascension $\alpha$ and declination $\delta$ was then carried out. The four CCDs of the WFC maintain a fixed geometrical pattern relative to the camera rotator centre however, the prime focus corrector of the INT introduces a cubic radial distortion term to the plate scale of the form

$$r_{\text{true}} = r + kr^3,$$

where $r_{\text{true}}$ is the actual radial distance in radians from the field centre, $r$ is the measured radial distance and $k$ is a constant. For the WFC, $k$ was measured to be $220.0$ radians$^{-2}$ (Irwin, private communication).

The astrometry is split into two stages. Initially, each individual CCD frame is calibrated independently by roughly matching objects in the images with objects in the corresponding Digitised Sky Survey images (Lasker & Team 1998). Matched objects are then used to converge upon an astrometric fit for each frame via an iterative process. This is performed using the ASTROM package which relates the measured $x, y$ to the true $\alpha, \delta$ coordinates by fitting a six coefficient transformation, which includes orientation of the images, plate scale and radial distortions. These fits gave rms residuals of the order of $1''$ for each frame. The large residuals
Figure 8. Scatter diagram of the astrometric differences in arc seconds between the matched ODT and USNO objects for an example field. The rms differences are small. The pixel size is 0.33″.

Figure 9. Histogram of the rms astrometric residuals between the ODTS and USNO data found for each individual CCD frame after the final iteration of the astrometric matching procedure for the V band Andromeda data.

Figure 10. Scatter diagram of the astrometric differences in arc seconds between the matched objects in all the overlap regions of the reduced V band Andromeda data. Objects with V < 24.5 have been used so as to avoid using data from overlapping frames which reach different depths.

Figure 11. The V band magnitude (photometric) difference between objects in the overlap region of two adjacent frames plotted against the mean magnitude, where each point represents a matched pair of objects. The three lines represent the value of the mean determined after the first (solid line), second (short broken line) and third (long broken line) iterations of linear fitting to the data, where points deviating from the mean by > 1.5σ are rejected after each fit (crossed out objects). The magnitude dependence of the photometric errors determined during source extraction is obvious.

6 PHOTOMETRIC CALIBRATION

Producing a final catalogue with consistent photometry throughout requires each contiguous field to have a common zeropoint. At this stage, the individual zeropoints derived in section 4.1 will each have a residual uncertainty due to differing observing conditions and airmass and extinction variations between observations. Many observations were taken in non-photometric conditions. In order to achieve homogeneity in the photometric calibration, the
zeropoints of the individual frames must be adjusted relative to a common zeropoint adopted for the whole survey. This was carried out in two stages, where the first involved using the $V$ band as the calibrator band (see section 6.1) and considering the magnitude differences between common objects in the overlap regions of the $V$ band pointings. The photometric zeropoints could then be corrected relative to a chosen calibrator frame, effectively creating a common zeropoint across the $V$ band data. Following this, the zeropoints of all the other bands were corrected relative to the $V$ band via stellar locus fitting (see section 6.2). This was done by examining the colours of stars in each frame and adjusting their zeropoints until the stars had the expected colours of the stellar main sequence.

6.1 Overlap Matching

To ensure a common photometric zeropoint for the $V$ band, the approach introduced by Glazebrook et al. (1994) was adopted whereby the magnitudes of objects common to overlapping images are compared in order to ascertain the difference in their zeropoints. Objects in the overlap regions of adjacent fields were matched with a tolerance of $\sim 1''$, also a useful check of the astrometric accuracy. Figure 10 shows the astrometric differences for all the matched objects in the overlap regions of the $V$ band data. Following this, the zeropoints of all the other bands were corrected relative to the $V$ band via stellar locus fitting (see section 6.2). This was done by examining the colours of stars in each frame and adjusting their zeropoints until the stars had the expected colours of the stellar main sequence.

Figure 12. The best fit polynomials (black lines) used in the photometric calibration of the ODTS data. Filled red circles represent the colours of Pickles (1998) stellar data in the ODTS filter system, as seen in six different colour-colour planes.
Figure 13. Stellar colours with uncorrected photometric zeropoints for an example frame. The open blue circles represent the colours of Pickles (1998) stellar data in the ODTS filter system and the red crosses show the ODTS stellar data. Large initial offsets were expected due to the differing observing conditions.

$\theta_{ij} = \begin{cases} 1 & \text{if } i \text{ and } j \text{ overlap} \\ 0 & \text{if } i \text{ and } j \text{ don't overlap} \\ 1 & \text{if } i=j \end{cases}$

Of the $n$ frames involved, $(1,...,m)$ are, by design, uncalibrated and $(m+1,...,n)$ are calibrated. For the ODTS, only one frame in the central region of the field was adopted as the calibration frame based on its position, good seeing, photometric conditions during observation, and galaxy number counts. The systematic errors in the plate to plate variations should be (and were) $\leq 0.05$ magnitudes to avoid introducing artificial large-scale structure (Geller, de Lapparent & Kurtz 1984).

Initially, overlap matching to find a common photometric zeropoint was carried out for all bands and it was the $V$ band that was found to possess the smallest scatter in zeropoint corrections. This, combined with the $V$ band having the largest coverage, being less likely than $B$ to be affected by variations in both Galactic and atmospheric extinction and being free from fringing effects present in $R$ and $i'$ data justifies the choice of $V$ as the calibrator band.

6.2 Stellar Sequence Fitting

To calibrate the $UBRi'$ data, the colours of the stellar objects in the ODTS were compared with the expected colours of stars, obtained from the Pickles (1998) stellar library. The model stellar colours were determined by convolving the ODTS spectral response curves (seen in figure 1) with the SEDs of the Pickles (1998) sources. Model stellar sequences were derived in six different colour-colour regimes using $6^{th}$ order polynomials of the form

$$y = \sum_{j=0}^{n} a_j x^j$$

where $x$ and $y$ are the chosen colours and $a_j$ are the polynomial coefficients. The best fit polynomials are shown in figure 12.

Stellar objects were selected from each ODTS frame by choosing stars with $17 < R < 21$ and a star-galaxy classification of $> 0.9$ (see section 4.3). This made use of data with small photometric measurement errors and reliable SExtractor star-galaxy classification. Any stellar objects lying more than 0.2 magnitudes from the main sequence of objects (in the colour-colour diagrams) were excluded as outliers.

For each frame, in each colour-colour plane shown in figure 12, the zeropoints were allowed to vary for each of the three colours being examined, with the exception of the $V$ band zeropoint. This remains fixed as $V$ is the chosen calibrator band and the zeropoint correction factors for other bands are calculated relative to this. The $\chi^2$ statistic was then computed via
Figure 14. Stellar colours with corrected photometric zeropoints for an example frame. The open blue circles represent the colours of Pickles (1998) stellar data in the ODTS filter system and the red crosses show the ODTS stellar data.

\[
\chi^2 = \sum_{i=1}^{N} (y_i - Y(x_i))^2
\]  

(5)

where there are \(N\) data points with positions \(x_i\) and \(y_i\), and \(Y(x_i)\) is the value of the best fitting polynomial (from equation 4) evaluated at \(x_i\). The shifts in \(x\) and \(y\) which minimise this statistic were computed, as was the final change in colours required for the stellar loci of the ODTS data to match those of Pickles (1998). This process was carried out for all six colour-colour regimes (or 4 if only \(BV\) \(Ri'\) data was available).

If the zeropoint for a given frame in a certain band differs from the 'true' zeropoint by a correction factor, \(C_i\), then the measured shifts in colour correspond to the difference between the zeropoint correction factors of two different bands, \(C_i\) and \(C_j\). Using the same formalisation introduced in the previous section, the \(T_{ij}\) matrix which can be solved to find the \(C_i\) values for each frame. As the combination of colour-colour regimes constrain the zeropoint corrections for each band, the rms scatter in each zeropoint determination can be computed from

\[
\text{rms} = \frac{\sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij} \theta_{ij} (T_{ij} + C_j - C_i)^2}{\sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij} \theta_{ij}}
\]  

(6)

Typical rms values were found to be of the order 0.02 magnitudes. An example of the six colour-colour planes showing data before and after correction is shown in figures 13 and 14. Comparing the \(UBRi'\) overlap matches after zeropoint corrections were applied gave offsets \(< 0.05\) magnitudes suggesting that the photometry is internally consistent at this level.

### 6.3 Photometric Errors

A number of sources of error can affect the photometry. Random errors are estimated during the extraction and measurement of photon counts for an object, and its subsequent conversion to a magnitude. These measurement errors are estimated by SExtractor for each source extraction. For a typical \(V\)-band frame, these errors are \(< 0.025\) mag at \(V \leq 22\), rising to \(\sim 0.075\) mag by \(V \sim 23\) and \(\sim 0.3\) mag at \(V \sim 24.5\). An alternative error estimate was made by plotting the magnitude difference between objects in the overlap region, after photometric calibration, against the average magnitude. This is shown for the \(V\) band in figure 16, where 2\(\sigma\) error curves have been superimposed. The error estimates given by SExtractor appear to be systematically lower (by \(\approx 0.03\) mags) than the errors obtained by examining the photometry of common objects in overlap regions after photometric calibration. This is the case for all the bands.

Two sources of calibration error are introduced during the photometric calibration process; one from the zeropointing of the \(V\) band mosaic, typically good to \(\sim 0.03\) magnitudes, and the
The Oxford-Dartmouth Thirty Degree Survey I: Observations and Calibration

Figure 15. \( U \) band galaxy number counts from the ODTS compared with a complication of results taken from various sources. All counts have been converted to the standard photoelectric system. Conversion of the ODTS \( U \) data to the standard \( U \) filter (using equation 8) requires matches in \( U \) and \( B \), and consequently the completeness of the \( U \) data will be dependent of the shallowest depths reached by the matched ODTS \( U \) and \( B \) band data. Here, \( U \) is found to be complete to a depth of 24.4.

**Figure 16.** \( V \) band magnitude difference between common objects in overlap regions against the mean magnitude for the reduced Andromeda data after photometric calibration. 2\( \sigma \) error curves have been plotted and objects with \( V < 24.5 \) have been used so as to avoid using data from overlapping frames which reach different depths.

other from the zeropoint calibration of the other bands relative to \( V \) using the stellar locus fitting technique, found to introduce errors of \( \sim 0.03 \) magnitudes. Adding these errors in quadrature confirmed that the photometry is *internally consistent* in all bands at the \( < 0.05 \) magnitude level. A final source of uncertainty comes from the calibration of the \( V \) band data using the photometric standards. The frame used as the calibrator had a zeropoint uncertainty of 0.07 magnitudes, resulting in overall photometric uncertainties of \( < 0.1 \) magnitudes.

### 7 MATCHED CATALOGUE GENERATION

The final catalogues were created by matching the detections within the single colour catalogues to produce one master catalogue for each field, containing magnitudes and errors in all bands, and the corresponding extraction flags.

Routines were constructed to match the single-colour ODTS data using the following approach. All of the astrometric solutions and hole positions were read, along with each of the single colour catalogues. The catalogues were then sorted in turn by right ascension, and matched to the other catalogues using an astrometric tolerance of 3\( \arcsec \). A large array was subsequently produced which contained all the matching information for every object in each filter, and a record of which objects in the other bands they matched. Any inconsistencies arising after the first iteration of the matching
Figure 17. B band galaxy number counts from the ODTS compared with a complication of results taken from various sources. All counts have been converted to the standard photoelectric system. Conversion of the ODTS B data to the standard B filter (using equation 9) requires matches in B and V, and consequently the completeness of the B data will be dependent of the shallowest depths reached by the matched ODTS B and V band data. Here, B is found to be complete to a depth of 25.1.

routine, e.g. an object de-blended by SExtractor in one filter but not in others due to complex morphology, were isolated and flagged appropriately. The matching process was then repeated taking account of the new flags. Within the programme, checks were made to establish whether observations in the filter being matched existed, if the object being matched lay within a hole, or if there simply was not a detection in that band. Table 6 gives a list of the flags that were assigned to each detection in the final matched catalogue. The −2 and −3 flags took precedence over the SExtractor extraction flags unless the SExtractor flag was > 4, which indicates satura-

Table 6. Flags used in the matched catalogues determining the reliability of objects or reasons for not matching. The catalogue stores one flag for each filter for every catalogue object.

| Flag Value | Description |
|------------|-------------|
| 0+         | Detected object given its SExtractor extraction flag. |
| −1         | No object detected (but region has been observed). |
| −2         | Object lies in a drilled region (bright star or bad area of the chip). |
| −3         | Object lies in a drilled region (bright extended source). |
| −4         | Inconsistent matching, would need follow-up by eye. |
| −8         | Region yet to be observed. |

8 PHOTOMETRIC REDSHIFTS

Photometric redshifts were obtained by comparing the ODTS photometric data with an extensive set of model spectra taken from Kinney, Calzetti et al. (1996) galaxy templates, PEGASE stellar synthesis code (Fioc & Rocca-Volmerange 1997), SDSS QSO libraries (Budavari et al. 2001) and the Pickles (1998) stellar templates. Galaxy and QSO models were translated to longer wavelengths, effectively providing comparison spectra over a range of redshifts, and the complete set of templates were then multiplied with the ODTS spectral response functions to obtain potential U − B, B − V, V − R and R − I colours. The photometric data for each object were then compared with the possible model template colours and likelihoods obtained for each fit. Each object was then
The Oxford-Dartmouth Thirty Degree Survey I: Observations and Calibration

Figure 18. V band galaxy number counts from the ODTS compared with a complication of results taken from various sources. All counts have been converted to the standard photoelectric system. As the Harris V filter used in the ODTS is approximately the same as the standard V filter, no conversion of the ODTS data was required. Consequently, the completeness of the V data will only be dependent on the shallowest depths reached by the ODTS V data. Here, V is found to be complete to a depth of 24.8.

Figure 19. Determined photometric redshifts versus the error in the redshift for a subsection of the matched data from the Andromeda field. All galaxies have $R < 23$ to avoid including fainter galaxies with large photometric errors.

Photometric redshifts were determined for the Andromeda pointings with matched UBVRI′ data and figure 19 shows the determined redshifts against $\sigma_z$ for a subsection of this data. Objects were chosen to have $R < 23$ in order to avoid including the fainter objects which have larger associated photometric errors. Within this representative sample, ≈ 8000 (81%) were found to have $\sigma_z < 0.1$ and ≈ 6000 to have $\sigma_z < 0.05$ (60%).

An estimate for the median redshift of the ODTS was obtained using the redshift distributions of Fernández-Soto, Lanzetta & Yahil (1999), Cohen et al. (2000), Cowie et al. (2004) and Wirth (2004). From Baugh & Efstathiou (1994), a magnitude dependent redshift distribution can be defined using

$$n(z,R) \propto z^2 \exp \left[ -\frac{z}{z_0(R)} \right]^{1.5}$$

(7)
where \( z_0(R) = z_m(R)/1.4 \) and \( z_m(R) \) is the median redshift as a function of \( R \) band magnitude. The \( z_m(R) \) is estimated from the redshift distribution of galaxies with known spectroscopic or photometric redshifts sampled in \( R \) band magnitude bins of width 0.5 magnitudes. Summing the magnitude dependent model redshift distributions, weighted according to the magnitude distribution of the ODTS, results in an estimate of the redshift distribution for the ODTS, found to be \( z_m \approx 0.7 \). This was in good agreement with the \( z_m \) determined from the median magnitude/median redshift relationship, derived from the COMBO-17 survey, documented in Brown et al. 2003, where the ODTS median \( R \) band magnitude of \( R_m = 23.2 \), corresponds to \( z_m \approx 0.7 \).

9 GALAXY NUMBER COUNTS

All of the ODTS magnitudes were converted to the standard Johnson-Morgan-Cousins photoelectric filter system, denoted here as UBVRI, using the following colour transformation equations\(^3\)

\[
U = \frac{(U_{\text{KPGO}} - B_{\text{KPGO}})}{12.167} + U_{\text{KPGO}} - 0.119 \quad (8)
\]

\[
B = \frac{(B_{\text{KPGO}} - V_{\text{Har}})}{7.008} + B_{\text{KPGO}} - 0.001 \quad (9)
\]

\[
I = i'_{\text{SLm}} - 0.2006(R_{\text{Har}} - i'_{\text{SLm}} - 0.004) \quad (10)
\]

The Harris \( V \) and \( R \) filters used in the ODTS were deemed close enough to the standard photoelectric bands to warrant no conversion. Galaxy number counts for the ODTS are shown in figures 15, 17, 18, 20 and 21 and are found to be in excellent agreement with previous results. It should be noted that the results shown use all of the data from the Andromeda field, thus represent the average depths reached. For a few pointings, where data was acquired in the best conditions, i.e. when the seeing was \( \leq 1 \), the target depths given in table 2 were reached. For the \( V \) and \( R \) bands, where no filter conversions are needed, the depths reached in figures 18 and 20 depend only on on the depths of the ODTS \( V \) and \( R \) data respectively. However, to enable the conversion of the \( U, V \) and \( i' \) ODTS data (as in equations 8, 9 and 10), only galaxies from the matched catalogue with the necessary multi-colour data could be used to derive the galaxy number counts shown. Hence the depths reached in figures 15, 17, and 21 will depend on the most shallow of the multi-band data used. As a result of this, the depths reached are \( U = 24.4, B = 25.1, I = 22.8 \), slightly shallower than the average.
The Oxford-Dartmouth Thirty Degree Survey I: Observations and Calibration

10 SUMMARY

The Oxford-Dartmouth Thirty Degree Survey (ODTS) is a deep, wide, multi-band imaging survey. The Wide Field Camera on the 2.5m Isaac Newton Telescope on La Palma has been used to obtain $UBVRI'$ data and the $Z$ band data are being acquired using the 2.4m Hiltner Telescope at the MDM observatory on Kitt Peak. A complementary $K$ band survey is currently being carried out using the 1.3m McGraw-Hill Telescope at MDM. Four survey regions of $5\text{-}10\text{ deg}^2$, centred at $00:18:24 +34:52$ (Andromeda), $09:09:45 +40:50$ (Lynx), $13:40:00 +02:30$ (Virgo) and $16:39:30 +45:24$ (Hercules) have been covered to average $5\sigma$ limiting depths (Vega) of $B=25.5$, $V=25.1$, $R=24.6$, and $i'=23.5$, with $U$ and $K$ subsets covered to depths of 25.1 and 18.5 respectively. Initial data analysis indicates that the ODTS reaches depths $\approx 0.5$ magnitudes shallower than previously anticipated, attributed to less than optimal seeing during observations. On completion of INT observations for the ODTS, approximately 23 square degrees have been covered in $BVRI'$, with a subset of 1.5 square degrees in $U$.

This paper details the process from data acquisition, through data reduction and calibration, to the resultant multi-colour catalogues.

Photometric redshifts were calculated for a representative sample of objects in the Andromeda field, and were found to have $\sigma_z < 0.1$ for $\sim 80\%$ of the data and $\sigma_z < 0.05$ for $\sim 60\%$ of the data. The median redshift of the survey to date was estimated to be $z \approx 0.7$.

Galaxy number counts were determined and were found to compare well with previous survey results.

Preliminary evaluation of the ODTS data shows that the overall quality and quantity of the data is sufficient to meet the initial science objectives of the ODTS. Research undertaken using the ODTS and the results obtained will be documented in the forthcoming papers of this series.
