Abstract

Rust is a modern systems language focused on performance and reliability. Complementing Rust’s promise to provide “fearless concurrency”, developers frequently exploit asynchronous message passing. Unfortunately, sending and receiving messages in an arbitrary order to maximise computation-communication overlap (a popular optimisation in message-passing applications) opens up a Pandora’s box of subtle concurrency bugs.

To guarantee deadlock-freedom by construction, we present Rumpsteak: a new Rust framework based on multiparty session types. Previous session type implementations in Rust are either built upon synchronous and blocking communication and/or are limited to two-party interactions. Crucially, none support the arbitrary ordering of messages for efficiency.

Rumpsteak instead targets asynchronous async/await code. Its unique ability is allowing developers to arbitrarily order send/receive messages while preserving deadlock-freedom. For this, Rumpsteak incorporates two recent advanced session type theories: (1) \( k \)-multiparty compatibility (\( k \)-MC), which globally verifies the safety of a set of participants, and (2) asynchronous multiparty session subtyping, which locally verifies optimisations in the context of a single participant. Specifically, we propose a novel algorithm for asynchronous subtyping that is both sound and Decidable.

We first evaluate the performance and expressiveness of Rumpsteak against three previous Rust implementations. We discover that Rumpsteak is around 1.7–8.6x more efficient and can safely express many more examples by virtue of offering arbitrary ordering of messages. Secondly, we analyse the complexity of our new algorithm and benchmark it against \( k \)-MC and a binary session subtyping algorithm. We find they are exponentially slower than Rumpsteak’s.

CCS Concepts:
• Software and its engineering → Development frameworks and environments: Source code generation;
• Computer systems organization → Reliability.

Keywords: Rust, Asynchronous Message Passing, Message Reordering, Computation-Communication Overlap, Multiparty Session Types

1 Introduction

Rust is a statically-typed language designed for systems software development. It is rapidly growing in popularity and has been voted “most loved language” over five years of surveys by Stack Overflow [19]. Rust aims to offer the safety of a high-level language without compromising on the performance enjoyed by low-level languages. Message passing over typed channels is common in concurrent Rust applications, where (low-level) threads or (high-level) actors communicate efficiently and safely by sending messages containing data.

To improve performance by maximising computation-communication overlap [14, 37, 56], developers often wish to arbitrarily change the order of sending and receiving messages—we will present several examples of this technique, which we refer to as asynchronous message reordering (AMR). Our challenge is to remedy communication errors such as deadlocks, which can easily occur in message-passing applications, particularly those that leverage AMR.

To achieve this, we introduce Rumpsteak: a framework for efficiently coordinating message-passing processes in Rust using multiparty session types. Session types [28, 57] (see [62] for a gentle introduction and [23] for a more exhaustive one) coordinate interactions through linearly typed channels, that must be used exactly once, ensuring protocol compliance without deadlocks or communication mismatches.

Current state of the art. Since Rust’s affine type system is particularly well-suited to session types by statically guaranteeing a linear usage of session channels, there are several previous attempts at implementing session types in Rust [12, 34, 38, 41]. However, their current limitations prevent them from guaranteeing all four of deadlock-freedom, multiparty communication, asynchronous execution and AMR.

Our framework. We motivate the importance of each feature and explain how Rumpsteak incorporates this.

Deadlock-freedom. One of the most important properties of concurrent/parallel systems is that their computations
When one task is blocked, another’s work can be scheduled while preserving deadlock-freedom. To motivate this, we introduce a running example of the double buffering protocol. This approach suffers from performance limitations since threads are blocked while waiting to receive messages. Rumpsteak instead uses asynchronous communication, where lightweight asynchronous tasks share a pool of threads. When one task is blocked, another’s work can be scheduled in the meantime to prevent the wasting of computational resources.

Although [12] is also based on asynchronous communication, only Rumpsteak closely integrates with Rust’s modern async/await syntax, allowing asynchronous programs to be written sequentially. To achieve this, asynchronous functions are annotated with async, causing them to return futures. Developers can await calls to these functions, denoting that execution should continue elsewhere until a result is ready.

Asynchronous message reordering. Our main contribution is offering AMR, which no existing work can provide while preserving deadlock-freedom. To motivate this, we introduce a running example of the double buffering protocol [33]. Buffering is frequently used in multimedia applications where a continuous stream of data must be sent from a source (e.g. a graphics card) to a sink (e.g. a CPU). To prevent the source from being blocked while the sink is busy, it writes to a buffer, which is later read by the sink.

Asynchronous execution. Most previous Rust implementations [12, 34, 38] support only binary session types, which is limited to two-party communication. On the other hand, the majority of real-world communication protocols consist of more than two participants. Rumpsteak therefore uses multiparty session types (MPST) [29, 30] to ensure deadlock-freedom in protocols with any number of participants (or roles).

Multiparty communication. Many previous Rust implementations [34, 38, 41] use synchronous communication channels. This approach suffers from performance limitations since threads are blocked while waiting to receive messages. Rumpsteak instead uses asynchronous communication, where lightweight asynchronous tasks share a pool of threads. When one task is blocked, another’s work can be scheduled in the meantime to prevent the wasting of computational resources.

Although [12] is also based on asynchronous communication, only Rumpsteak closely integrates with Rust’s modern async/await syntax, allowing asynchronous programs to be written sequentially. To achieve this, asynchronous functions are annotated with async, causing them to return futures. Developers can await calls to these functions, denoting that execution should continue elsewhere until a result is ready.

Asynchronous message reordering. Our main contribution is offering AMR, which no existing work can provide while preserving deadlock-freedom. To motivate this, we introduce a running example of the double buffering protocol [33]. Buffering is frequently used in multimedia applications where a continuous stream of data must be sent from a source (e.g. a graphics card) to a sink (e.g. a CPU). To prevent the source from being blocked while the sink is busy, it writes to a buffer, which is later read by the sink.

We illustrate this effect in Fig. 2. With a single buffer, both the source and sink are constantly blocked as we cannot read and write simultaneously. However, adding a second buffer allows the source and sink to operate on different buffers at once so that (in the best case) they are never blocked and throughput can increase twofold.

As we will see in § 2, the double buffering protocol takes advantage of AMR so it cannot be expressed with standard MPST theory [29]; communication with the source and sink are overlapped so both buffers can be accessed at once. The goal of this paper is to provide a method for ensuring that protocols optimised in this way preserve deadlock-freedom.

Rumpsteak framework. We achieve these features while allowing three different approaches, summarised in Fig. 1.

In the top-down approach, the developer writes a global type, which describes the entire protocol (see § 2 for an example). We project this onto each participant to obtain a local finite state machine (FSM), which describes the protocol from that participant’s perspective. Next, the developer uses AMR to propose optimised FSMS for each participant. We locally verify that each optimised FSM is compatible with the projected one using an asynchronous subtyping algorithm. From each optimised FSM, we generate an API so that the developer can write a Rust process implementation.
API uses Rust’s type checker to ensure that these processes conform to the protocol, and are therefore deadlock-free.

In the **bottom-up approach**, the developer manually writes an API and process implementation for each participant. We derive the optimised FSMs directly from these APIs and ensure that they are safe using \(k\)-multiparty compatibility \((k\text{-MC})\) [43]. \(k\text{-MC}\) globally verifies that multiple FSMs are compatible with each other without using a global type.

Finally, we propose a **hybrid approach** where the projected FSMs are generated from a global type on one side (as in the top-down approach). On the other side, the developer writes both the APIs and process implementations directly, and we derive the optimised FSMs (as in the bottom-up approach). We then locally verify that the optimised FSMs are asynchronous subtypes of the projected FSMs.

To summarise, our subtyping algorithm used in the top-down/hybrid approaches locally verifies the correctness of optimisations. This makes it far more scalable than \(k\text{-MC}\) as we will see in §4. These approaches are also more intuitive to the developer since they use safety by construction—it is much easier to write a global type than to determine why a \(k\text{-MC}\) analysis has failed for a complex protocol.

**Contribution and outline.** In §2, we give an overview of the design and implementation of Rumpsteak. In §3, we present our new asynchronous subtyping algorithm used to check that an optimised FSM is correct. We prove our new algorithm is sound (Theorem 7) against the precise MPST asynchronous subtyping theory [25], terminates (Theorem 6) and analyse its complexity (Theorem 9). In §4, we compare the performance and expressiveness of our framework with existing work [7, 12, 38, 41, 43]. We show (1) Rumpsteak’s runtime is faster and can express many more asynchronous protocols than other Rust implementations [12, 38, 41]; and (2) our subtyping algorithm is more efficient than existing algorithms [7, 43], confirming our complexity analysis. §5 discusses related work and concludes. The supplementary materials available in the full version [17] contain further examples and proofs of the theorems. We include our source code and benchmarks in a public GitHub repository [3].

## 2 Design and Implementation

This section presents Rumpsteak and explains its three workflows: a **top-down approach** using asynchronous subtyping, a **bottom-up approach** using \(k\)-multiparty compatibility (\(k\text{-MC}\)) [43] and a **hybrid approach** combining the two.

### 2.1 Top-Down Approach

All three approaches result in the same final application, so we use the example of the top-down workflow (Fig. 1a) to give a general overview of Rumpsteak’s implementation.

**Two-party protocol.** Before going into the details of the top-down approach, we first give an informal insight into how the protocol is represented at each stage, shown in Fig. 3. For this, we use the example of a simple streaming protocol, later introduced in §4.

**Global session type** describes the protocol from a global perspective and includes all participants in the protocol. The global type for the streaming protocol (shown below) is read as follows: participant \(t\) first sends \(ready\) to participant \(s\). Next, \(s\) replies to \(t\) with two possible messages: either \(value\) or \(stop\). In the latter case, the protocol terminates (type end). In the former case, the protocol continues with \(x\), which is a type variable that is bound by \(\mu x\), i.e. the protocol starts over.

\[
G_{ST} = \mu x. t \rightarrow s : \{ ready.s \rightarrow t : \{ value.x, \ stop.end \}\}
\]

In Rumpsteak, developers express global types syntactically with Scribble [55, 63]: a widely used and target-agnostic language for describing multiparty protocols. We show the corresponding Scribble description for the streaming protocol in Fig. 3a.

**A local finite state machine** describes the protocol from the perspective of a single participant. It shows the send and receive actions of that participant, independent of what other participants may be doing in the meantime.

In Fig. 3b, we show the local FSMs for each participant in the streaming protocol, where \(!\) and \(?\) denote send and receive respectively in session type syntax [62]. For example, the FSM for the source first receives \(ready\) from the sink, then chooses to either send \(value\) and start over or simply send \(stop\) and finish.

**The Rust API** is an encoding of a local FSM as Rust code. This code then uses Rust’s type checker to confirm that a toolchain—i.e. the protocol starts over.

\[
G_{DB} = \mu x. k \rightarrow s : \{ ready.s \rightarrow k : \{
\begin{array}{l}
\text{value}\ t \rightarrow k : \{ ready.k \rightarrow t : \{ value.x \}\}}
\end{array}\}
\]

**Projection.** Once we have created a global type, we use a projection algorithm to derive the local FSM for each participant. In Rumpsteak, we perform projection using \(v\text{Scr}\) [2]: a new lightweight and extensible Scribble toolchain implemented in OCaml.
Listing 1. Scribble representation of the double buffering protocol.

```
1   global protocol DoubleBuffering(role s, role k, role t) {
2       rec loop { 
3           ready() from k to s;  
4           value() from s to k;  
5           ready() from t to k;  
6           value() from k to t;  
7           continue loop;  
8       } or {  
9           stop() from s to t;  
10       }
11   }
```

(a) Scribble protocol description

(b) FSMs for the source and sink

(c) Rust API code (simplified excerpt)

Figure 3. Different session type representations used within Rumpsteak.

Asynchronous message reordering. Unfortunately, global types cannot represent overlapping communication. Therefore, the projection $M_k$ cannot achieve the simultaneous interactions we saw in Fig. 2. In practice, developers use AMR to produce an optimised FSM for the kernel $M_k'$ (shown in Fig. 4b). Here, the kernel initially sends two `ready` messages to the source. This allows the source to write to the second buffer while the sink is busy reading from the first. Note that the asynchronous queue is effectively acting as the second buffer—the second message from the source waits in the queue while the kernel is processing the first.

Crucially, Rumpsteak verifies that $M_k'$ is safe to use in the place of $M_k$ without causing deadlocks or other communication errors. Otherwise, we would be throwing away the safety benefits that come with MPST. To achieve this, we must determine that $M_k'$ is an asynchronous subtype of $M_k$, which we perform using our algorithm presented in § 3.

API design. Once we arrive at an optimised FSM $M_k'$ for each participant, our challenge is to create a Rust API $A_i$, which uses Rust’s type checker to ensure that a developer-written process $P_i$ conforms to $M_k'$ (a relevant introduction to the Rust programming language can be found in Jung’s thesis [36, Chapter 8]). In the top-down approach, this API is automatically generated from an optimised FSM.

To illustrate, we show the API for the kernel ($A_k$) in Listing 2, which checks conformance to $M_k'$.

Roles (Participants). Each role is represented as a struct, which stores its communication channels with other roles. The struct for the kernel (ls. 1 to 6) contains channels to and from $s$ and $t$. Developers can in fact use any custom channel that implements Rust’s standard `Sink` or `Stream` interfaces [15] for asynchronous sends and receives respectively. This approach minimises the expensive creation of channels.

We show the projected local FSM for each of the participants in Fig. 4. For instance, the kernel, whose projected type $M_k$ is shown in Fig. 4a, (1) informs the source that it is ready to receive; (2) receives a value from the source; (3) waits for the sink to become ready; (4) sends a value to the sink; and (5) repeats from step 1.
in cases where only bounded or unidirectional channels are required.

Our `[derive(Role)]` macro generates methods for programmatically retrieving these channels from the struct. Moreover, an optional `[derive(Roles)]` macro can be applied on a struct containing every role to also generate code for automatically instantiating all roles at once. This will create the necessary combination of channels and assign them to the correct structs in order to reduce human error.

**Sessions.** Following the approach of *MultiCrusty* [41], we build a set of generic primitives to construct a simple API. For instance, the Send primitive (l. 21) takes a role, label and continuation as generic parameters. In contrast to the standard approach of creating a type for every state [31], these primitives reduce the number of types required and avoid arbitrary naming of these `state types`. For brevity, our API elides two additional parameters used to store channels at runtime, which are reinserted with the `[session]` macro.

**Labels.** Internally, *Rumpsteak* sends a Label enum (l. 9) over reusable channels to communicate with other participants. Each label is represented as a type (ls. 14 to 15) and our `[derive(Message)]` macro generates methods for converting to and from the Label enum.

**Choice.** The kernel’s API does not contain choice but we show an example of this below. Choice is represented as an enum where each branch contains the label sent/received and a continuation. This design allows processes to pattern match on external choices to determine which label was received. Methods allowing the enum to be used with Branch (an external choice, l. 3) or Select (an internal choice) are also generated with the `[session]` macro. Even so, the enum is still necessary since Rust’s lack of variadic generics means choice cannot be easily implemented as its own primitive.

**Process implementation.** Using the API $A_k$, the developer writes an implementation for the process $P_k$; we show an example in Listing 3. We discuss how our API uses Rust’s type system to check that $P_k$ conforms to the protocol.

**Linearity.** The linear usage of channels is checked by Rust’s *affine type system*, preventing channels from being used multiple times. When a primitive is executed, it consumes itself, preventing reuse, and returns its continuation.

Developers are prevented from constructing primitives directly using visibility modifiers. They must instead use `try_session` (l. 2). This function accepts a reference to the role being implemented and a closure (or function pointer) to its process implementation. The closure takes the input session type as an argument and returns the terminal type End. If a session is discarded, thereby breaking linearity, then the developer will have no End to return and Rust’s compiler will complain that the closure does not satisfy its type.

**Infinite recursion.** At first glance, it seems impossible to implement processes with infinitely recursive types using this approach. Nevertheless, for types without an End primitive, such as Kernel, we can use an infinite loop (l. 4) to get around this problem. Conveniently, infinite loops are assigned `!`, Rust’s never (or bottom) type, which can be implicitly cast to any other type. This allows the type of the loop to be coerced to End, enabling the closure to pass the type checker as before.

**Channel reuse.** We allow roles to be reused across sessions since the channels they contain are usually expensive to create. Crucially, to prevent communication mismatches between different sessions, we must ensure that the same role is not used in multiple sessions at once. Therefore, `try_session` takes an exclusive reference to the role, causing Rust’s borrow checker to enforce this requirement.
2.2 Bottom-Up Approach
In the top-down approach, we generate a Rust API $A_i$ from an optimised FSM $M'_i$. In the bottom-up approach (Fig. 1b), we do the reverse: we serialise each API $A_i$ to obtain an FSM $M_i'$. Next, we use k-MC on the set of FSMs $M'_1,...,n$. If they are indeed compatible, then the processes $P_{i,1,...,n}$, which implement their respective APIs, are free from deadlocks.

$k$-MC takes the optimised FSMs of all participants and verifies deadlock freedom. In contrast, asynchronous subtyping checks the optimisation of a single participant’s FSM in isolation. Therefore, $k$-MC can be seen as a global analysis of the protocol and asynchronous subtyping as a local analysis of a single participant.

To perform the serialisation of an API to an FSM we provide a Rust function serialize<>() -> Fsm (this is a simplified version). It takes a session type API (such as Kernel from § 2.1) as a generic type parameter $S$ and returns its corresponding FSM. This FSM can be printed in a variety of formats and passed into the $k$-MC tool for verification.

2.3 Hybrid Approach
Developers may naturally prefer the bottom-up approach since code generation, as used in the top-down approach, can be quite opaque and difficult to understand or debug. Nevertheless, the top-down approach has the advantage of using asynchronous subtyping rather than $k$-MC—analyising the local types for all participants in the protocol at once is challenging to do scalably (see § 4).

Moreover, when a $k$-MC analysis fails, it can be difficult to determine how a developer should update a complex protocol to make it free from deadlocks. Safety by construction, as used in the top-down approach, is easier to work with since verification is done locally on each participant.

Therefore, we also propose a third, hybrid approach (Fig. 1c). In this workflow, a global type $G$ is provided by the developer and projected to obtain the FSMs $M'_{i,1,...,n}$ as before. Rather than the developer proposing the optimised FSMs $M'_{i,1,...,n}$ directly, they instead simply write the APIs $A_{i,1,...,n}$ (as in the bottom-up approach). These are serialised to $M'_{i,1,...,n}$ which can (as in the top-down approach) be checked for safety against $M_{i,1,...,n}$ using asynchronous subtyping. In essence, the hybrid approach uses the same theory as the top-down approach, but presents a more developer-friendly interface that uses serialisation rather than code generation.

We begin by formally defining global and local session types. In the remainder of this section, we will omit sorts $S$ from the syntax to simplify the presentation.

**Definition 1** (Global and local types).

$$
S ::= \text{i32 | u32 | i64 | u64 | ...} \\
G ::= \text{end | p \rightarrow q : \{f_i(S_i) G_{1,1} | } \mu \text{T.G} | t \\
T ::= \text{end | } \oplus \text{int} p!f_i(S_i) T_i | \& \text{int} p?f_i(S_i) T_i | \mu \text{T.G} | t
$$

where $\oplus \text{int} p!f_i(S_i) T_i$ and $\& \text{int} p?f_i(S_i) T_i$ represent internal and external choices respectively where ! and ? denote send and receive respectively, and all $f_i$ are pairwise distinct.

Defining sound message reordering is non-trivial since it may introduce deadlocks, as shown in the example below.

**Example 2** (Correct/incorrect AMR). Consider the following local types

$$
T_Q = p?f_1.p|f_2.end \quad T_P = q!f_1.q?f_2.end
$$

which are given by projecting a global type

$$p \rightarrow q : \{f_1.q \rightarrow p : \{f_2.end\}\}
$$

Reordering the actions of $q$ to become $T_Q' = p|f_2.p?q\end{f_1}$, first sending before receiving, retains deadlock-freedom as messages are stored in queues and their reception can be delayed. However, if instead we reorder $p$’s interactions to become $T_P' = q?f_2.q?f_1\end{f_2.end}$, we arrive at a deadlock since both processes are simultaneously expecting to receive a message that has not yet been sent.

3.1 Precise Asynchronous Multiparty Session Subtyping

**Multiparty session subtyping** formulates refinement for communication protocols with more than two communicating processes. A process implementing a session type $T$ can be safely used whenever a process implementing one of its supertypes $T'$ is expected. This applies in any context, ensuring that no deadlocks or other communication errors will be introduced. Replacing the implementation of $T'$ with that of the subtype $T$ may allow for more optimised communication patterns as we have seen. Ghilezan et al. [25] present the precise asynchronous subtyping relation $\preceq$ for multiparty session processes. Precision is characterised by both soundness (safe process replacement is guaranteed) and completeness (any extension of the relation is unsound).

Crucially, asynchronous subtyping supports the optimisation of communications. Under certain conditions, the subtype can anticipate some input/output actions occurring in the supertype, performing them *earlier* than prescribed to achieve the most flexible and precise subtyping. Such reorderings can take two forms:

- **R1.** anticipating an input from participant $p$ before a finite number of inputs that are not from $p$; or
- **R2.** anticipating an output to $p$ before a finite number of outputs that are not to $p$. Note that such reorderings must be safe to perform.
R2. anticipating an output to participant p before a finite number of inputs (from any participant), and also before other outputs that are not to p.

To denote such reorderings, two kinds of finite sequences of inputs/outputs are defined by [25], where p ≠ q. \( A^{(p)} \) is a sequence containing receives from participants apart from p; \( B^{(p)} \) is a sequence containing receives from any participant (r = p is allowed) and sends to participants apart from p.

\[
A^{(p)} := q|t | A^{(p)} \quad B^{(p)} := r|t | B^{(p)} \quad q|t \]

The tree refinement relation \( \subseteq \) is defined coinductively on infinite session type trees that contain only single-inputs (SI) and single-outputs (SO). We leave the formal definition of \( \subseteq \) in [25] and shall explain its essence with our sound algorithm. Based on \( \subseteq \), the subtyping relation \( \leq \) for all types (including internal and external choice) is given as

\[
\forall U \in \llbracket T \rrbracket_{sO} \forall V' \in \llbracket T' \rrbracket_{sI} \exists W' \in \llbracket U \rrbracket_{sI} \exists W \subseteq W' \quad T \leq T'
\]

where \( \llbracket T \rrbracket_{sO} \) (resp. \( \llbracket T \rrbracket_{sI} \)) is the minimal set of trees containing only single outputs (resp. inputs) of the session type tree \( T \). Using existential quantifiers for \( \llbracket U \rrbracket_{sI} \) and \( \llbracket V' \rrbracket_{sO} \) allows external choices to be added and internal choices to be removed (see the Appendix B.2.1 for examples of \( \subseteq \)).

3.2 Our Algorithm

The precise asynchronous subtyping in [25] is undecidable—even when limited to two participants, as proven in [42]. This subsection introduces our practical algorithm which is sound and terminates, through the use of a bound on recursion.

**Prefixes.** We first define reduction rules for finite single-input and single-output (SISO) session type prefixes.

**Definition 3.** (Prefix reduction) Let us define the syntax of prefixes as \( \pi, \rho := \varepsilon | \pi | \rho \pi | \pi \rho | \pi_{1} \pi_{2} \) where “\( \rho \)” denotes the concatenation operator. We define the reduction \( \pi \rightarrow \pi' \) as the smallest relation that ensures

\[
[-\varepsilon] \quad \langle \pi \epsilon \rangle \rightarrow \langle \pi \rangle
\]

\[
[-\rho] \quad \langle \pi \rho \rangle \rightarrow \langle \pi \rangle
\]

\[
[-A] \quad \langle t \pi \rangle \rightarrow \langle t \rangle A^{(p)}
\]

\[
[-B] \quad \langle t \pi \rangle B^{(p)} \rightarrow \langle t \rangle B^{(p)}
\]

\([-\varepsilon] \) and \([-\rho] \) erase the top input and output prefixes respectively; \([-A] \) formalises R1 from §3.1 (permuting the input \( p|\ell \)) while \([-B] \) represents R2 (permuting the output \( p|\ell \)).

**Example 4.** (Prefix reduction) In Example 2, We can consider both \( T_{Q} \) and \( T_{P} \) as prefixes since they already contain no choice. The (safe) reordering \( T_{Q} \) can be achieved using \([-B] \), where \( B^{(p)} = p|\ell_{1} \):

\[
\langle p|\ell_{2}, p|\ell_{1} \rangle \rightarrow \langle p|\ell_{1}, p|\ell_{2} \rangle
\]

On the other hand, the (unsafe) reordering \( T_{P} \) cannot be achieved with \([-A] \), since \( A^{(q)} = q|\ell_{1} \) violates the definition of \( A^{(q)} \).

![Figure 5. Asynchronous subtyping algorithm rules.](image-url)
left to check and we terminate with success ([END]). (2) If \( \langle \pi \parallel T \rangle \leq \langle \pi' \parallel T' \rangle \) is already in our set of assumptions, then we perform a check on \( \pi' \) to ensure that no actions have been forgotten by the subtype (see the Appendix B.3 for more detail). If this check passes, then we terminate with success ([ASM]). (3) We attempt to reduce the pair of prefixes \( \langle \pi \parallel \pi' \rangle \). If we can, then the algorithm repeats from (1) ([SUB]). (4) If not, we try to pop one action from the start of both \( T \) and \( T' \) and push them to the end of \( \pi \) and \( \pi' \) respectively. If this is possible, we repeat from (1) ([OLD, O Ole, O ILO]). Note that the quantifiers permit subtyping for internal and external choices. For example, \([oo]\) says \( T \) is a subtype of \( T' \) if it has a subset of \( T' \)'s internal choices (defined with \( \forall i \in I, \exists j \in J \)). (5) Otherwise, we attempt to unroll recursion in \( T \) (resp. \( T' \)), decrement the bound \( n \) (resp. \( n' \)) by one and repeat from (1). If the bound is already zero, we instead terminate ([μL, μR]).

**Double buffering example.** We show the execution of our algorithm to check the optimised type from § 2 for the kernel in the double buffering protocol (i.e. \( T \leq T' \)).

See also the Appendix B.4 for the ring and alternating bit protocols, which include internal and external choices.

**Properties.** We prove the correctness and complexity of our algorithm. See the Appendix B for the proofs. We define the size of prefixes as \(|\pi| = 0\) and \(|\pi? t. \pi| = |\pi? t. \pi| = 1 + |\pi|\).

**Lemma 5.** Given finite prefixes \( \pi \) and \( \pi' \), \( \langle \pi \parallel \pi' \rangle \) can be reduced only a finite number of times.

**Theorem 6 (Termination).** Our subtyping algorithm always eventually terminates.

**Theorem 7 (Soundness).** Our subtyping algorithm is sound.

**Lemma 8.** Given finite prefixes \( \pi \) and \( \pi' \), the time complexity of reducing \( \langle \pi \parallel \pi' \rangle \) is \( O(\min(|\pi|, |\pi'|)) \).

**Theorem 9 (Complexity).** Consider \( T \) and \( T' \) as (possibly infinite) trees \( T \) and \( T' \) with asymptotic branching factors \( b \) and \( b' \) respectively [21, 39]. Our algorithm has time complexity \( O(n \min(b, b')^n) \) and space complexity \( O(n \min(b, b')) \) in the worst case to determine if \( T \leq T' \) with bound \( n \).

**Algorithm implementation.** In practice, we make some minor alterations to the algorithm when implementing it in Rumpsteak. As outlined in § 2, Rumpsteak acts on FSMS rather than local types so we modify our bounds-checking accordingly. We also represent prefixes as lazily-removable lists for greater memory efficiency—this additionally allows a slightly simplified termination condition in the case of [ASM]. Finally, we provide some opportunities for the algorithm to "short circuit" in cases where we can tell early that a subtype is not valid. See the Appendix B.5 for more details.

## 4 Evaluation

In this section, we evaluate how Rumpsteak performs with respect to existing tools. First, in § 4.1, we evaluate the runtime performance of programs written in Rumpsteak versus the same benchmarks implemented using other Rust session type tools. In the spirit of Rust’s emphasis on efficiency, this runtime performance is of particular significance for developers. Secondly, in § 4.2, we evaluate how Rumpsteak’s verification of message reordering (our subtyping algorithm) scales compared to existing verification tools. Although not a runtime cost, subtyping is known to be a computationally challenging problem that often scales poorly.

### 4.1 Session-Based Rust Implementations

We compare Rumpsteak’s runtime against three other session type implementations in Rust: (1) Sesh [38], a synchronous implementation of binary session types; (2) Ferraite [12], an implementation of shared binary session types [5] supporting asynchronous execution; and (3) Multicrusty [41], a synchronous MPST implementation based on Sesh.

We perform a series of benchmarks shown in Fig. 6. We execute these using a 16-core AMD Opteron™ 6200 Series
We benchmark the protocol by varying the number of `G` version. 1.11.0 of the Tokio library [60].

18.04.5 LTS and Rust Nightly 2021-07-06. We use version 0.3.5 of the Criterion.rs library [27] to perform microbenchmarking and a multi-threaded asynchronous runtime from version 1.11.0 of the Tokio library [60].

**Streaming.** This protocol has two participants, a source `s` and a sink `t`, with a combination of recursion and choice. As stated previously, its global type `GST` is given as

\[
GST = \mu x.t \rightarrow s : \{\text{ready.s} \rightarrow t : \{\text{value.x}, \text{stop.end}\}\}
\]

We benchmark the protocol by varying the number of values that are sent before the exchange stops. We use AMR to create an optimised version for Rumpsteak: if the source knows it will send at least `n` values before stopping, then these messages can be unrolled and sent all at once—only receiving `ready` from the sink after sending all `n` values. For benchmarking, we unroll the first 5 values in the optimised version.

Our results show Rumpsteak reaches around 14.5x the throughput of other implementations. At first, it is limited by channel creation overheads, the cost of which becomes less significant as more messages are sent. The throughput levels off as message passing overheads become the bottleneck. The optimised version eases this overhead, as the source is less frequently blocked on receiving `ready` from the sink—this effect could be increased by unrolling more messages.

Sesh and MultiCrusty have much lower throughputs since they use more expensive synchronous communication. These implementations also create a new channel for each interaction. This causes their throughput to stay constant as there are fewer one-time costs to spread than in Rumpsteak. Interestingly, Ferrite performs similarly to Sesh and MultiCrusty, despite employing asynchronous execution like Rumpsteak. This is because its design requires that the source and sink are implemented using recursion rather than iteration. Ferrite also requires particularly strong safety requirements at compile time. Therefore, the sink’s output buffer must be guarded with a mutex instead of being accessed directly.

### Double Buffering
We benchmark our running example by performing only two iterations. This allows for both of the kernel’s buffers to be filled and, importantly, for the protocol to terminate. Sesh and Ferrite do not support MPST so their implementations use binary session types between pairs of participants. This approach does not provide the same safety as MPST and so we cannot verify deadlock-freedom as we can in MultiCrusty and Rumpsteak (see Table 1).

We parameterise the size of the buffers and measure the throughput. Performance is similar to that of the stream benchmark; Rumpsteak’s throughput reaches around 3.2x that of the others. Moreover, we confirm the intuition described in §1. Increasing the size of the buffers does generally improve throughput. However, it remains limited when only a single buffer can be used at once. Fig. 6 shows that optimising the kernel as described in §2 increases the throughput since the source and sink operate on different buffers at once.

### FFT
The fast Fourier transform (FFT) is an algorithm for computing the discrete Fourier transform of a vector. We take `n x 8 matrices`, where the FFT is computed on each column to produce a new, transformed matrix, and implement the Cooley-Tukey FFT algorithm which divides the problem into—in our case—eight. Each of these problems can be solved independently by different processes, which communicate with one another using message passing. The exchanges between participants are described in [11, Fig. 7].

We have chosen to use FFT as a benchmark as it is a standard problem with numerous implementations, and we can therefore compare implementations based on MPST with actual high-optimised implementations.

We implement a concurrent version of the algorithm in Sesh, Ferrite, MultiCrusty and Rumpsteak, which uses eight processes. Each process works on an array of `n` inputs, representing one column. Arithmetic operations are performed in a pairwise fashion on two of these arrays.

We use the same approach as in the double buffering protocol to write the binary implementations for Sesh and Ferrite. Interestingly, to represent this as a sequence of binary

---

**Figure 6.** Benchmarking Rumpsteak’s runtime performance against previous work in Rust (raw data in the Appendix C.1).
they are unable to guarantee deadlock-freedom in protocols with more than two participants. MultiCrusty has greater expressiveness than SESH and Ferrite since it implements MPST but, unlike Rumpsteak, still cannot ensure deadlock-freedom for protocols optimised using AMR. In addition, many optimisations, like the ones we have benchmarked, break duality between pairs of participants so are not expressible at all by SESH, Ferrite and MultiCrusty. Meanwhile, our powerful API and new subtyping algorithm allow Rumpsteak to express many examples using AMR.

4.2 Verifying Asynchronous Message Reordering

We perform a second set of benchmarks, shown in Fig. 7, to evaluate Rumpsteak’s asynchronous subtyping algorithm. We compare it against (1) SoundBinary [7], a sound subtyping algorithm defined for binary session types only; and (2) k-MC [43], an algorithm for directly checking the compatibility of a set of FSMs without the need for a global type. Compatibility is checked up to a bound $k$ on the size of each process’ asynchronous queue. We note that neither SoundBinary nor k-MC provide a runtime framework like Rumpsteak does, they are used only to verify the AMR.

We benchmark with the same machine as before. SoundBinary and k-MC are written in Haskell so we must run each tool’s binary rather than simply timing Rust functions. We, therefore, provide a command-line for Rumpsteak’s subtyping algorithm so it is comparable with these other tools. Rumpsteak’s binary is compiled with Rust 1.54.0 and we use Hyperfine [51] to compare the execution time for each tool.

Streaming (from § 4.1). We vary $n$, the number of values we unroll. Using SoundBinary and Rumpsteak, we check

| Protocol                  | $n$ | C | R | IR | AMR | SESH | Ferrite | MultiCrusty | Rumpsteak | k-MC | SoundBinary |
|---------------------------|-----|---|---|----|-----|------|---------|-------------|-----------|------|-------------|
| Two Adder [2]             | 2   | ✓ | ✓ | ✓  |     | ✓    | ✓       | ✓           | ✓         | ✓    | ✓           |
| Three Adder               | 3   |   |   |    |     |      |         |             |           |      |             |

- $n$: Number of participants
- C: Choice
- R: Recursion
- IR: Infinite recursion
- AMR: Asynchronous message reordering
- ✓: Expressible
- x: Expressible using endpoint types (but without deadlock-freedom guarantee)
- ✗: Not expressible

Table 1. Expressiveness of Rumpsteak compared to previous work.

sessions, we require additional synchronisation of all participants at each stage of the protocol. While we can perform AMR to Rumpsteak’s version, in practice we found that this does not have much effect since the protocol is already heavily synchronised so cannot progress any faster.

We benchmark the protocol by varying the number of columns in the matrix. We also compare these implementations with the most downloaded open-source Rust FFT implementation, RustFFT [61]. RustFFT does not use concurrency and computes the FFT of a matrix by iteratively performing the Cooley-Tukey algorithm on each column.

Ferrite performs better than before since its FFT implementation does not suffer from the limitations explained previously. Like Rumpsteak, it benefits from the use of asynchronous execution, although the additional synchronisation from representing the problem as a set of binary sessions causes Rumpsteak’s throughput to remain around 1.9x greater.

Most excitingly, Rumpsteak achieves RustFFT’s throughput for large matrices. RustFFT’s implementation is highly tuned for low-level efficiency and does not incur any overheads associated with message passing. Moreover, asynchronous executors are generally designed for higher-level tasks such as networking; MPI-based communication [44] would more likely be used to parallelise this problem in practice. Therefore, we think it impressive that even a basic parallel implementation using Rumpsteak can reach the same performance as a state-of-the-art sequential implementation.

Expressiveness. Table 1 discusses the expressiveness of Rumpsteak compared with SESH, Ferrite and MultiCrusty. Since SESH and Ferrite support only binary session types, they are unable to guarantee deadlock-freedom in protocols with more than two participants. MultiCrusty has greater expressiveness than SESH and Ferrite since it implements MPST but, unlike Rumpsteak, still cannot ensure deadlock-freedom for protocols optimised using AMR. In addition, many optimisations, like the ones we have benchmarked, break duality between pairs of participants so are not expressible at all by SESH, Ferrite and MultiCrusty. Meanwhile, our powerful API and new subtyping algorithm allow Rumpsteak to express many examples using AMR.
that the optimised source is a subtype of its projected version and, using k-MC, we check that the optimised source is compatible with the sink. Our results show that Rumpsteak scales significantly better than both SoundBinary and k-MC. While all three implementations can verify up to 100 unrolls in under a second, the execution time taken by SoundBinary and k-MC increases exponentially while Rumpsteak’s remains mostly flat. This is consistent with our complexity analysis in Theorem 9, since unrolling more values does not increase the branching factor of the subtype.

**Nested choice.** We next consider a protocol from Chen et al. [13, Fig. 3] containing nested choice. We perform this nesting up to a parameterised number of levels \( n \) to increase the complexity. Specifically, we check that \( T_n \leq T_n' \) where

\[
T_0 = T_0' = \text{end}
\]

\[
T_{n+1} = !m.(!r.T_n \& \& s.T_n \& \& u.T_n) \oplus !p.(!r.T_n \& \& s.T_n)
\]

\[
T_{n+1}' = !r.((!m.T_n' \oplus !p.T_n' \oplus !q.T_n') \& \& s.(!m.T_n' \oplus !p.T_n')
\]

We find that Rumpsteak again performs more scalably than SoundBinary and k-MC. Here, Rumpsteak’s improved efficiency is significant—for five levels, k-MC takes around 40s while Rumpsteak requires only a fraction of a second. Nonetheless, we observe that Rumpsteak also exhibits exponential performance, in contrast to our stream benchmark. This is because our algorithm bounds recursion but not choice, causing an explosion in the paths to visit as the number of nested choices increases. This is also explained by our complexity analysis in Theorem 9 since a greater number of nested choices increases the depth to which we must explore.

**Ring [11].** We consider a ring protocol with a parameterised number of participants. Each participant (aside from the first, which initiates the protocol) receives a value from its preceding neighbour then sends a value to its succeeding neighbour. Providing that this receive is not dependent on the send, we can use AMR to send before receiving.

We benchmark verifying this optimisation using both k-MC and Rumpsteak. In this case, we cannot use SoundBinary since the protocol is multiparty. While Rumpsteak can verify each participant’s subtype individually, k-MC must consider the entire protocol at once. Unsurprisingly, k-MC is significantly less scalable as its running time grows exponentially, whereas Rumpsteak’s performance remains mostly constant.

**k-buffering.** We extend the double buffering protocol to a parameterised number of buffers. We benchmark verifying the optimisation to the kernel discussed previously. Crucially, with a greater number of buffers, we can unroll a greater number of ready messages. We again compare only k-MC and Rumpsteak since the protocol is multiparty. Similarly to other benchmarks, Rumpsteak scales more efficiently than k-MC.

**Expressiveness.** Table 1 discusses the expressiveness of Rumpsteak’s algorithm against SoundBinary and k-MC (note again that SoundBinary and k-MC only verify AMR and do not provide language implementations like Rumpsteak). As we discussed, SoundBinary supports only two parties so cannot express many of the case studies. However, it can express some unbounded binary protocols that Rumpsteak and k-MC cannot, such as the Hospital example [7, §1]. Unsurprisingly, k-MC’s expressiveness in the table coincides with Rumpsteak’s as k-MC with \( k=\infty \) is equivalent to the liveness property induced by asynchronous multiparty subtyping [25, Theorem 7.3]. On the other hand, k-MC can verify a wider syntax of local FSMs than those corresponding to Definition 1.

5 Conclusion and Related Work

There are a vast number of studies on session types, some of which are implemented in programming languages [4] and tools [24]. The top-down approach using Scribble [2, 55, 63] we presented in this paper has been implemented for a number of other programming languages such as Java [31, 32, 40], Go [10], TypeScript [45], Scala [54], MPI-C [49], Erlang [47], Python [18], F# [46], F [64] and Actor DSL [26]. Several implementations use an EFMS-based approach to generate

---

1. Notice, for the case of Rumpsteak, that we can manually write the endpoints, and the framework checks the conformance to the protocol. However, Rumpsteak cannot verify the deadlock-freedom property of the protocol, hence the amber cross.
APIs from Scribble for target programming languages such as [10, 31, 32, 45, 46, 54, 64] to ensure correctness by construction, but none are integrated with AMR like Rumpsteak.

Rumpsteak provides three approaches for gaining efficiency and ensuring deadlock-freedom in message-passing Rust applications: (1) the top-down approach for ensuring correctness/safety by construction and maximising asynchrony with local analysis; (2) the bottom-up approach using global analysis on a set of FSMs; and (3) the hybrid approach, which combines inference with local analysis. All three approaches are backed by Rumpsteak’s API (described in § 2), which uses Rust’s affine type system to ensure protocol compliance.

Note that Rumpsteak is the first framework (for any programming language) to enable the bottom-up (by integrating with k-MC [43]) and the hybrid approaches.

Rust session type implementations. We closely compared the performance and expressiveness of Rumpsteak with three existing works in § 4: (1) Sesh [38], a synchronous implementation of binary session types; (2) Ferrite [12], an implementation of shared binary session types [5] supporting asynchronous execution; and (3) MultiCrusty [41], a synchronous MPST implementation based on Sesh.

Of these previous implementations, only MultiCrusty can also support MPST with deadlock-freedom. However, to represent a multiparty session, MultiCrusty requires defining a tuple of binary sessions for each role as well as their order of use. This leads to a more complex and less intuitive API than Rumpsteak’s. Our API requires fewer definitions and is also both more expressive and performant (see § 4).

Rumpsteak and Ferrite support asynchronous execution, which is more efficient than the synchronous and blocking communication used by Sesh and MultiCrusty. However, only Rumpsteak supports Rust’s idiomatic async/await syntax. Ferrite instead requires nesting sequential communication, which is more verbose and less efficient. Iteration cannot be easily expressed (see § 4) and it requires stricter compile-time concurrency guarantees than Rumpsteak. We do not compare directly against [34] (another synchronous implementation of binary session types) as this uses an older edition of Rust and has several limitations already discussed in [38, 41].

Rumpsteak can perform AMR, which is not possible in any of these existing implementations. Combined with its straightforward design and use of asynchronous execution, we found that it is therefore much more efficient than all previous work. It has around 14.5x, 3.2x and 1.9x greater throughput than the next fastest implementation in the stream, double buffering and FFT protocols respectively. Rumpsteak can also compete with a popular Rust implementation in the FFT benchmark, achieving the same throughput for large input sizes.

Recent work [20] builds a DSL to offer protocol conformance for Rust, supported by typestates. They do not yet explore combining the DSL with communication channels like Rumpsteak and [5, 34, 38, 41]. If this is achieved, it would be interesting to integrate session type tooling with their DSL and compare this with Rumpsteak.

Verification of asynchronous subtyping. Interest in AMR has grown recently, both in theory and practice. An extension of the Iris framework, Actris [35], formalises a variant of binary asynchronous subtyping, which is in turn implemented in the Coq proof assistant. The asynchronous session subtyping defined in [13, 25] is precise but was shown to be undecidable, even for binary sessions [9, 42]. Hence, in general, checking $M_1 \leq M_2$ is undecidable. Various limited classes of session types for which $M_1 \leq M_2$ is decidable [7, 8, 11, 42] are proposed but they are not applicable to our use cases since (1) the relations in [7, 9, 42] are binary and the same limitations do not work for multiparty sessions; and (2) the relation in [11, Def. 6.1] does not handle subtyping across unrolling recursions, e.g. the relation is inapplicable to the double buffering algorithm [33] (see [11, Remark 8.1]).

Our new algorithm for asynchronous optimisation is terminating (see Theorem 6), sound (see Theorem 7) and capable of verifying optimisations in a range of classical examples (see § 4). It is also more performant than a global analysis based on k-MC, and an existing two-party sound algorithm [7] (see § 4). This is because our algorithm is implemented efficiently (see § 3.2) and can often execute in linear rather than exponential time (see Theorem 9).

Deadlock detection. There is also recent progress [52, 53] on static deadlock detection in Rust by tracking locks and unlocks in Rust’s intermediate representation (MIR) [59]. This targets shared memory, rather than message-passing applications, and does not attempt safety by construction. In future work, we could also analyse the MIR directly in Rumpsteak, replacing the use of our API. However, it is difficult to identify concurrency primitives in the MIR (this would be made harder with async/await); [52] currently supports only three concurrent data structures from Rust’s ecosystem.

Acknowledgments

We thank (in alphabetical order) Julia Gabet, Paul Kelly, Roland Kuhn, Nicolas Lagaillardie, Julien Lange, and Fangyi Zhou, for their valuable proofreading, feedback and advice on early versions of this work. We also thank the PPoPP reviewers for the helpful comments in their reviews.

A Artifact

A.1 Content of the artifact

The artifact contains the following files:

|-- Artifact.md
|-- Artifact.pdf
|-- Dockerfile
|-- gen_fig_6.sh
|-- gen_fig_7.sh
|-- getting_started.sh

Note that an internet connection is required to use the artifact.

A.2 Getting started guide (Docker artifact)

In this subsection, we will run the benchmarks used to produce Figs. 6 and 7 of the paper in a Docker container. At the end of this section, you should have all the plots of those figures.

Note that the benchmark results may not match those in Figs. 6 and 7 when run in a Docker container or a machine with different specification than used in the paper. See the subsection on Claims supported or not by the artifact for more discussion of this.

To run the getting started guide, we assume you are running a Linux machine with Docker and Gnuplot installed, as well as standard Unix tools (tail, awk, cut, etc.).

This Getting started subsection is fully automated: extract the archive and run the getting_started.sh script. The script takes a long time to run all the benchmarks. On the author’s laptop, it took approximately 2 hours and 15 minutes. When the script finishes, you should have a few *.png plots which correspond to the plots shown in Figs. 6 and 7 of the paper.

1 $ cd /path/to/extracted/artifact/
2 $ ./getting_started.sh

Once run, to clean-up your system, in addition to removing the archive folder, you should remove the docker image (the following command assumes you don’t have other docker images/containers on your system):

1 $ docker rmi rumpsteak_tool
2 $ docker system prune

A.2.1 Output. The getting_started.sh generates figures similar to the one used in the paper.

We show in Fig. 8 the figures fft.png and ring.png that are the equivalent of Fig. 6 (subfigure FFT) and Fig. 7 (subfigure Ring) in the paper.

A.2.2 Analysing the raw data.

They are not exactly the same in the sense that they are not produced by the same tool (Tikz vs. Gnuplot), but the data they use is produced similarly.

Figure 8. Two examples of the figures generated. Note that those figure are obtain from a different run of the artifact, in a lower-end computer, which explains the differences with figures presented in the paper.

Figure 9. The files created by the Criterion benchmark (in results/criterion/). A detailed report is available by viewing index.html in a browser.

Runtime benchmarks. The results used to generate Fig. 6 are generated with Criterion. Criterion produces the tree of files shown in Fig. 9. The report can be viewed in a web browser.

Subtyping benchmarks. Hyperfine generates a CSV file (located at results/data/*/*.csv) for the results of each benchmark. For each row, this file contains

1. command: the actual command that was run;
2. mean: the mean time to execute the command;
3. stddev: the standard deviation of executing the command;
4. median: the median time to execute the command;
5. user: the mean user time to run the command;
6. system: the mean system time to run the command;
7. min: the minimum time to run the command;
8. max: the maximum time to run the command; and
9. parameter_n: the value of the parameter used in the command

where all times are given in seconds. Since we do not care about execution time spent in the kernel (all relevant computation is done in user space) we take only the timings
in the user column. We provide a script to plot the mean user execution time against the parameter value for each tool.

A.3 Claims supported or not by the artifact

A.3.1 Claims supported by the artifact.
- Results presented in Fig. 7 are fairly stable across different machines, even when run in Docker. One should expect to obtain similar plots on their machine.

A.3.2 Claims partially supported by the artifact.
- Results presented in Fig. 6 are quite dependent on the number of cores provided by the machine and on other programs being run on the machine simultaneously. The results presented in the paper are run on a 16-core AMD Opteron 6200 Series at 2.6GHz with hyperthreading and 128GB of RAM. Attempts run on lower-end processors or from within a Docker container may not provide similar results (in particular, the rustfft implementation is highly optimised for sequential execution and outperforms approaches based on message passing on processors with fewer cores). Nonetheless, the performance of Rumpsteak vs. other MPST implementations would remain mostly comparable.

A.3.3 Claims not supported by the artifact.
- NuScr is an external tool not contributed by the authors, and therefore not part of the claims of the paper.

B Multiparty Asynchronous Subtyping

In the main paper, we mentioned a few definitions from [25] that we omitted due to space constraints. We explain these in the first section of this appendix. In the later sections, we provide examples of the rules shown in the paper, as well as proofs of the theorems stated. Finally, we provide more details on its implementation.

B.1 Synchronous session subtyping

We first give the rules for synchronous session subtyping given by Chen et al. [13] in Fig. A.10. The relation $\leq$ on sorts is defined as the least reflexive binary relation such that $\text{nat} \leq: \text{int} [25]$.

\begin{align*}
\text{end} \leq \text{end} & \quad \text{[SUB-END]} \\
\forall i \in I & \quad S_i \leq S'_i, T_i \leq T'_i & \quad \text{[SUB-BRA]} \\
\& \quad i \notin I & \quad p?t_i.T_i \leq & \quad \& \quad i \notin I & \quad p?t_i.T_i & \quad \text{[SUB-SEL]}
\end{align*}

Figure A.10. Subtyping rules for synchronous session types.

B.2 Precise Asynchronous Multiparty Subtyping

Asynchronous subtyping is more complex as it allows the order of operations to be swapped for efficiency. The tree refinement relation $\lessapprox$ is defined coinductively on session types that have only single-inputs (SI) and single-outputs (SO). It is specified for type trees, which are possibly infinite trees representing a session type. An example of a type tree is given in Fig. A.13 and the tree refinement relation by Ghilezan et al. [25] is given in Fig. A.11. The function act($W$), the set of input and output actions in a tree $W$, is defined in Fig. A.12.

Single-input and single-output types are session types which do not include branching, i.e. a type generated from the grammar (Ghilezan et al. [25]) $T := \text{end} \mid p?t.T \mid p!t.T$.

Remark. As mentioned in [25], checking the set of actions $\text{act}(W)$ for the grammar (Ghilezan et al. [25]) is given in Fig. A.11. The function $\text{act}(W)$, the set of input and output actions in a tree $W$, is defined in Fig. A.12.

Asynchronous subtyping is more complex as it allows the order of operations to be swapped for efficiency. The tree refinement relation $\lessapprox$ is defined coinductively on session types that have only single-inputs (SI) and single-outputs (SO). It is specified for type trees, which are possibly infinite trees representing a session type. An example of a type tree is given in Fig. A.13 and the tree refinement relation by Ghilezan et al. [25] is given in Fig. A.11. The function act($W$), the set of input and output actions in a tree $W$, is defined in Fig. A.12.

Single-input and single-output types are session types which do not include branching, i.e. a type generated from the grammar (Ghilezan et al. [25]) $T := \text{end} \mid p?t.T \mid p!t.T$.

\[ T \leq \text{act}(W) \]

Asynchronous subtyping is more complex as it allows the order of operations to be swapped for efficiency. The tree refinement relation $\lessapprox$ is defined coinductively on session types that have only single-inputs (SI) and single-outputs (SO). It is specified for type trees, which are possibly infinite trees representing a session type. An example of a type tree is given in Fig. A.13 and the tree refinement relation by Ghilezan et al. [25] is given in Fig. A.11. The function act($W$), the set of input and output actions in a tree $W$, is defined in Fig. A.12.

Single-input and single-output types are session types which do not include branching, i.e. a type generated from the grammar (Ghilezan et al. [25]) $T := \text{end} \mid p?t.T \mid p!t.T$.

\[ T \leq \text{act}(W) \]

B.2 Precise Asynchronous Multiparty Subtyping

Asynchronous subtyping is more complex as it allows the order of operations to be swapped for efficiency. The tree refinement relation $\lessapprox$ is defined coinductively on session types that have only single-inputs (SI) and single-outputs (SO). It is specified for type trees, which are possibly infinite trees representing a session type. An example of a type tree is given in Fig. A.13 and the tree refinement relation by Ghilezan et al. [25] is given in Fig. A.11. The function act($W$), the set of input and output actions in a tree $W$, is defined in Fig. A.12.

Single-input and single-output types are session types which do not include branching, i.e. a type generated from the grammar (Ghilezan et al. [25]) $T := \text{end} \mid p?t.T \mid p!t.T$.

\[ T \leq \text{act}(W) \]

Asynchronous subtyping is more complex as it allows the order of operations to be swapped for efficiency. The tree refinement relation $\lessapprox$ is defined coinductively on session types that have only single-inputs (SI) and single-outputs (SO). It is specified for type trees, which are possibly infinite trees representing a session type. An example of a type tree is given in Fig. A.13 and the tree refinement relation by Ghilezan et al. [25] is given in Fig. A.11. The function act($W$), the set of input and output actions in a tree $W$, is defined in Fig. A.12.

Single-input and single-output types are session types which do not include branching, i.e. a type generated from the grammar (Ghilezan et al. [25]) $T := \text{end} \mid p?t.T \mid p!t.T$.

\[ T \leq \text{act}(W) \]
As before, we consider the tree types \( T = T (T) \) and \( T' = T' (T') \) which are already both SI and SO trees. Therefore, to prove that \( T \leq T' \) we need only to show that \( T \preceq T' \).

\[
T' \preceq W \quad \text{[ref-end]}
\]
\[
t!\text{copy}.T' \preceq t!\text{copy}.W \quad \text{[ref-end]}
\]
\[
t?\text{ready}.t!\text{copy}.T' \preceq t?\text{ready}.t!\text{copy}.W \quad \text{[ref-end]}
\]
\[
s?\text{copy}.t?\text{ready}.t!\text{copy}.T' \preceq s?\text{copy}.t?\text{ready}.t!\text{copy}.W \quad \text{[ref-end]}
\]
\[
s!\text{ready}.W \preceq s?\text{copy}.t?\text{ready}.t!\text{copy}.s!\text{ready}.W \quad \text{[ref-out]}
\]

\[
T = s!\text{ready}.T' \preceq s!\text{ready}.W = T'
\]
\[
W = s?\text{copy}.t?\text{ready}.t!\text{copy}.T'
\]

B.3 Proofs for the Subtyping Algorithm

Lemma 3. Given finite prefixes \( \pi \) and \( \pi' \), \( \langle \pi \parallel \pi' \rangle \) can be reduced only a finite number of times.

Proof. We prove this in a similar style to [22, Lemma 10], using a well-founded relation. We first consider the relation \( R = \{ \langle \langle \pi_1 \parallel \pi'_1 \rangle, \langle \pi_2 \parallel \pi'_2 \rangle \rangle \mid \langle \pi_2 \parallel \pi'_2 \rangle \rightarrow \langle \pi_1 \parallel \pi'_1 \rangle \} \). We define the function \( \text{terms}(\pi) \), which returns the number of terms in \( \pi \), such that

\[
\text{terms}(\epsilon) = 0
\]
\[
\text{terms}(p?\ell(S)) = 1 \quad \text{terms}(p?\ell(S)) = 1
\]
\[
\text{terms}(\pi_1, \pi_2) = \text{terms}(\pi_1) + \text{terms}(\pi_2)
\]

and we define \( \text{terms}(\langle \pi \parallel \pi' \rangle) \) such that \( \text{terms}(\langle \pi \parallel \pi' \rangle) = \langle \text{terms}(\pi) \parallel \text{terms}(\pi') \rangle \). We also define the lexicographical ordering

\[
\langle m \parallel n \rangle < \langle m' \parallel n' \rangle \iff m < m' \text{ or } (m = m' \text{ and } n < n')
\]

We next show that reducing a pair of prefixes decrements the number of terms in the pair by induction over our reduction rules.

\[
(\langle \pi_1 \parallel \pi'_1 \rangle, \langle \pi_2 \parallel \pi'_2 \rangle) \in R \implies \text{terms}(\langle \pi_1 \parallel \pi'_1 \rangle) < \text{terms}(\langle \pi_2 \parallel \pi'_2 \rangle)
\]

• Case [-1]. We have that \( \pi_2 = p?\ell(S) \cdot \pi_1 \) and \( \pi'_2 = p?\ell(S') \cdot \pi'_1 \).
Theorem 4 (Termination). Our subtyping algorithm always eventually terminates.

Proof. We prove termination by arguing that each of our subtyping algorithm rules can be run only a finite number of times.

- \text{[END]} and \text{[ASM]} can be run only once since they are terminating rules.
- \text{[SUB]} can be run only a finite number of times since a pair of prefixes can be reduced only a finite number of times, as proven in Lemma 3.
- \text{[oi]}, \text{[oo]}, \text{[in]} and \text{[io]} can be run only a finite number of times since (1) the number of terms in T and T' is finite and (2) recursion must be explicitly unrolled with \text{[μL]} or \text{[μR]}, which themselves can only be run a finite number of times.

Since \langle \pi_1 \parallel \pi'_1 \rangle \rightarrow \langle \pi_2 \parallel \pi'_2 \rangle, we have that, by definition of R, \((\langle \pi_1 \parallel \pi'_1 \rangle, \langle \pi_2 \parallel \pi'_2 \rangle) \in R\).

As we know that \text{terms}(\pi_1) = \text{terms}(\pi_1) + 1 and \text{terms}(\pi'_1) = \text{terms}(\pi'_1) + 1, we also have that

\[ \text{terms}(\langle \pi_1 \parallel \pi'_1 \rangle) < \text{terms}(\langle \pi_2 \parallel \pi'_2 \rangle) \]

as required.

- Case [-o]. We have that \pi_2 = p?l(S).\pi_1 and \pi'_2 = p?l(S').\pi'_1.

Since \langle \pi_2 \parallel \pi'_2 \rangle \rightarrow \langle \pi_1 \parallel \pi'_1 \rangle, we have that, by definition of R, \((\langle \pi_1 \parallel \pi'_1 \rangle, \langle \pi_2 \parallel \pi'_2 \rangle) \in R\).

As we know that \text{terms}(\pi_1) = \text{terms}(\pi_1) + 1 and \text{terms}(\pi'_1) = \text{terms}(\pi'_1) + 1, we also have that

\[ \text{terms}(\langle \pi_1 \parallel \pi'_1 \rangle) < \text{terms}(\langle \pi_2 \parallel \pi'_2 \rangle) \]

as required.

- Case [-A]. We have that \pi_2 = p?l(S).\pi_1 and \pi'_2 = \mathcal{A}(p).p?l(S').\pi'_1.

Since \langle \pi_2 \parallel \pi'_2 \rangle \rightarrow \langle \pi_1 \parallel \mathcal{A}(p).\pi'_1 \rangle, by definition of R, we have that \((\langle \pi_1 \parallel \mathcal{A}(p).\pi'_1 \rangle, \langle \pi_2 \parallel \pi'_2 \rangle) \in R\).

As we know that \text{terms}(\pi_1) = \text{terms}(\pi_1) + 1 and \text{terms}(\pi'_1) = \text{terms}(\mathcal{A}(p).\pi'_1) + 1, we have that \text{terms}(\langle \pi_1 \parallel \mathcal{A}(p).\pi'_1 \rangle) < \text{terms}(\langle \pi_2 \parallel \pi'_2 \rangle) as required.

- Case [-B]. We have that \pi_2 = p?l(S).\pi_1 and \pi'_2 = \mathcal{B}(p).p?l(S').\pi'_1.

Since \langle \pi_2 \parallel \pi'_2 \rangle \rightarrow \langle \pi_1 \parallel \mathcal{B}(p).\pi'_1 \rangle, by definition of R, we have that \((\langle \pi_1 \parallel \mathcal{B}(p).\pi'_1 \rangle, \langle \pi_2 \parallel \pi'_2 \rangle) \in R\).

As we know that \text{terms}(\pi_1) = \text{terms}(\pi_1) + 1 and \text{terms}(\pi'_1) = \text{terms}(\mathcal{B}(p).\pi'_1) + 1, we have that \text{terms}(\langle \pi_1 \parallel \mathcal{B}(p).\pi'_1 \rangle) < \text{terms}(\langle \pi_2 \parallel \pi'_2 \rangle) as required.

The ordering of terms of pairs is well-founded since both components are bounded from below by 0. Therefore, from Eq. (1), R is also well-founded and so pairs of prefixes cannot be reduced ad infinitum. \qed

Theorem 5 (Soundness). Our subtyping algorithm is sound.

Proof. To prove that our algorithm is sound, we must show that each rule in the precise subtyping by [25] is matched by a rule in our algorithm.

- The subtyping relation rule is matched by [oi], [oo], [in] and [io].
- \text{[REF-END]} is matched by \text{[END]}. Since both prefixes are empty and T = T' = end, we trivially have that \pi.T \leq \pi'.T'.
- The coinductive behaviour of the refinement relation rules is matched by \text{[asm]}. From our map of assumptions \Sigma, we have that \pi.T \leq \pi'.T'.
- \text{[REF-IN]} and \text{[REF-OUT]} are matched by [-i] and [-o] respectively, which can be applied with \text{[sub]}.
- \text{[ref-A]} and \text{[ref-B]} are matched by [-A] and [-B] respectively, which can be applied with \text{[sub]}. To ensure that actions are not forgotten when using coinduction, the refinement relation rules additionally require that the actions of the resulting type trees are equal. Our reduction rules emit this check since they deal only with finite sequences. We instead prevent actions from being forgotten in our \text{[asm]} rule by ensuring that each reordered action in the supertype (which is contained in \pi'_1) is encountered in the recursive part of the subtype (\rho') by using the subset relation.

Ghilezan et al. [25] use the example of checking T = \mu t.p?l.t \leq q?t.T = T' to demonstrate why comparing the actions is necessary—we show how our algorithm also correctly rejects this subtype in Fig. A.14 (with a bound of 2 for brevity).

We cannot apply \text{[asm]} as the final rule since

\[ \text{act}(p?l.end) = \{p?\} \not\subseteq \{q?\} = \text{act}(q?l.end). \]

This subset check spots that the q? action was not present in the recursive part of the supposed subtype. Otherwise, our algorithm would incorrectly conclude that T \leq T'.

It is straightforward to also argue that our algorithm preserves reflexivity. We have that (\epsilon, T, n) \leq (\epsilon, T, n), providing n is sufficiently large to ensure that each recursion can be visited at least once. The prefixes of both sides will always be identical so will reduce to (\epsilon \parallel \epsilon) using [-i] or [-o]. These
reductions will be applied using \([\text{sub}]\) until either end is encountered and \([\text{end}]\) can be applied or the algorithm loops, which allows the application of \([\text{asm}]\).

\(\square\)

**Lemma 6.** Given finite prefixes \(\pi\) and \(\pi'\), the time complexity of reducing \(\langle \pi \parallel \pi' \rangle\) is \(O(\min(|\pi|, |\pi'|))\).

**Proof.** We prove this quite simply by induction over our reduction rules.

- **Inductive case** \(\langle p?I.\pi \parallel p?I.\pi' \rangle\). Then, we can perform a \([-i]\) reduction to get \(\langle \pi \parallel \pi' \rangle\). By the inductive hypothesis, the complexity of reducing \(\langle \pi \parallel \pi' \rangle\) is \(O(\min(|\pi|, |\pi'|))\). Therefore, since we require one additional reduction step, the complexity of reducing \(\langle p?I.\pi \parallel p?I.\pi' \rangle\) is \(O(\min(|\pi|, |\pi'|)+1) = O(\min(|\pi|+1, |\pi'|+1)) = O(\min(|p?I.\pi|, |p?I.\pi'|))\) as required.

- **Inductive case** \(\langle p?I.\pi \parallel p?I.\pi' \rangle\). Then, we can perform a \([-\mathcal{A}]\) reduction to get \(\langle \pi \parallel \mathcal{A}^{(p)}\pi' \rangle\). By the inductive hypothesis, the complexity of reducing \(\langle \pi \parallel \mathcal{A}^{(p)}\pi' \rangle\) is \(O(\min(|\pi|, |\mathcal{A}^{(p)}\pi'|))\). Therefore, since we require one additional reduction step, the complexity of reducing \(\langle p?I.\pi \parallel \mathcal{A}^{(p)}\pi \parallel p?I.\pi' \rangle\) is \(O(\min(|\pi|, |\mathcal{A}^{(p)}\pi'|)+1) = O(\min(|\pi|+1, |\mathcal{A}^{(p)}\pi'|+1)) = O(\min(|p?I.\pi|, |\mathcal{A}^{(p)}\pi'|))\) as required.

- **Inductive case** \(\langle p?I.\pi \parallel B^{(p)}p?I.\pi' \rangle\). The proof is the same as for the \(\langle p?I.\pi \parallel \mathcal{A}^{(p)}\pi \parallel p?I.\pi' \rangle\) case, except a \([-\mathcal{B}]\) reduction is applied.

- **Base case** \(\langle \pi \parallel \pi' \rangle\) where \(\langle \pi \parallel \pi' \rangle\) cannot be reduced. Since \(\forall \pi. |\pi| > 0\), the complexity of reducing \(\langle \pi \parallel \pi' \rangle\) is \(O(0) = O(\min(|\pi|, |\pi'|))\) as required.

\(\square\)

**Theorem 7** (Complexity). Consider \(T\) and \(T'\) as (possibly infinite) trees \(T\) (\(T\)) and \(T'\) (\(T'\)) with asymmetric branching factors \(b\) and \(b'\) respectively \([21, 39]\). Our algorithm has time complexity \(O(n \min(b, b')^n)\) and space complexity \(O(n \min(b, b')^n)\) in the worst case to determine if \(T \leq T'\) with bound \(n\).

**Proof.** Let us consider for now only the left tree \(T\) (\(T\)) which has asymmetric branching factor \(b\). In the worst case, the number of nodes we have to explore in the tree is

\[1 + b + b^2 + \ldots + b^{n-1} = \sum_{i=0}^{n-1} b^i = \frac{b^n - 1}{b - 1}\]

Therefore, exploring the left tree up to a depth of \(n\) has time complexity \(O(b^n)\). Similarly, exploring the right tree \(T'\) (\(T'\)) to depth \(n\) has complexity \(O(b'^n)\). Note that in the worst case we cannot reduce any prefixes as we go along and must therefore do the entire reduction at the end of each exploration path.

Suppose at the end of some exploration path we have the pair of prefixes \(\langle \pi \parallel \pi' \rangle\). Since \(|\pi| = |\pi'|\) (our algorithm does not add an uneven number of terms to either side of the prefix pair), the time complexity of reducing this pair is \(O(\min(|\pi|, |\pi'|)) = O(|\pi|)\) from Lemma 8.

At the end of our exploration, we will have \(b^{n-1}\) prefixes, each with size \(n\). Therefore, the complexity of reducing all the pairs of prefixes is \(O(nb^{n-1})\) so the total complexity for the exploration and reduction is \(O(b^n + nb^{n-1}) = O(nb^n)\).

Our algorithm stops when the bound \(n\) is reached in either of the two trees so the overall time complexity of exploration is \(O(\min(nb^n, nb'^n)) = O(n \min(b, b')^n)\).

Considering space complexity, it is clear that the greatest amount of memory will be required at the end of an exploration path (when the prefixes are greatest in length). For the left tree, at this point, we will need to store (1) a prefix of length \(n\) (since we are considering the worst case); and (2) the other \(b\) siblings to visit at \(n - 1\) levels.

Therefore, the total space complexity for the left tree is \(O(n + b(n - 1)) = O(nb)\) and the space complexity for exploring both trees is \(O(\min(nb, nb')) = O(n \min(b, b'))\).

\(\square\)

**B.4 Algorithm Examples**

**Ring protocol.** We again use the ring protocol with choice and show that our algorithm can successfully check the
We then use our subtyping algorithm to confirm that the type given by the protocol specification for the receiver [1] is a subtype of its projected version. In this derivation, we omit some exploration paths for brevity. The derivation trees are shown in Fig. A.15.

\[
\begin{align*}
 G &= \mu s.t \rightarrow r : \begin{cases}
 d0.r \rightarrow s : \{ a0.m.u.s \rightarrow r : \begin{cases}
 d1.r \rightarrow s : \{ a0.u \} \} \} \} \} \} \\
 &= \mu s.t \rightarrow r.' : \begin{cases}
 a0.m.x.r.' \rightarrow d1.r. : \{ a0.x \} \} \} \} \\
 G \mid s &= \mu r.'!d0.r. : \begin{cases}
 a0.m.x.r.' \rightarrow d1.r. : \{ a0.x \} \} \} \\
 G \mid r &= \mu r.s ? !d0.s. : \begin{cases}
 a0.m.s \rightarrow r : \begin{cases}
 d1.s \rightarrow a.l.t \} \} \} \\
 T &= \mu s.t \rightarrow r : \begin{cases}
 d0.s \rightarrow a.l.t \} \}
 T' &= G \mid r
\end{cases}
\end{cases}
\end{align*}
\]

We then use our subtyping algorithm to confirm that the type given by the protocol specification for the receiver [1] is a subtype of its projected version. In this derivation, we omit some exploration paths for brevity. The derivation tree is in Fig. A.16.

**Alternating bit protocol.** We consider the alternating bit protocol [1]. We construct a global type \( G \) for the protocol such that when projected onto the receiver, its local type matches the protocol specification.

\[
G = \mu s.t \rightarrow r : \begin{cases}
 d0.r \rightarrow s : \{ a0.m.u.s \rightarrow r : \begin{cases}
 d1.r \rightarrow s : \{ a0.u \} \} \} \} \} \\
 a1.t \}
\end{cases}
\]

Elements can be lazily removed either by incrementing start or by setting the element’s boolean to true and adding its index to removed. We favour the first option so as to maintain the invariant

\[
\text{transitions}.\text{len()} > 0 \implies !\text{transitions}[0].0
\]

\[
\begin{align*}
\text{transitions}: & \text{Vec}<(\text{bool}, \text{Transition})>, \\
\text{start}: & \text{usize}, \\
\text{removed}: & \text{Vec}<\text{usize}>
\end{align*}
\]

where the tuple indexing syntax \((x, y).0\) will evaluate to \(x\), the first element of the tuple. To ensure that this invariant holds, we must advance start as far as possible when removing a transition at the head of the prefix.

We also give the option of storing snapshots to previous versions of a prefix. A snapshot stores (1) the size of the transitions list; (2) the value of the start field; and (3) the size of the removed list, all taken at the time of the snapshot.

\[
\begin{align*}
\text{transitions}.\text{len()} > 0 \implies !\text{transitions}[0].0
\end{align*}
\]

\[
\begin{align*}
\text{transitions}: & \text{Vec}<(\text{bool}, \text{Transition})>, \\
\text{start}: & \text{usize}, \\
\text{removed}: & \text{Vec}<\text{usize}>
\end{align*}
\]

We can easily revert a prefix to a previous snapshot by (1) finding the elements of removed that have been added since the snapshot; (2) setting the boolean to false for each of these elements to restore them; (3) truncating transitions to its previous size; (4) restoring start to its previous value; and (5) truncating removed to its previous size.

**Visitor.** We use the visitor pattern [50] to traverse a pair of FSMs \( M \) and \( M' \). In our visitor, we store (1) the fsms we are traversing; (2) a matrix of history (as we will see, this is equivalent to the assumptions map \( \Sigma \) in the theory); and (3) a pair of prefixes, as in the theory.

\[
\begin{align*}
\text{transitions}: & \text{Vec}<(\text{bool}, \text{Transition})>, \\
\text{start}: & \text{usize}, \\
\text{removed}: & \text{Vec}<\text{usize}>
\end{align*}
\]

The history matrix stores a value for each combination of states in \( M \) and \( M' \) (it effectively has the type \(|M| \times |M'| \rightarrow \text{Previous}\)). Each of these values stores a Previous struct containing the number of visits this combination of states has remaining and optionally (if it has been visited before) a pair of snapshots taken during the last visit to this combination.

\[
\begin{align*}
\text{transitions}: & \text{Vec}<(\text{bool}, \text{Transition})>, \\
\text{start}: & \text{usize}, \\
\text{removed}: & \text{Vec}<\text{usize}>
\end{align*}
\]

\[
\begin{align*}
\text{transitions}: & \text{Vec}<(\text{bool}, \text{Transition})>, \\
\text{start}: & \text{usize}, \\
\text{removed}: & \text{Vec}<\text{usize}>
\end{align*}
\]
\[
\begin{align*}
\text{(⋆) } & \quad \rho_3; \Sigma_2 \vdash \langle \text{c!} \text{add} \cdot \text{a?add} \cdot \text{T}, 0 \rangle \leq \langle \text{a?add} \cdot \text{c!} \text{sub} \cdot \text{T}', 0 \rangle \\
\rho_1; \Sigma_2 \vdash \langle \text{c!} \text{add} \cdot \text{a?add} \cdot \text{T}, 0 \rangle \leq \langle \text{a?add} \cdot \text{c!} \text{add} \cdot \text{T}', 0 \rangle \\
\rho_4; \Sigma_2 \vdash \langle \text{c!} \text{sub} \cdot \text{a?add} \cdot \text{T}, 0 \rangle \leq \langle \text{a?add} \cdot \text{c!} \text{add} \cdot \text{T}', 0 \rangle \\
\end{align*}
\]

\[
\begin{align*}
\text{[●]} & \quad \rho_3; \Sigma_2 \vdash \langle \text{c!} \text{add} \cdot \text{a?add} \cdot \text{T}, 0 \rangle \leq \langle \text{a?add} \cdot \text{c!} \text{sub} \cdot \text{T}', 0 \rangle \\
\rho_1; \Sigma_2 \vdash \langle \text{c!} \text{add} \cdot \text{a?add} \cdot \text{T}, 0 \rangle \leq \langle \text{a?add} \cdot \text{c!} \text{add} \cdot \text{T}', 0 \rangle \\
\rho_4; \Sigma_2 \vdash \langle \text{c!} \text{sub} \cdot \text{a?add} \cdot \text{T}, 0 \rangle \leq \langle \text{a?add} \cdot \text{c!} \text{add} \cdot \text{T}', 0 \rangle \\
\rho_1 = \text{c!} \text{add} & \quad \rho_2 = \text{c!} \text{sub} & \quad \rho_3 = \rho_1 \cdot \text{a?add} & \quad \rho_4 = \rho_2 \cdot \text{a?add} \\
\Sigma_1 = \{ \langle \epsilon \parallel \text{T} \rangle \leq \langle \epsilon \parallel \text{T}' \rangle \mapsto \epsilon \} & \quad \Sigma_2 = \{ \langle \epsilon \parallel \text{c!} \text{add} \cdot \text{a?add} \cdot \text{T} \rangle \leq \langle \epsilon \parallel \text{T}' \rangle \mapsto \epsilon \}
\end{align*}
\]

**Figure A.15.** Derivation trees to verify the subtyping of the Ring protocol

In the theory, termination is guaranteed by allowing recursions to be unrolled only \(n\) times. Here, our \('n' \) is the value of visits, which limits how many times the same combination of states can be visited. Since \(M \) and \(M' \) each contain a finite number of states and their cross product is also finite, this will achieve termination just as in the theory (provided that \(n\) is also finite). Otherwise, this is identical to the theory—our history matrix corresponds to the map of assumptions \(\Sigma\) and the Previous struct represents a single mapping (we use snapshots in place of prefixes).

Each state in an Fsm is given a unique StateIndex that identifies it. Our Visitor is executed using its recursive visit method, which takes a mutable reference to the Visitor and a StateIndex for each Fsm.

```rust
impl Visitor {
    fn visit(&mut self, states: Pair<StateIndex>) -> bool {
        [...] // omitted
    }
}
```

This visit method performs our asynchronous subtyping algorithm as follows.

1. We look up the current combination states in our history to ensure visits is positive, as in [●] and [●]. If it is not then our bound has been exhausted and we return false.
2. We attempt to reduce the pair of prefixes, as in [sub]. This reduction process follows precisely the same rules as in the theory, lazily removing transitions where appropriate.
3. If the current combination of states has been visited before, we attempt to use our assumptions map to return true, as in [asm]. The method we use to check the actions sets, explained below, differs slightly from the theory.
4. If both FSMs are in a terminal state and the prefixes are empty then we return true, as in [end].
5. If both FSMs are in a non-terminal state then we
   - take a snapshot of the current prefixes;
   - update the history matrix for the current combination of states, setting visits to visits - 1 and snapshots to the snapshots we just took;
   - for each pair of transitions we can take from the current combination of states we
     - add each transition in the pair to its corresponding prefix;
     - recurse using the visit method, setting the states argument to the pair of end states corresponding...
instance, we would need to store a separate visitor for each
improves the efficiency of our algorithm by avoiding copy-
history

\begin{align*}

Figure A.16. Derivation trees to verify the subtyping of the Alternating-Bit protocol

... to our transitions; and after the recursive call returns

- revert the changes made to the prefixes by using
the snapshot we took previously;
- restore the current history matrix entry to its original value; and
- return a value depending on the results of the recursive calls and whether the current combination of states performs input or output actions, as described by the quantifiers in [[in-out]-[in-out]].

6. Otherwise, one of the FSMs has reached a terminal state but the other has not. In this case, there is no way to progress and we return false.

By performing a depth-first search we can make changes to the history and prefixes fields of our visitor and revert them later, using a snapshot for each prefix. This method improves the efficiency of our algorithm by avoiding copying memory. If we instead used a breadth-first search, for instance, we would need to store a separate visitor for each frontier of our search. This would require an expensive copy of the history and prefixes.

Checking actions. In the theory, our [asm] rule compares two sets of actions to ensure that it is safe to apply an assumption. Specifically, it checks that the actions of the supposed supertype’s prefix (\(\pi'\)) are a subset of the actions performed by the subtype since the assumption was made (\(\rho'\)). In our algorithm, we can actually perform a far cheaper but equivalent check thanks to our use of lazy removal. We need only to confirm that

\[ \text{transitions[start..]} = \text{transitions[...snapshot.size][snapshot.start..]} \]

for each prefix/snapshot combination. The syntax \(x[i..]\) evaluates to \(x\) with the first 1 elements removed and \(y[j..]\) evaluates to the first \(j\) elements of \(y\). Surprisingly, this check is identical in effect to the one performed in the theory due to two observations.
1. Comparing the full list of transitions (which include labels and sorts) rather than only their actions is sound since the reduction rules do not allow sends or receives to or from the same participant to be reordered. We can easily prove this by contradiction. Suppose \( p?\ell(S) \in \pi' \) and \( p?\ell'(S') \in \rho' \) and we can apply \([asm]\). Clearly, \( p?\ell(S) \) has not been reduced by \([ref-in]\), otherwise, it would not still be in \( \pi' \). Therefore, at some point since the assumption was added to \( \Sigma \), \([ref-A]\) must have been used to move \( p?\ell(S) \) before \( p?\ell'(S') \). This is a contradiction because \( \mathcal{A}^{(p)} \) cannot contain \( p?\ell'(S') \) by definition so \([ref-A]\) cannot have been applied. A similar argument can be made for the output case.

2. The version in the theory is intuitively checking whether there is an action that ‘hangs on’ to the far left of \( \pi' \) for multiple iterations of a recursive type without ever being reduced. If this is the case, then the action will not be matched by any of the actions in \( \rho' \) (otherwise it would have been reduced) so \( \rho' \not\supset \pi' \).

In our implementation, if an action hangs on to the supertype’s prefix then it will never be lazily removed. This means that the size of the prefix will grow on each iteration of the FSM since \( start \) is never advanced.

\[
\text{Eq. (2) is trivially false. Note that the full check in Eq. (2) must be performed, rather than only comparing the lengths, to ensure that the prefixes do actually match those of the assumption, as in } [asm].
\]

**Fail-early reductions.** Our practical implementation performs the same reduction rules on prefixes as described in the theory. However, we add a practical optimisation to, in some cases, determine that a particular path cannot succeed before even reaching the bound.

For example, consider the pair \( (p?\ell(S), p?\ell'(S')) \). Regardless of what \( \pi \) and \( \pi' \) are set to, this pair cannot be reduced as it will require using the \([ref-A]\) but \( q!\ell'(S') \) cannot be contained in \( \mathcal{A}^{(p)} \). Therefore, if at some point we reach a pair of prefixes which looks like \( (p?\ell(S), p?\ell'(S')) \), we can immediately return \( \text{false} \) as there is no way that it can ever be reduced by adding more terms.

C Benchmarking results
