Additional index words. postharvest, quality, radiation, Citrus sinensis, C. reticulata

Abstract. Tolerance of many citrus cultivars to low-dose irradiation treatment is not known. Ten citrus cultivars grown in Florida, including the five orange [Citrus sinensis (L.) Osbeck] cultivars, Ambersweet, Hamlin, Navel, Pineapple, and Valencia, and the five mandarin hybrids (Citrus reticulata Blanco), ‘Fallglo’, ‘Minneola’, ‘Murcott’, ‘Sunburst’, and ‘Temple’, were exposed to irradiation at 0, 0.15, 0.3, and 0.45 kGy, and stored for 14 days at 1 °C ± 0.5 °C plus 3 days at 20 °C, to determine dose tolerance based on fruit injury, Softening of ‘Valencia’, ‘Minneola’, ‘Murcott’, and ‘Temple’ was dose-dependent, but that of other cultivars was unaffected. Only ‘Ambersweet’, ‘Valencia’, ‘Minneola’, and ‘Murcott’ did not develop peel pitting at 0.15 kGy or higher. Total soluble solids of ‘Ambersweet’ and ‘Sunburst’ declined slightly with increasing dose. Titratable acidity (TA) of oranges was not affected, but TA of ‘Sunburst’ and ‘Temple’ juice was slightly reduced by irradiation at 0.45 kGy. Juice flavor of ‘Hamlin’, ‘Navel’, ‘Valencia’, and ‘Minneola’, and pulp flavor of ‘Hamlin’, ‘Valencia’, ‘Fallglo’, ‘Minneola’, and ‘Murcott’ was less acceptable after irradiation at 0.3 or 0.45 kGy. The appearance of all cultivars was negatively affected by the loss of glossiness with the 0.45 kGy dose. Less than 1.0% of fruit decayed and irradiation treatment had no effect on decay. Our study indicates that growers and shippers need to be aware that the effects of irradiation on citrus fruits are highly variable and both cultivar-dependent and dose-dependent.

During the 1960s, there was considerable interest in determining the efficacy of ionizing radiation as a means to control organisms causing rot of fresh fruits and vegetables. Most of these studies exposed fruit, including citrus cultivars, to relatively high doses (>1.0 kGy) of irradiation. Bramlage and Couey (1965) found that growth of Penicillium digitatum [(Pers.: Fr.) Sacc.] was retarded by a dose of 1.0 kGy, and rot development was prevented by 1.5 kGy in ‘Washington Navel’ oranges, but only when fruit were irradiated immediately after inoculation. However, moderate peel pitting developed at doses >0.5 kGy. Grierson and Dennison (1965) exposed ‘Valencia’ oranges and ‘Marsh’ grapefruit to 1.5, 3.0, and 4.5 kGy, and found that neither Diplodia natalensis [Pole-Evans] nor Penicillium sp. was controlled, and that both fruits developed peel pitting after 1 week of storage at 20 °C following irradiation at all doses. Dennison et al. (1966) irradiated ‘Duncan’ grapefruit, and ‘Temple’, ‘Pineapple’, and ‘Valencia’ oranges at 1.0, 2.0, and 3.0 kGy prior to storage at 4.4 or 20 °C. The severity of peel injury increased with increasing dosage, and decay was not eliminated. In addition, the effect of irradiation dose on peel color of ‘Navel’ and ‘Temple’ oranges was dependent on the degree of initial peel color (fruit maturity) and on storage temperature (Ahmed et al., 1966). California-grown ‘Washington Navel’ and ‘Valencia’ oranges tolerated irradiation doses to 2.0 kGy without injury or any decline in organoleptic properties (Maxie et al., 1969). Irradiation-induced injury on ‘Shamouti’ oranges was more severe in immature than in mature fruit (Monselise and Kahan, 1966). Riov et al. (1968) demonstrated immediate and sustained increases in phenylalanine ammonia-lyase activity after irradiation (2.0 kGy) of ‘Shamouti’ oranges and ‘Marsh’ grapefruit, which could have contributed to peel pitting. Riov (1975) observed accumulation of phe-nolic compounds in damaged flavedo cells shortly after exposure to irradiation (2.4 kGy, at 1.55 kGy), resulting in cell death and peel pitting. Belli-Donini et al. (1974) irradiated ‘Valencia’, ‘Ovale’, and ‘Tarocco’ oranges and showed that various accumulated terpenes compounds diffused into the damaged exocarp cells and caused peel damage, suggesting that the natural resistance to peel damage was cultivar-dependent. Nagai and Moy (1985) shipped California-grown ‘Valencia’ oranges to Hawaii for irradiation treatment for quarantine purposes and found that the fruit would tolerate dosages up to 0.75 kGy. The negative effects of irradiation included loss of aroma, flavor, and pulp texture, but not peel injury. O’Mahony et al. (1985) evaluated California-grown ‘Navel’ oranges following irradiation at 0.6 to 0.8 kGy; peel blemishes were observed after 5 to 6 weeks of storage. Mitchell et al. (1991) found that the juice of ‘Valencia’ oranges irradiated at 0.75 or 3.0 kGy was acceptable. Control of quarantine pests has been the reason for much of the irradiation research on fresh fruits and vegetables since the mid-1980s. Hallman (1999) surveyed the current state of commercial irradiation and established its importance as a viable alternative to methyl bromide fumigation for quarantine treatment of fruit flies. The development of disease causing organisms generally could not be controlled even with irradiation doses higher than 1.0 kGy, but doses of 0.225 kGy or less needed for sterilization of most fruit fly larvae, and many of the pests were controlled at <1.0 kGy. These lower doses caused less damage to fresh fruits and vegetables. Currently, a 1.0 kGy maximum absorbed dose is allowed for use on fresh fruits and vegetables (Federal Register, 1986). The proposed USDA policy for application of irradiation as a quarantine treatment against major fruit flies is outlined in the Federal Register (1996).

Thresholds of tolerance to irradiation injury for specific orange or mandarin cultivars grown in Florida are not available, but this information is required for irradiation of citrus for quarantine purposes. The purpose of this study was to determine the physical or physiological tolerance of 10 commercial orange and mandarin cultivars grown in Florida to low-dose irradiation.

Materials and Methods

Five orange cultivars, Ambersweet, Hamlin, Navel, Pineapple, and Valencia, and five mandarin hybrids, Fallglo, Minneola, Murcott, Sunburst, and Temple, were either: 1) harvested three times at 1-week intervals; or 2) obtained from a single harvest directly from a packinghouse (within 24 h of harvest) prior to processing, during the 1997–98 or 1998–99 production seasons. Fruit harvested at 1-week intervals were replicated over harvests. Fruit obtained from a packinghouse were replicated over three lots. All fruit were taken to the U.S. Horticultural Research Laboratory in Orlando and washed, waxed (500 HG; FMC Corp., Lakeland, Fla.), and randomly sorted into three replicates (cartons) for each of four irradiation doses. Fruit numbers of each cultivar differed, as fruit size varied by cultivar, and fruit were packed into three, 14.1-L (0.4 bu) commercial fiberboard citrus cartons (Table 1). Within 24 h of harvest, fruit were irradiated at FTS, Mulberry, Fla. using Co60, and the absorbed dose was monitored with Gammachrome YR dosimeters (range 0.1–0.3 kGy) Harwell Laboratory, Oxfordshire, UK (Table 2). Irradiation was applied at a rate of 0.14 kGy·min–1 and...
doses were targeted at 0, 0.15, 0.3, and 0.45 kGy. However, the actual mean absorbed dosages over all fruit irradiated at the three levels were 0.19, 0.4, and 0.58 kGy, respectively (Table 2). Dosimeters were placed at the center and edges of the fruit mass in each carton to ensure that the center fruit received the minimum dose. Consequently, the mean absorbed dose was higher than the target dose, but the range of absorbed dose within targeted dose categories was relatively low. Following irradiation, all fruit were returned to the Orlando Laboratory for cold storage and evaluation. Before storage, 20 fruit in each carton were randomly marked and placed for 14 d at either 1 or 5 °C, depending on USDA recommendations (Hardenburg et al., 1986), plus 3 d at 20 °C, and then evaluated. At the end of storage, fruit firmness, weight loss, total soluble solids (TSS), titratable acidity (TA), juice color, and pulp flavor were determined. Firmness was determined using an Instron Food Texture instrument (model 4411; Intron Firm, Canton, Mass.) using an 11-mm cylinder pen- 

| Cultivar                  | Type/hybrid       | Harvest date | Mean fruit diam. (mm) | No. fruit per box | Storage temp (°C) |
|--------------------------|-------------------|--------------|-----------------------|------------------|------------------|
| Ambersweet               | Sweet orange (SO) | Nov. 1997    | 81.1                  | 45               | 1                |

Results

Fruit firmness. The 0.3 and 0.45 kGy doses resulted in softer ‘Valencia’ orange fruit than did 0 and 0.15 kGy treatments (Table 3). ‘Murcott’ and ‘Temple’ mandarins subjected to 0.45 kGy, and ‘Minneola’ receiving 0.3 kGy, were softer than fruit from other doses (Table 4).

Peel pitting. Irradiation at all levels caused peel pitting in ‘Hamlin’ and ‘Navel’ oranges (Table 3). Only ‘Ambersweet’ (1.3%) and ‘Valencia’ (1.5%) had sufficiently low peel pitting to be commercially acceptable. ‘Minneola’ and ‘Murcott’ fruit were not affected by irradiation up to 0.45 kGy. Peel pitting occurred at all irradiation doses on ‘Fallglo’, Sunburst’, and ‘Temple’ fruit (Table 4).

Weight loss. Irradiation did not affect weight loss of any orange cultivar with the exception of ‘Navel’ treated at 0.15 kGy (Table 3). All irradiation doses increased weight loss in ‘Sunburst’ and ‘Temple’ fruit, and 0.15 kGy increased the loss in ‘Murcott’ fruit (Table 4).

Total soluble solids and titratable acidity. Irradiation did not affect TSS or TA of orange cultivars, with the exception of a decrease in TSS in ‘Ambersweet’ at a dose of 0.3 kGy (Table 3). A dose of 0.45 kGy reduced TSS of ‘Sunburst’ mandarin and TA of both ‘Sunburst’ and ‘Tangelo’, and 0.3 kGy increased TA of ‘Murcott’ (Table 4).

Juice color. Juice color of oranges (Table 3) and mandarins (Table 4) was not affected by irradiation at any dose.

Juice and fruit flavor. Acceptability of juice flavor of ‘Hamlin’ and ‘Navel’ oranges and ‘Minneola’ mandarin was reduced by irradiation at 0.45 kGy, while that of ‘Valencia’ was reduced at all doses. Pulp flavor of ‘Hamlin’ and ‘Valencia’ orange and of ‘Fallglo’, ‘Minneola’, and ‘Murcott’ mandarin was negatively affected at 0.45 kGy (Table 3). Acceptability was also reduced at 0.15 kGy for ‘Fallglo’, and at 0.3 kGy for ‘Murcott’ mandarin.

Discussion

Tolerance of the various orange and mandarin cultivars to low-dose irradiation varied widely, especially in effects on peel pitting and flavor. Peel pitting was the major indicator of irradiation stress in these fruits. Fresh fruit showing peel lesions or discoloration are not acceptable for fresh market sales. The minimum dose required for quarantine treatment against Caribbean fruit fly (Aanstrepha suspensa (Loew)) larva is 0.15 kGy. ‘Ambersweet’, ‘Valencia’, ‘Minneola’, and ‘Murcott’ showed good pitting tolerance to irradiation at the highest absorbed dosage applied in this study (mean 0.58 kGy), but ‘Hamlin’, ‘Navel’, ‘Pineapple’, ‘Fallglo’, ‘Sunburst’, and ‘Temple’ were not sufficiently tolerant for fresh market sales, even at the minimum absorbed dose of 0.15 kGy. The reason for less pitting of ‘Temple’ fruit at the highest than at lower doses is not known. Based on the percentage of fruit with symptoms of peel pitting, ‘Sunburst’, ‘Fallglo’, and ‘Temple’ were not tolerant of irradiation

Table 2. Irradiation absorbed doses for various citrus fruit cultivars.

| Cultivar        | Target doses (kGy) | Actual doses (kGy) |
|-----------------|--------------------|--------------------|
| Ambersweet      | 0.15 0.30 0.45     | 0.15 0.30 0.45     |
| Hamlin          | 0.19 0.39 0.61     | 0.19 0.39 0.61     |
| Navel           | 0.19 0.40 0.56     | 0.19 0.40 0.56     |

* Determined by chromometer. The higher the value, the more commercially acceptable the juice.
* Subjectively determined by an untrained seven-member panel on a hedonic scale from 1 (extremely unacceptable) to 100 (extremely acceptable).
* Mean separation within cultivars by Duncan's multiple range test, at P ≤ 0.05.

at 0.3 kGy, and ‘Sunburst’ was the least tolerant of all cultivars evaluated. The navel orange in our study was a Florida selection (‘Nucellar Navel’), which apparently does not tolerate irradiation treatment as well as the ‘Washington Navel’ grown in California (Guerrero et al., 1967; Maxie et al., 1969). Fruit used by Maxie et al. (1969) was harvested in California, but was not irradiated in Hawaii until 8 d later. The delay in treatment may have contributed to the resistance of the fruit to peel pitting at 1.0 kGy, Bramlage and Couey (1965) found that ‘Washington Na-"valley’ seriously pitted at 0.5 kGy, which is more comparable with our results. However, ‘Valencia’ oranges grown in Florida were as tolerant to irradiation stress as those grown in California (Nagai and Moy, 1985).

Another main indicator of quality of irradiated fruit is juice or pulp flavor. Juice flavor of ‘Hamlin’, ‘Navel’, and ‘Valencia’ and pulp flavor of ‘Hamlin’ and ‘Valencia’ oranges was reduced at the highest absorbed dose. The juice flavor of ‘Minneola’ and pulp flavor of ‘Fallglo’, ‘Minneola’, and ‘Murcott’ mandarins were the least acceptable at the highest dosage. The TA was slightly reduced in ‘Sun-"burst’ and ‘Temple’ at 0.45 kGy, but acceptability of juice or pulp flavor was not affected.

In conclusion, the tolerance of fresh citrus fruits irradiated for quarantine or other purposes is cultivar-dependent. Minimum and maximum irradiation doses for quarantine treatment for fruit fly larvae may injure some citrus cultivars. If irradiation becomes the treatment of choice by citrus fruit growers/ shippers in the future, further research on the use of a heat treatment prior to irradiation may be warranted for those cultivars that will not tolerate required irradiation doses (Miller and McDonald, 1998).
