In this work we consider a simple random walk embedded in a generic branched structure and we find a close-form formula to calculate the hitting time \( H(i, f) \) between two arbitrary nodes \( i \) and \( j \). We then use this formula to obtain the set of hitting times \( \{H(i, f)\} \) for combs and their expectation values, namely the mean-first passage time (MFPT), where the average is performed over the initial node while the final node \( f \) is given, and the global mean-first passage time (GMFPT), where the average is performed over both the initial and the final node. Finally, we discuss applications in the context of reaction-diffusion problems.

PACS numbers:

I. INTRODUCTION

Random walks (RWs) on inhomogeneous structures have been first introduced to describe anomalous diffusion \([1-3]\), but they actually constitute a convenient model for many real phenomena, ranging from soft matter (e.g. gels and biological structures \([4]\)), to condensed matter (e.g., fractures \([5]\) and light scattering \([6]\)).

Here we will focus on the so-called “branched structures”, namely graphs \( V \) obtained by attaching to each vertex \( j \) of a base graph \( G_0 \) a different graph \( G_j \) called fiber (see Fig. 1). Branched structures were used to describe the energy transfer in polymers \([7]\), the transport of calcium in spiny dendrites \([8-10]\), the excitation of nano-antennas \([11]\), the anomalous diffusion in real structure with similar topology \([11, 12, 15]\). In particular, we will consider a specific class of branched structures called combs, namely graphs where the base graph as well as the fiber ones are linear chains, in such a way that \( G_j \) is site independent and equivalent to \( Z \) (see Fig. 2).

Diffusion on combs has been shown to display many peculiar features ultimately stemming from their highly inhomogenous topology (see e.g., \([17-20]\)). Now, most of the previous results have been proven in the thermodynamic limit, namely for structures of infinite size, while real systems are intrinsically finite. In this work we aim to investigate the problem of diffusion in finite comb lattices and we will especially focus on first-passage quantities such as the hitting time \( H(i, f) \) from \( i \) to \( f \) (i.e., the mean time for a random walker to first reach site \( f \) starting from \( i \)), the mean first-passage time MFPT\(_f\) to \( f \) (i.e., the mean time needed to first reach the vertex \( f \), averaged over the starting site), and the global mean-first passage time GMFPT (i.e., the mean time to go from a random vertex to a second random vertex).

These quantities have been extensively studied in the past, also due to the number of different applications in several research areas: pharmacokinetics \([21]\), reaction-diffusion processes \([22]\), excitation transport in photosystems \([23, 24]\), target search processes \([25]\), disease spreading \([26]\) and many other physical problems \([27, 33]\). Pha-
macokinetics and reaction-diffusion processes could also be affected by the occupation time, namely the mean time spent in a subset of graph’s vertices.

In this work we calculate the above mentioned quantities for \((d\text{-dimensional})\) combs using the resistance method: the original graph \(G\) is mapped into a resistance network by replacing any link \((a,b)\) between two adjacent nodes \(a\) and \(b\) with a unitary resistance \(\mathcal{R}\). Then, we use Tetali’s formula \([37]\) to calculate the exact value of the hitting time between \(i\) and \(f\) as

\[
H(i, f) = mR_{i,f} + \frac{1}{2} \sum_{z \in V} g(z) \{ R_{f,z} R_{i,z} \}, \tag{1}
\]

where \(m\) is the number of links in the graph, \(g(z)\) is the coordination number of the vertex \(z\), and \(R_{a,b}\) is the effective resistance between the vertices \(a\) and \(b\).

II. Hitting Time of Branched Structures

In this section we will use Eq. (1) to calculate the value of the hitting time for generic branched structures (see Fig. 1).

When the starting point \(i\) and the ending point \(f\) belong to different fibers, we can divide vertices of \(V\) into three disjoint subsets, referred to as \(\mathcal{I}, \mathcal{F}\) and \(\mathcal{B}\) respectively (see Fig. 2): \(V = \mathcal{I} \cup \mathcal{F} \cup \mathcal{B}\). More precisely, the subset \(\mathcal{I}\) contains all vertices belonging to the fiber-graph \(\mathcal{G}_i = (\mathcal{I}, \mathcal{L}_i)\), the sub-set \(\mathcal{F}\) contains all vertices belonging to the fiber-graph \(\mathcal{G}_f = (\mathcal{F}, \mathcal{L}_f)\) and finally the subset \(\mathcal{B}\) contains all vertices belonging to the fiber-graphs \(\mathcal{G}_k = (\mathcal{K}_k, \mathcal{L}_k)\) with \(k \neq (i, f)\), formally \(\mathcal{B} = \bigcup_{k \neq (i,f)} \mathcal{K}_k\), where \(\mathcal{L}_j\) is the adjacency matrix of the fiber graph \(\mathcal{G}_j\).

![Figure 3](image)

This procedure allows us to write the sum in (1) as:

\[
\sum_{z \in \mathcal{V}} g(z) \left( R_{f,z} - R_{i,z} \right) = \sum_{z \in \mathcal{I}} g(z) \left( R_{f,z} - R_{i,z} \right) + \sum_{z \in \mathcal{F}} g(z) \left( R_{f,z} - R_{i,z} \right) + \sum_{z \in \mathcal{B}} g(z) \left( R_{f,z} - R_{i,z} \right). \tag{2}
\]

Then, after some algebraic manipulations we find that

\[
H(i, f) = mR_{i,f} + \frac{1}{2} \sum_{z \in \mathcal{V}} g(z) \left( R_{f,z} - R_{i,z} \right) + 2(m - m_f) R(f, r_f) + H_i(i, r_i) + H_f(r_f, f), \tag{4}
\]

where \(m_k\) is the number of links in the sub-graph \(\mathcal{G}_k\), and \(H_k(a, b)\) the mean time for a walker to go from \(a\) to \(b\), \((a, b) \in \mathcal{G}_0\), without ever exiting out from the fiber \(\mathcal{G}_0\).

We have obtained a summation similar to that with which we began, but now resistances are considered between points of the base-graph. This allows us to factorize the difference \(R_{f,z} - R_{i,z}\), by splitting the summation over \(z \in \mathcal{V}\) into the summation over every vertex of all fiber-graphs:

\[
\sum_{z \in \mathcal{V}} g(z) \left( R_{f,z} - R_{i,z} \right) = \sum_{k \in \mathcal{G}_0} \sum_{z \in \mathcal{G}_k} g(z) \left( R_{f,z} - R_{i,z} \right). \tag{5}
\]

Previously we noticed that the difference of resistances depends only on the fiber graph, so we can factorize it:
\[
\sum_{z \in \mathcal{V}} g(z) (R_{r_f,r_z} - R_{r_z,r_z}) = \\
= \sum_{k \in \mathcal{G}_0} (R_{r_f,r_k} - R_{r_z,r_k}) \sum_{z \in \mathcal{G}_k} g(z) \\
= \sum_{k \in \mathcal{G}_0} (R_{r_f,r_k} - R_{r_z,r_k}) 2m_k.
\]

Finally, merging the previous results we get
\[
H(i,f) = H_i(i,r_i) + \sum_{k \in \mathcal{G}_0} m_k (R_{r_f,r_k} - R_{r_z,r_k}) + \\
+ H_f(r_f,f) + 2(m - m_f) R(f,r_f) \\
+ mR_{r_i,r_f}.
\]

Of course, this formula recovers the Tetali one \[1\] when all the branched graphs \(G_i\) are composed only of a single vertex (the one that is shared with \(G_0\), i.e. the root \(r_i\)). The details of the fibers only enter in the summation term, and the only important things about these graphs are the position on the base graph and the number of links \(m_k\), neither the topology nor the number of vertices of these fiber graphs affect \(H(i,f)\).

### A. Particular Cases:

There are special cases where the formula in Eq. \[5\] can be significantly simplified. In particular when the ratio between the coordination number \(g(k)\) of any vertex \(k\) belonging to the base graph and the number of links \(m_k\) in the \(k\)-th subgraph is independent of \(k\). This allows us to write \(m_k = \gamma g(k)\), being \(\gamma\) a constant value which is the same for every vertex of the base graph \(G_0\). Then, the summation in Eq. \[5\] becomes:

\[
\sum_{k \in \mathcal{G}_0} m_k (R_{r_f,r_z} - R_{r_z,r_z}) = 2\gamma \left[H_0(r_i,r_f) - m_0R_{r_i,r_f}\right],
\]

and, using this result, Eq. \[5\] becomes:

\[
H(i,f) = H_i(i,r_i) + 2\gamma H_0(r_i,r_f) + H_F(r_f,f) + \\
+ 2(m - m_f) R(f,r_f) + (m - 2m_0) R_{r_i,r_f},
\]

where \(H_I(a,b)\) and \(H_F(a,b)\) represent the mean time taken by a walker to first go from a node \(a\) to a node \(b\) (being \(a,b \in \mathcal{I}\) and \(a,b \in \mathcal{F}\) respectively) without ever exiting out of \(\mathcal{I}\) and \(\mathcal{F}\) respectively; analogously \(H_0(a,b)\) represent the mean time to first reach \(b\) starting from \(a\) (being \(a,b \in \mathcal{G}_0\)) and moving only on the base graph. In this case the mean time to go from \(i\) to \(f\) can be expressed by a sum of three hitting times, and some constant value.

Another interesting case appears when the position of the root of the starting vertex \(r_i\) and the root of the ending one \(r_f\) displays a symmetry such that

\[
H(r_i,r_f) = H(r_f,r_i)
\]

in this particular case Eq. \[5\] becomes
\[
H(i,f) = H_i(i,r_i) + H_f(r_f,f) + \\
+ 2(m - m_f) R(f,r_f) + mR_{r_i,r_f},
\]

This formula allows us to calculate the hitting times for any "symmetric structure" (according to Eq. \[8\]), like a Sierpinski fibrated with linear chains, (see Fig. 4). Let us consider a Sierpinski gasket of generation \(n\) and as fibers linear chains with \(L\) vertices. The total number of vertices in the base-graph is \[38\] \(|\mathcal{V}_0^{(n)}| = \frac{3(3^n+1)}{2}\) and the total number of links is \[38\] \(m_0^{(n)} = 3^{n+1}\). For instance let us try to evaluate the mean time to first reach the node \(f\) belonging to a tooth stemming from a corner, starting from a node \(i\) belonging to a tooth stemming from another corner (see Fig 4). Neri et al. in \[39\] showed that \(R_{r_i,r_f} = \frac{2.5^n}{3^{n+1}+1}\). Using Eq. \[6\] it is straightforward to show that \(H(i,f)\) reads as

\[
H_{\text{Max}} = 3L^2 + \left(1 + \frac{L}{2}\right) (3^{n+1} + 2 \cdot 5^n) + \left(\frac{5}{3}\right)^n L.
\]

### B. Bidimensional Combs

Bidimensional combs are branched structures where the base-graph \(G_0\) is a monodimensional graph, like a linear chain or a ring, usually called backbone, and fiber graphs are linear chains usually called teeth, see Fig. 2. Here, we consider two different cases according to the the boundary conditions applied to the backbone: we
call “Bidimensional Open Combs” those combs whose backbone is a linear chain, and “Bidimensional Closed Combs” those whose backbone is a ring; teeth are always taken as open (i.e., reflecting at boundaries).

As shown in Fig. 2, the size of the backbone is $2L + 1$, and each linear chain departing from the backbone counts $\alpha L$ vertices, in such a way that $\alpha$ measures the degree of inhomogeneity along the two directions (e.g., when $\alpha = 1$ the comb is square).

Using Eq. (4) we are now able to calculate the value of $H(i, f)$ for those graphs.

In the following, exploiting the fact that combs are embedded in 2–dimensional lattices, the position of the arbitrary point $k$ will be denoted as $(x_k, y_k)$ where $x_k$ indicates the projection of $k$ on the backbone, and $y_k$ its length along the related tooth. Let us start with open combs for which we apply Eq. (5), with some algebra we get

$$H(i, f) = mR_{i,f} + (y^2 - y_i^2) + 2\alpha L + 1 (x_j^2 - x_i^2) +$$

$$+ \left(|y_j| - |y_i|\right) \left(L^2 4\alpha + 2L\right),$$

where the resistance between two generic points $a = (x_a, y_a)$ and $b = (x_b, y_b)$ for open combs is

$$R_{a,b} = \delta_{x_a,x_b}|y_a - y_b| + \left(1 - \delta_{x_a,x_b}\right) (|x_a - x_b| + |y_a| + |y_b|).$$

From this equation we can extract important information, for example the mean time to cross the whole backbone and the mean time to “climb” a tooth. These quantities are, respectively,

$$H(-L, 0 \rightarrow L, 0) = L^3 (8\alpha) + L^2 (4 + 4\alpha),$$

and

$$H(\{0, 0\} \rightarrow \{0, \alpha L\}) = L^3 (8\alpha^2) + L^2 (4\alpha + 3\alpha^2).$$

Using Eq. (5) we can also calculate the Hitting Time for closed combs, $H_C(i, f)$, where we used the apex $\circledcirc$ to emphasize that this quantity is referred to a closed comb $^2$:

$$H_C(i, f) = mR_{i,f} + (|y_j| - |y_i|) \left[4\alpha L^2 + 2L + 1\right] + (y^2_j - y_i^2),$$

where the resistance between two generic points $a = (x_a, y_a)$ and $b = (x_b, y_b)$ for close combs is

$$R_{a,b} = \delta_{x_a,x_b}|y_a - y_b| + \left(1 - \delta_{x_a,x_b}\right) \times$$

$$\times \left(|x_a - x_b| + |y_a| + |y_b| - \frac{(x_a - x_b)^2}{2L + 1}\right).$$

From Eq. (11) we can extract the time needed to cross half backbone as

$$H_C(\{0, 0\} \rightarrow \{L, 0\}) = L^3 (6\alpha) + L^2 (3 + 2\alpha) + L,$$

and the time to climb a tooth as

$$H_C(\{0, 0\} \rightarrow \{0, \alpha L\}) = L^3 (8\alpha^2) + L^2 (4\alpha + 3\alpha^2) + L (2\alpha).$$

We can notice that the leading order of the mean time needed to cross the backbone is proportional to $\alpha$ (consistent with results in $^3$) and the leading order of the mean time to climb a tooth is proportional to $\alpha^2$.

### C. d-dimensional Open Combs

We define $d$-dimensional open combs recursively (see also Fig. 5):

- a 1–dimensional open comb is a linear chain;
- a 2–dimensional open comb is a branched graph $G$ whose base graph is a linear chain and whose fiber graphs are linear chain;
- ...;
- a $d$–dimensional open comb is a branched graph $G$ whose base graph is a $(d-1)$–dimensional combs and whose fibers are linear chains.

As shown in Sec. D 11 $^2$ a finite 2-dimensional comb can be defined by fixing two parameters: the length of the backbone $L$ and the ratio $\alpha$ between the length of a tooth
and the length of the backbone, in such a way that the thermodinamic limit $L \to \infty$ is well defined. Now, to fix a $d$–dimensional comb we introduce $d$ parameters: $(L, \alpha_2, \ldots, \alpha_d)$, being $\alpha_i$ the ratio between the length of the tooth in the $i$-th direction (i.e. added at the $i$–th iteration) and the length of the backbone: $\alpha_i = \frac{L_i}{L}$.

We label every vertices with $d$ coordinates and call $i = (x_1, \ldots, x_d)$ and $f = (y_1, \ldots, y_d)$, where the first coordinate labels the vertices on the base graph and it takes value from $-L$ to $L$, the second one goes from $-\alpha_2L$ to $\alpha_2L$ and labels the base of the fiber graphs, the third one goes from $-\alpha_3L$ to $\alpha_3L$ and so on.

We define $H^{(d)} (i, f)$, the Hitting Time from $i$ to $f$ in a $d$–dimensional comb and we will use Eq. [5] to calculate its leading order. Using Tsetal’s equation it is straightforward to observe that $H^{(d)} (i, f) \sim O (L^{d+1})$.

In fact, the first term of the right hand side in Eq. (1) is

$$H \sim L^{d+1} \prod_{i=2}^{d} \alpha_i \times$$

and its maximum value going from $\eta = (-1, 0)$ to $\xi = (1, 0)$, as

$$H^{(d)} \{(-1, 0) \to (1, 0)\} \sim L^{d+1} \prod_{i=2}^{d} \alpha_i,$$

and its maximum value going from $\eta = (-1, 1)$ to $\xi = (1, 1)$:

$$H^{(d)} \{-1, 1\} \to \{1, 1\} \sim L^{d+1} \prod_{i=2}^{d} \alpha_i \left[ 1 + \sum_{k=2}^{d} \alpha_k \right].$$

### III. TRAPPING TIMES

In this section, we will analyze some average quantities, in particular we introduce the mean first-passage time defined by $\text{MFPT} = \frac{1}{d} \left[ E_i \left( H (i, f) \right) \right]$ and the Global Mean First Passage Time, defined by $\text{GMFPT} = \frac{1}{d} \left[ E_j \left( H (i, f) \right) \right]$. The first quantity represents the mean time to reach a fixed reaction node placed in $f$, starting from a random one. The second one is the mean time to reach a random vertex starting from another random one.

#### A. MFPT

The MFPT was introduced by Montroll for regular graphs [24] to describe the excitation transfer on a photosintic complex. Later this quantities was extended for irregular graph, see [27, 31, 40–43]. Once we know every value of $H (i, f)$ we can calculate exactly this quantitity using $\text{MFPT} = \frac{1}{V} \sum_{i \in V} H (i, f)$, where $V$ is the volume of the graph $\mathcal{G}$.

1. **Bidimensional Open Combs**

Knowing the values of $H (i, f)$ for every couple of nodes $(i, f)$ (see Eq. [10]), it is straightforward to calculate the value of $\text{MFPT} = \frac{1}{V} \sum_{i \in V} H (i, f)$, where $V$ is the volume of the graph $\mathcal{G}$. To achieve this results it is convenient to split Eq. (10) in three parts:

$$H (i, f) = \{m_{R_{i,f}} \} + \{ (2\alpha L + 1) \left( x_1^2 - x_2^2 \right) \} + \{ (y_1^2 - y_2^2) + (|y_1| - |y_2|) \cdot (L^2 \alpha + 2L) \} \sim (A) + (B) + (C),$$
and calculate these separately. The first contribution, $E_i[A]$, can be written as

$$E_i[A] = \sum_{x_i=-L}^{L} \sum_{y_i=-\alpha L}^{\alpha L} m \left| \delta_{x_i,x_f} |y_i - y_f| + (1 - \delta_{x_i,x_f}) (|x_i - x_f| + |y_i| + |y_f|) \right| ,$$

and after the summation on $x_i$ it becomes:

$$E_i[A] = m \frac{1}{V} \sum_{y_i=-\alpha L}^{\alpha L} \left[ |y_i - y_f| + [2L (|y_i| + |y_f| + x_f^2 + L + L^2)] \right] ,$$

and finally

$$E_i[A] = y_f^2 \frac{m}{V} + |y_f| \left[ \frac{m}{V} (2\alpha L + 1) 2L \right] + x_f^2 \left[ \frac{m}{V} (2\alpha L + 1) \right] + \frac{m}{V} \alpha L (\alpha L + 1) + L (L + 1) (\alpha L + 1) + 2\alpha L^2 (\alpha L + 1) .$$

Performing similar calculation the second contribution, $E_i[B]$, can be written as

$$E_i[B] = \sum_{x_i,y_i} \left( 2\alpha L + 1 \right) \left[ x_f^2 - x_i^2 \right] ,$$

and the third contribution, $E_i[C]$, becomes:

$$E_i[C] = |y_f| 2L (2\alpha L + 1) - y_f^2 - \alpha L \left( \frac{1}{3} + 2L \right) .$$

Merging these three contributions we find the exact value of $\text{MFPT}_f$:

$$\text{MFPT}_{(x_f,y_f)}(0,\alpha L) = \phi(x_f,y_f) + \text{MFPT}_{(0,0)} ,$$

where

$$\phi(x_f,y_f) = \left( 1 + \frac{m}{V} \right) \left[ y_f^2 + x_f^2 (2\alpha L + 1) |y_f| (4\alpha L^2 + 2L) \right] + |y_f| (4\alpha L^2 + 2L) + \frac{1}{3(1+2L)(1+2\alpha L)} \times \left[ 16\alpha^2 L^5 + L^3 \left( 16\alpha + 24\alpha^2 + 8\alpha^3 \right) \right] \times \left( 1 + \alpha \right) + L^2 \left( 1 + \alpha \right) L^3 \left( 4 + 18\alpha + 14\alpha^2 + 4\alpha^3 \right) .$$

The position of the trap affects only the contribute in the first square bracket. Therefore, $\text{MFPT}_{(x_f,y_f)}$ can be written as the sum of two terms, the former depends on the final vertex, and the latter depends only on $L$ and $\alpha$ and is exactly the value of $\text{MFPT}_{(0,0)}$:

$$\text{MFPT}_{(x_f,y_f)}(L,\alpha) = \phi(x_f,y_f) + \text{MFPT}_{(0,0)} .$$

We have numerically tested this result for three positions of the trap $(x_f,y_f)$ and for several values of $L$ and $\alpha$, as shown in Figs. 0, 7 and 8. In each of those figures the value of $(x_f,y_f)$ is fixed and we changed the value of $L$ and $\alpha$. The values of $(x_f,y_f)$ are respectively $(0,0),(L,0)$ and $(L,\alpha L)$, $L$ takes values from 8 and 256, and $\alpha$ goes from 1/32 to 128.
Simul./Theor.
MFPT\(_{(L,\alpha L)}\)

\[\text{Figure 8: Numerical check of the theoretical predictions of Eq. (15) for } (x_f, y_f) = (L, \alpha L). \text{ In both figures the results of the simulations are divided by the theoretical value of MFPT\(_{(L,\alpha L)}\).}\]

The asymptotic behaviour of MFPT\(_f\) is

\[
\text{MFPT}_f(L, \alpha) \sim L^3 \left\{ 4\alpha \left[ \frac{1}{3} + \left( \frac{x_f}{L} \right)^2 \right] + 8\alpha \left| \frac{y_f}{L} \right| \right\} \tag{17}
\]

\[
\sim \frac{4}{3} \alpha L^3,
\]

where the last relation holds as long as both \(x\) and \(y\) are finite. The dependence on \(L^3\) is consistent with previous asymptotic results \[20, 31\].

2. Bidimensional Close Combs

Analogous arguments can be applied to calculate the exact value of the Mean First Passage Time for close combs, and we call this quantity MFPT\(_\square\). We skip lengthy passages and provide straightforwardly the final result:

\[
\text{MFPT}_\square(x_f, y_f) = \left[ |y_f| \left( 1 + 4L + 8L^2\alpha \right) + 2y_f^2 \right] + \frac{1}{3 + 6\alpha L} \times \left[ L (2 - \alpha) + L^2 (2 + 8\alpha + 3\alpha^2) + L^3 4\alpha (2 + 2\alpha + \alpha^2) + L^4 (8\alpha^2) \right]. \tag{18}
\]

Of course, MFPT\(_\square\) does not depend on \(x_f\), due to the periodic condition on the \(x\) axis. Moreover, as done in Eq. (16) we can distinguish two contribution highlighting the dependence of the trap position (height) as

\[
\text{MFPT}_\square(x_f, y_f) (L, \alpha) = \phi_\square(y_f) + \text{MFPT}_\square(0).
\]

\[\text{Figure 9: Numerical check of the theoretical predictions of Eq. (18) for } (y_f) = (0). \text{ In both figures the results of the simulations are divided by the theoretical value of MFPT}_\square(0).\]

The asymptotic behaviour reads as:

\[
\text{MFPT}_f(L, \alpha) \sim L^3 \left\{ \frac{4}{3} \alpha + 8\alpha \frac{y_f}{L} \right\} \tag{19}
\]

\[
\sim \frac{4}{3} \alpha L^3,
\]

where the last relation holds as longs \(y\) is finite.

\[\text{Figure 10: Numerical check of the theoretical predictions of Eq. (18) for } (y_f) = (\alpha L). \text{ In both figures the results of the simulations are divided by the theoretical value of MFPT}_\square(\alpha L).\]
We have numerically tested this result for two values of $y_f$ and for several values of $L$ and $\alpha$, as shown in Figs. 9 and 10. In each of those figures the value of $y_f$ is fixed and we changed the value of $L$ and $\alpha$. The values of $y_f$ are respectively 0 and $\alpha L$. $L$ takes values from 8 and 256, and $\alpha$ goes from 1/32 to 128.

### B. GMFPT

We define the Global Mean First Passage Time, GMFPT, as the mean Hitting Time averaged on starting and on ending points:

$$\text{GMFPT} = \mathbb{E}_{i,f} [H(i, f)];$$

$$= \frac{1}{V^2} \sum_{i \in V} \sum_{f \in V} H(i, f)$$

GMFPT depends qualitatively on the topological properties of the underlying structure and this has been proven from different perspectives. For instance, it is well known that GMFPT is related with the Kirchhoff index [14], $K = \mathbb{E}_{i,f} [R_{i,f}]$ (in fact, from Chandra’s formula $H(i, f) + H(f, i) = 2m_{R_{i,f}}$ [45] it follows straightforwardly that GMFPT $\sim m(R)$).

Moreover, Benichou et al. [46] found a very general asymptotic expression reading as:

$$\text{GMFPT}_B \sim \begin{cases} V & d_w < d_f \\ V \log(V) & d_w = d_f \\ V^{d_w/d_f} & d_w > d_f \end{cases}$$

where $d_w$ is the walk dimension and $d_f$ is the fractal dimension. Their definition of global mean first passage time, is slightly different from ours: theirs is averaged over links,

$$\text{GMFPT}_B = \frac{1}{m} \sum_{i,f \in V} \frac{H(i, f) g(i) g(f)}{(m - g(f))}$$

while ours is averaged over vertices:

$$\text{GMFPT} = \frac{1}{V^2} \sum_{i,f \in V} H(i, f).$$

Despite this different definitions they showed (via numerically simulation) that these lead to the same asymptotics. Now, for comb lattice the walk dimension $d_w$ is not unique [47] and Einstein’s relation $d da_w = 2d_f$ does not hold directly and one could therefore calculate GMFPT in a more ”pedestrian” way. Now, we report the exact value of GMFP for the combs structures outlined above, and compare their asymptotic behaviors with Eq. 20.

#### 1. Bidimensional Open Combs

To calculate the GMFPT for open combs, we start from Eq. 19. We recall that $\text{MFPT}_f$ can be written as the sum two terms, the former depends on the final vertex, and the latter is exactly the value of $\text{MFPT}_{(0,0)}$, in a such way that in order to obtain the exact value of GMFPT we have to average only on the former; namely

$$\text{GMFPT} = \mathbb{E}[f(x_f, y_f)] + \text{MFPT}_{(0,0)}. \quad (21)$$

and after some algebra we find:

$$\text{GMFPT} = \sum_{x_f=-L}^{L} \sum_{y_f=-\alpha L}^{\alpha L} \text{MFPT}_f =$$

$$= \frac{1}{3(1+2L)(1+2\alpha^2)} \left[ 8L^2 (1 + 2\alpha + \alpha^2) + 8L^3 (1 + 8\alpha + 8\alpha^2 + \alpha^3) + 8L^4 (4\alpha + 15\alpha^2 + 5\alpha^3) + 16L^5 \alpha^2 (2 + 3\alpha) \right],$$

whose leading order is:

$$\text{GMFPT}(L, \alpha) \sim L^3 \left( \frac{8}{3} \alpha + 4\alpha^2 \right). \quad (23)$$

We have numerically tested this result for many values of $L$ and $\alpha$, as shown in Fig. 11. In this figure we changed the value of $L$ from 8 to 256 and $\alpha$ from $\frac{1}{32}$ to 128.

#### 2. Bidimensional Close Combs

We now apply analogous arguments to calculate the exact value of the global mean first passage time for close combs, hereafter referred to as $\text{GMFPT}_C$; averaging $\text{MFPT}_f$ over $f$ we find the exact value of $\text{GMFPT}_C$...
as
\[
\text{GMFPT}^\odot \ (L, \alpha) = \frac{2}{3} [L (1 + 2\alpha) + L^2 (1 + 8\alpha + 2\alpha^2) + L^3 (2\alpha + 6\alpha^2)]
\]
whose leading order is:
\[
\text{GMFPT}^\odot \ (L, \alpha) \sim L^3 \left( \frac{4}{3} \alpha + 4\alpha^2 \right). 
\]

We have numerically tested this result for many values of \(L\) and \(\alpha\), as shown in Fig. 12. In this figure we changed the value of \(L\) from 8 and 256 and \(\alpha\) from \(\frac{1}{32}\) and 128.

![Figure 12: Numerical check of the theoretical predictions of Eq. (24). In both figures the results of the simulations are divided by the theoretical value of GMFPT.](image)

IV. CHEMICAL-KINETICS PERSPECTIVE

In this section we frame the previous results within a chemical-kinetics perspective. Imagine having two reactants, say A (static) and B (dynamic). If we are allowed to choose the position of A, but we have no control on B (namely we can not fix its starting point), which will diffuse freely thorough the lattice, we can choose for the static reactant the place which minimize the reaction time. In fact, this is just the node \(f\) that minimize \(\text{MFPT}_f\).

As shown in Sec. III A 1 and in Sec. II B 2, the MFPT for both open and close combs can be written as \(\text{MFPT}_f = \phi(f) + \text{const.}\). In both combs previously analyzed we found that \(\phi(f) \geq 0\) for every final vertex \(f\). In particular, in open combs \(\phi(f) = 0\) when \(f = (0,0)\), and in close ones it is zero when \(f = (i,0)\); the maximum value of \(\text{MFPT}_f\) arises when the value of \(\phi(f)\) is maximized, this occurs for \(f = (\pm L, \pm\alpha L)\) for open combs and \(f = (i, \pm\alpha L)\) for close ones. Of course, for close combs there is no dependence on the \(x\) coordinate due to the periodic condition on the \(x\) axis.

Now, if we can not control the position of A, but this is stochastic, which is the typical time \(\tau_f = \text{MFPT}_f\) for the reaction to occur? In particular, the reaction will be considered “slow” if \(\tau_f > \text{GMFPT}\) and “fast” if \(\tau_f < \text{GMFPT}\). We characterize the boundary between the two regimes finding those vertices \(f\) for which \(\text{GMFPT} = \text{MFPT}_f\). We will obtain this results in the limits of \(L \to \infty\) by imposing the asymptotic equality between Eq. 17 and 23, and between Eq. 19 and 25. Recalling that \(f = (x_f, y_f)\) we will looking for the functional form \(y_f(x_f, L, \alpha)\) such that \(\text{GMFPT} \sim \text{MFPT}_{x_f,y_f}\).

A. GMFPT vs MFPT\(_f\) in Open Combs

Let us consider the leading value of GMFPT and MFPT\(_f\) from, Eqs. (17) and (23):
\[
\begin{align*}
\text{GMFPT}(L, \alpha) &\sim L^3 \left( \frac{8}{3} \alpha + 4\alpha^2 \right) \\
\text{MFPT}_f(L, \alpha) &\sim L^3 \left( 4\alpha \left( \frac{1}{3} + X^2 \right) + 8\alpha^2 |Y| \right),
\end{align*}
\]
where we normalized the coordinates as \(X = x/L\) and \(Y = y/\alpha L\). Now vertices \(f\) for which \(\text{MFPT}_f = \text{GMFPT}\) are those whose coordinates fulfill the following equality:
\[
\frac{8}{3} \alpha + 4\alpha^2 = \frac{4\alpha \left( \frac{1}{3} + X^2 \right) + 8\alpha^2 |Y|}{2\alpha}.
\]
Solving for \(Y\) we find
\[
|Y| = \left( \frac{1}{2} + \frac{1}{6\alpha} \right) - \frac{X^2}{2\alpha}.
\]
It is interesting to note that the fraction of vertices for which the reaction is slow, \(F_{\text{slow}}\), or fast, \(F_{\text{fast}}\), are exactly the same for every value of \(\alpha\). This is obtained integrating the value of \(Y\):
\[
F_{\text{slow}} = \int_0^1 |Y(X, \alpha)| dX = \frac{1}{2}.
\]

The phase diagram is shown in Fig. 13. As we can see, varying the value of \(\alpha\) there are three possible scenarios: when \(\alpha\) is sufficiently small there are some teeth totally
those whose coordinates fulfill the following equality:

\[ f \text{ the set of vertices } S \]

Solving for \( \alpha \) composed by "fast" vertices (like in \( MFPT \) composed by "slow" vertices but no one that is totally "fast" or "slow" (like in \( \alpha \) is large enough there are no teeth that are completely "fast" or "slow") the first case happens when \( |Y| \geq 1 \) for \( X = 0 \). This means that \( |Y| = \left( \frac{1}{2} + \frac{1}{6\alpha} \right) \geq 1 \), and solving in \( \alpha \) we find

\[ \alpha \leq \frac{1}{3} ; \]

the second case happens when \( |Y| \geq 0 \) for \( X = 1 \). This means that \( |Y| = \left( \frac{1}{2} + \frac{1}{6\alpha} \right) - \frac{1}{2\alpha} \geq 0 \), and solving in \( \alpha \) we find

\[ \alpha \geq \frac{2}{3} ; \]

the last case happens in the intermediate case:

\[ \frac{2}{3} > \alpha > \frac{1}{3} . \]

B. GMFPT vs MFPT\(_f\) in Close Combs

Let us consider the leading terms of GMFPT and MFPT\(_f\), Eqs. (19) and (25)

\[
\begin{cases}
\text{GMFPT} \circ \ (L, \alpha) & \sim L^3 \left( \frac{4}{3} \alpha + 4\alpha^2 \right) \\
\text{MFPT} \circ \ (L, \alpha) & \sim L^3 \left\{ \frac{4}{3} \alpha + 8\alpha^2 |Y| \right\},
\end{cases}
\]

the set of vertices \( f \) for which MFPT\(_f\) \sim GMFPT are those whose coordinates fulfill the following equality:

\[
\left( \frac{4}{3} \alpha + 4\alpha^2 \right) = \left\{ \frac{4}{3} \alpha + 8\alpha^2 |Y| \right\}.
\]

Solving for \( Y \) we find

\[ |Y| = \frac{1}{2}. \]

This means that the location of nodes \( f \) such that GMFPT = MFPT\(_f\), does not depend neither on \( X \) (and this is obvious due to the periodic boundary condition) nor on \( \alpha \). Therefore, if the target is placed sufficiently far from the backbone (i.e. at least at half the height of a tooth) the reaction turns out to be slow. Once again the fraction of vertices giving rise to slow and fast reactions is the same. The phase diagram is shown in Fig. 14.

V. CONCLUSIONS AND FUTURE PERSPECTIVES

In this work we found an useful formula, (5), to calculate the exact value of the hitting time, that is an alternative form of Tetali’s equation. This formula is particularly useful when the graph has ramifications. In particular we have calculated explicitly the value of \( H (i, f) \) for the bidimensional combs and its leading value for the \( d \)-dimensional ones.

We then used these results to calculate the MFPT\(_f\) and the GMFP for 2-dimensional combs, observing that the leading value is composed by two terms, one proportional to \( \alpha L^3 \), and the other one to \( \alpha^2 L^3 \), being \( \alpha \) the ratio between the size of the backbone and of the teeth.

As for the GMFPT we noticed that its asymptotic behaviour does not directly depends on its fractal and spectral dimension (as for homogeneous lattices and fractals) and we calculated it exactly. Finally we discussed our results in the context of reaction-kinetics. Infact the MFPT can be seen as the mean time taken by a mobile reactant A to reach a static reactant B, when the starting point of the mobile reactant is not known. Interestingly the typical time for the reaction to occur can be either larger (slow reaction) or smaller (fast reaction) than the GMFPT, and we outlined the set of trap locations for which these regimes are recovered.
