Objective: To evaluate the effects of 2 different dose regimens of propofol (low dose: < 1 mg/kg, high dose: ≥ 1 mg/kg) on the duration of the seizures, the required energy for the seizures, and the seizure threshold over the course of electroconvulsive therapy (ECT).

Methods: The electronic medical records of 165 patients receiving 971 sessions of ECT were analyzed retrospectively. Patients were evaluated in two groups according to the according to propofol doses that they had received for ECT. Group LP (n = 91): patients who received low dose propofol (< 1 mg/kg). Group HP (n = 74): patients who received high dose propofol (≥ 1 mg/kg).

Results: The required energy for seizures in Group HP were significantly higher than the Group LP in the 3rd, 4th, 5th, 6th, 7th, 8th, and 9th sessions (p < 0.05). The duration of seizures in the Group HP were significantly lower than the Group LP in the 1st, 2nd, 4th, 5th, 7th, and 8th sessions (p < 0.05). Higher electrical stimulus was needed to acquire a minimum length of seizure (> 25 sn) during the course of ECT in higher propofol doses. Although there was an increase in the seizure threshold over the course of ECT in both groups, this increase was found to be much more pronounced in the high-dose propofol group according to the low-dose propofol group. Longer duration of seizures was observed in the low-dose propofol group.

Conclusion: Higher doses of propofol in induction of anesthesia can lead to a more progressive rise in seizure threshold than lower doses of propofol.

KEY WORDS: Anesthesia; Electroconvulsive therapy; Propofol; Seizures.

INTRODUCTION

Electroconvulsive therapy (ECT) is a procedure which generalized seizures are induced by transcutaneous electrical stimuli to the brain. The ECT has been used in psychiatry since the early 1930s as an effective treatment of psychiatric disorders [1]. In the 1950s, ECT was receded with the development of antipsychotics and antidepressants. However, in the 1980s, when psychotropic drugs were found to be ineffective in some patients, ECT begun to gain importance again [2]. ECT is a preferred treatment modality in patients with major depression, affective disorders, schizophrenia, and other psychotic disorders, where pharmacological treatment is not adequate, and a rapid clinical response is desired. Several theories were hypothesized about mechanisms of action of ECT-including changes in cerebral blood flow and blood brain barrier, epigenetic modifications, changes in the levels of various hormones, neurotransmitters, and neurotrophic factors, alterations in neuroplasticity, and immune mechanisms [2,3]. In order for ECT to be effective, the required seizure time is > 25 seconds [4,5].

Anesthesia is an important factor for the safety and efficacy of ECT [6,7]. The anesthetic agents should provide rapid induction and recovery, must have fewer side effects, and should not reduce the duration and quality of ECT [8]. Thiopental shortens duration of the seizures, extends recovery, and causes hypotension. Etomidate has
minimal hemodynamic and cardiac adverse effects; on the other hand, it prolongs seizure duration and recovery time. Propofol is the most frequently used hypnotic agent in ECT. It is also known that propofol reduces duration of seizures, however its effect on seizure threshold is controversial. Wang et al. [9] emphasized that propofol can induce epileptiform electroencephalogram (EEG) changes after administration of low (< 1 mg/kg) doses, and this epileptiform EEG pattern was attenuated after administration of higher propofol doses.

In this study, 2 different dose regimens of propofol (low dose: < 1 mg/kg, high dose: ≥ 1 mg/kg) were compared by assessing the effects on duration of the seizures, required energy for the seizures, and seizure threshold over the course of ECT.

METHODS

After approval of the local ethical committee (Decree #14/13, January 4, 2019), the electronic medical records of the patients who received ECT sessions with a standardized protocol of anesthetic drugs (propofol and succinylcholine) between January 2015 and September 2018 were analyzed retrospectively. Patients with missing data, who received drugs that can affect seizures, and who received a different protocol of anesthetic drugs were excluded from the study.

It was observed that there was a significant difference in the regimen of propofol doses due to the different application methods of anesthesia of multiple anesthesiologists. Because of this reason, it was decided to evaluate the patients in 2 groups according to propofol doses. Group LP (n = 91): patients who received low dose propofol (< 1 mg/kg). Group HP (n = 74): patients who received high dose propofol (≥ 1 mg/kg). Propofol doses were calculated by dividing the total amount of propofol administered by the weight of the patient.

Data collection included demographic characteristics, psychiatric diagnosis, overall number of ECT sessions performed, doses and types of anesthetic drugs used, seizure thresholds, seizure durations, complications during the ECT sessions, clinical severity scores on admission and clinical improvement scores following ECT therapy. Before ECT, all patients had preanesthetic evaluation and informed consent was obtained from all patients. Pre-procedural medications of patients were reordered by a psychiatrist. Patients were scheduled for consecutive ECT sessions three times a week (Monday, Wednesday, Friday; except weekends).

In the periprocedural period, patients received no drugs which can affect seizures such as anticonvulsant, benzodiazepine, theophylline or methylphenidate. No premedication was administered to patients. Routine monotorization of non-invasive blood pressure, heart rate, and peripheral oxygen saturation were established. Seizures were monitored with a two-channel EEG. Following pre-oxygenation with 100% oxygen via face mask, propofol administered intravenously until the patient was unconsciousness, and loss of eyelash reflex. Succinylcholine was then administered for muscle relaxation, and ventilation was assisted. The drug doses for induction of anesthesia in the subsequent sessions were determined based on the previous administered drug doses. Electrical stimulus was delivered via bifrontotemporal electrodes the stimulus with the dosage titration procedure. Seizure threshold was defined as the stimulus dosage that elicited a seizure activity on EEG of at least 25 seconds duration. Duration of the seizure activity on EEG was evaluated by the psychiatrist. No additional anesthetic or muscle relaxant medications were given after the initial bolus. After the procedure, patients were monitored at the recovery room until modified Aldrete scores were 9 or higher.

The scores of the clinical severity of illness on admission and clinical improvement scores following ECT were assessed with Clinical Global Impressions scale (CGI) according to the clinician’s judgement, and these data were acquired from the clinical charts. The severity of the illness was rated on the 7-point CGI-Severity (CGI-S) scale from 1 (normal, not at all ill) to 7 (among the most extremely ill patients) [10]. The clinical improvement following ECT therapy was rated on the 7-point CGI-improvement (CGI-I) scale from 1 (very much improved since the initiation of treatment) to 7 (very much worse since the initiation of treatment) [10]. For evaluation of the response to ECT therapy, we dichotomized patients as responders (CGI-I score of 1, 2, and 3), and non-responders (CGI-I score of 4, 6, and 7).

Statistics

Statistical analyses were performed using computerized statistical software: IBM SPSS, version 24.0 (IBM Corp., Armonk, NY, USA). For intergroup comparisons of
categorical data, Pearson’s chi-square test was applied. For continuous variables, the Kolmogorov–Smirnov test was used for the normality of data distribution and followed by the Mann–Whitney_U test when a significant difference was found (p < 0.05). The correlation of the variables (the required energy for seizures and the duration of seizures) were analyzed using Pearson correlation analysis. Friedman variance analysis was used to evaluate the repeated measures of the required energy for seizures in the consecutive ECT sessions, and post-hoc Wilcoxon signed-ranks test was used for paired comparison of these repeated measures. All data were presented as median (min−max) or numbers as appropriate. A p < 0.05 was considered to be statistically significant.

RESULTS

A total of 971 ECT sessions were performed on 165 patients, including 74 males (55%) and 91 female (45%) patients. Three of the female patients underwent ECT because of pregnancy. It was observed that a mean of 1.56 mg/kg (median 1.83 mg/kg [min 1−max 2.56]) propofol was administered to the patients in high dose propofol group, and a mean of 0.67 mg/kg (median 0.6 mg/kg [min 0.4−max 0.89]) propofol was administered to the patients in low dose propofol group. There were no statistically significant differences between the groups in the demographic and clinical characteristics of the patients (Table 1).

There was a statistically significant difference in the required energy for seizures between the two groups. Required energy for seizures in Group HP were significantly higher than the Group LP in the 3rd, 4th, 5th, 6th, 7th, 8th, and 9th sessions (p < 0.05) (Table 2). There was a statistically significant difference in the duration of seizures between the two groups. The duration of seizures in the Group HP were significantly lower than the Group LP in the 1st, 2nd, 4th, 5th, 7th, and 8th sessions (p < 0.05) (Table 2). The correlation between the duration of seizures and the required energy for seizures showed a negative and statistically significant difference (p < 0.05). It was found that shorter duration of seizures correlated higher energy, in the 2nd, 3rd, 4th, 6th, 7th, 8th, and 9th sessions in Group HP, and the 2nd, 3rd, 4th, and 5th sessions in Group LP (Table 3). This means that higher electricity stimulus was needed to acquire a minimum length of seizure (> 25 sn) during the course of ECT in higher propofol doses.

Table 1. Demographic and clinical characteristics of the patients

| Variable                        | Group HP (n = 74) | Group LP (n = 91) | z   | χ²   | p value |
|---------------------------------|------------------|------------------|-----|------|---------|

Values are presented as mean±standard deviation, median (min−max), or number (%).

CGI-S, Clinical Global Impressions-Severity scale.

Mann–Whitney_U analysis, Pearson’s chi-square; *p < 0.05.
The main finding of this study was, although an increase in the seizure threshold was observed in all patients over the course of ECT, this increment was much more pronounced in the high-dose propofol group. In comparison with the low-dose propofol group, in 2 patients more pronounced increase in the seizure threshold was observed in the high-dose propofol group.

The correlation of the required energy for seizures and the duration of seizures over the course of the ECT sessions is presented in Figure 1. Although there was an increase in the seizure threshold over the course of ECT in both groups, this increase was found to be much more pronounced in the high-dose propofol group according to the Friedman variance analysis (p = 0.005). There was no statistically significant difference between the low-dose and high-dose propofol groups in the duration of seizures with post-hoc Wilcoxon signed ranks analysis (p > 0.05). All binary pairings were found to be statistically significant (p < 0.05). The measurement of the required energy for seizures in the 1st, 2nd, and 3rd session pair were found to be statistically significant (p < 0.05). All binary pairings were found to be statistically significant (p < 0.05).

The clinical response to the treatment according to the CGI-I scale. The number of responders (the number of patients with CGI-I scores < 3) and non-responders was assessed with the CGI-I scale. The number of responders was statistically significant (p = 0.03; χ² = 5.01) (Table 1). A brief asystole was observed in 3 patients during propofol administration and atropine was administered intravenously. Anaphylactic shock in 3 patients was observed in 1 patient, bradycardia in 1 patient, hypertension in 1 patient, self-limited rash in 1 patient, amnesia in 2 patients, and self-limited rash in 2 patients were observed as for the adverse effects of the treatment.

† Significant difference (p < 0.05). All binary pairings were found to be statistically significant (p < 0.05).

The measurement of the required energy for seizures in the 1st, 2nd, and 3rd session pair were found to be statistically significant (p < 0.05). All binary pairings were found to be statistically significant (p < 0.05).

Duration of seizures Friedman variance analysis and post-hoc Wilcoxon signed ranks analysis; *p < 0.05.

seizure thresholds [11], changes in the seizure thresholds, and the duration of seizures in ECT have been researched widely [12]. It is well-established that changes in the seizure threshold occur during the course of ECT [12,13]. Sex, age, electrode placement, and the cumulative number of treatments are associated with an increase in seizure threshold which is attributed to anticonvulsant effect of ECT [14]. Although, anesthetic drugs are known to have effect on seizure thresholds, the role of propofol on the seizure threshold during the course of ECT is uncertain.

Propofol is a frequently used anesthetic agent for both sedation and hypnosis. Propofol can inhibit seizure activ-
H.G. Aytuluk, et al.

Fig. 1. Correlation of the required energy for seizures and the duration of seizures over the course of the electroconvulsive therapy sessions.

Mechanism of action of propofol is to increase the inhibitory tonus in the cranial nervous system, by increasing gamma-aminobutyric acid (GABA) which is the principal inhibitory neurotransmitter. It has also been shown that electroconvulsive shock results in increased GABA concentrations in several neural regions [20,21]. Anticonvulsant effect of ECT was attributed to enhancement of GABAergic or endogenous opiate neurotransmission, which in turn could lead to a progressive rise in seizure threshold [13]. The significant increase in the seizure threshold over the course of ECT in high-dose propofol group may be the result of the additive effect of both higher doses of propofol and the anticonvulsant effect of ECT on GABA concentrations. At this point, randomized controlled trials are needed to explain the relation between propofol doses and seizure thresholds.

Some of the previous authors have suggested that rise in the seizure threshold was directly related with the clinical efficacy [22]. In contrast to these findings, following studies have failed to support this hypothesis [20,23]. Accordingly, clinical outcomes of this study were not affected by the magnitude of the rise in the seizure threshold.

ECT is related to some complications such as bone and soft tissue injury, sustained seizure activity, significant changes in autonomic function, facial flush, respiratory distress and oxygen desaturation [24,25]. Bradycardia, hypotension, and cardiac pause or a brief asystole can be caused by parasympathetic response [26]. Tachycardia and hypertension are related to sympathetic activation [27]. Postprocedural headache and myalgia (due to muscle fasciculations with succinylcholine) can be reduced with rocuronium and sugammadex [28]. The prevalence of the complications that we observed in this study was consistent with the literature.

1. The strengths of this study are, despite the lack of randomization, the two groups were well matched in terms of demographic and clinical characteristics. The standard type of anesthetic agents that were used for ECT allowed us to compare the different induction regimens of individual anesthesiologists. In many studies, anesthetic agents were tended to be switched in a single course of ECT, however, in this study the anesthetic drug doses in the subsequent sessions were determined based on the previous administered drug doses. Additionally, the large number of patients in comparison with other studies is another strength of this study.

First limitation of this study is that it is a retrospective analysis and it cannot be generalized yet. In the daily clinical practice of anesthesia, like many anesthetics, propofol is administered by titration until a desired clinical effect is achieved [29]. Although, a propofol dose between
1 to 2 mg/kg is adequate for induction of anesthesia in most cases, propofol requirement can be influenced by several factors which can affect pharmacodynamics and pharmacokinetics, such as degree of anxiety, speed of injection, cardiac output, lean body mass, drug interactions, etc. [30,31]. Because of the retrospective nature of the study, we could not be able to standardize these variables, nor study the effects of a fixed dose of propofol. Thus, we observed different propofol dosing regimens individualized for patients.

In conclusion, although an increase in the seizure threshold can be observed in all patients over the course of ECT, higher propofol doses (≥ 1 mg/kg) in induction of anesthesia can lead to a more progressive rise in seizure threshold over the course of ECT. Larger propofol doses according to lower doses are associated with shorter duration of seizures. Thus, when propofol doses remained below 1 mg/kg, it may be beneficial for inducing longer duration of seizures without a significant contribution to the rise of seizure threshold.
