Effects of thyroid hormone withdrawal on metabolic and cardiovascular parameters during radioactive iodine therapy in differentiated thyroid cancer

Jee Hyun An¹,², Kee-Ho Song¹, Dong-Lim Kim¹ and Suk Kyeong Kim¹

Abstract
Objective: To investigate the cardiometabolic effects of a severe hypothyroid state induced by withdrawal of thyroid hormone replacement before radioactive iodine therapy.

Methods: Patients with thyroid cancer who were scheduled to receive radioactive iodine ablation were enrolled. Cardiometabolic parameters were measured using blood samples taken immediately before levothyroxine withdrawal, 4 weeks following withdrawal (on radiotherapy day), and 4 weeks following reinstitution of levothyroxine.

Results: Out of 48 patients (age 49.4 ± 10.5 years; 77.1% [37/48] female), the severe hypothyroid state induced by levothyroxine withdrawal significantly aggravated the majority of lipid parameters, particularly in patients with a greater number of metabolic syndrome components. Fasting plasma glucose levels and homeostatic model assessment values for insulin resistance and β-cell function significantly decreased following levothyroxine withdrawal. Serum high-sensitivity C-reactive protein, fibrinogen and cystatin C levels significantly decreased, and homocysteine levels increased during the severe hypothyroid state. All of these changes were reversed by levothyroxine reinstitution.

Conclusions: Severe hypothyroid state induced pronounced changes in cardiometabolic parameters. Further studies should identify the long-term effects of changes in these parameters on cardiovascular morbidity and mortality in relation to thyroid disease.

Date received: 26 April 2016; accepted: 22 July 2016

Introduction
Hypothyroidism adversely affects cardiovascular morbidity and mortality, as thyroid hormone regulates lipid metabolism and cardiovascular haemodynamics. Hypothyroidism leads to lipid abnormalities that are characterized by hypercholesterolaemia with increased levels of low-density lipoprotein (LDL) and apolipoprotein B, due to reduced numbers of LDL receptors in the liver and subsequent decrease in LDL clearance. Furthermore, hypothyroidism increases systemic vascular resistance and impairs cardiac contractility and diastolic function. These changes in lipid profiles and haemodynamics are potentially associated with atherosclerosis and an increased risk of cardiovascular disease and mortality among patients with subclinical or overt hypothyroidism.

Thyroid hormone status has also been demonstrated to affect various adipocytokines and atherogenic inflammatory markers, which may lead to additional harmful effects that promote the progression of cardiovascular disease. In addition, patients with hypothyroidism exhibit elevated serum levels of high-sensitivity C-reactive protein (hs-CRP), homocysteine, and fibrinogen, which are well-known biomarkers and independent risk factors for atherosclerosis. Serum levels of cystatin C are a marker for renal function and cardiovascular disease, and have been reported to exhibit changes according to thyroid function. Whether these markers are independently correlated with thyroid function and whether they can be reversed following treatment of thyroid dysfunction, however, remains controversial. In addition, the abovementioned studies have included heterogeneous populations with different severities, durations, and aetiologies of thyroid dysfunction, which might confound any analyses of the effects of thyroid hormone on these markers.

During radioactive iodine therapy following thyroidectomy for differentiated thyroid cancer, patients experience a severe hypothyroid state after thyroid hormone treatment withdrawal, and they subsequently recover once thyroid hormone treatment is reinstated. Such serial changes in thyroid hormone status may cause drastic changes in cardiometabolic parameters, and produce a representative and well-controlled group of patients with homogeneous thyroid hormone status.

The present study aimed to evaluate the effects of the severe hypothyroid state following thyroid hormone withdrawal on cardiometabolic and vascular inflammatory parameters among patients who underwent radioactive iodine therapy after thyroidectomy, and to identify any patient subgroups who experienced more pronounced changes in these parameters.

Patients and methods
Study population and design
This prospective cohort study enrolled consecutive patients with differentiated thyroid cancer who were scheduled to receive radioactive iodine ablation following total thyroidectomy at Konkuk University Medical Center, Seoul, Korea between May 2012 and May 2013. Patients with chronic disease (including kidney, liver, and heart failure), acute infection or inflammatory conditions, or who were receiving drugs...
for diabetes mellitus, hypertension, dyslipidaemia, or other conditions that might affect metabolic parameters were excluded.

Blood samples were obtained at three time points to identify serial changes in various metabolic parameters (Figure 1): Visit 1, immediately before withdrawal of levothyroxine in preparation for radioactive iodine ablation (a mild thyrotoxic state due to receiving levothyroxine for thyroid stimulating hormone [TSH] suppression); Visit 2, day of radioactive iodine ablation following 4 weeks of levothyroxine withdrawal (a severe hypothyroid state with TSH levels ≥30 mU/l); and Visit 3, at 4 weeks following reinstitution of levothyroxine (recovery to a mild thyrotoxic state).

The study protocol was reviewed and approved by the institutional review board of Konkuk University Medical Center (KUH1010507), and this study was registered in the ClinicalTrial.gov registry (NCT01744769). All participants provided written informed consent.

**Outcome measures**

Blood pressure and heart rate were recorded three times between 7:00 and 9:00 h after the patients had been in a relaxed state for ≥10 min, and a 5-min rest period was provided between each measurement. The mean of three readings was used for analysis.

Between 7:00 and 9:00 h, and following a 14 h overnight fast, 20 ml of venous blood was drawn from the antecubital vein of each patient into tubes without anticoagulant and tubes containing ethylenediaminetetraacetic acid-2Na (1 mg/ml blood). Plasma was immediately separated by centrifugation at 2000 g at 4 °C for 10 min, and serum was prepared by allowing the blood sample to clot for 30 min at room temperature, followed by centrifugation at 2000 g at 4 °C for 10 min.

Biochemical measurements of cardiometabolic parameters were conducted immediately following sample preparation. Fasting plasma glucose (FPG), serum triglycerides, free fatty acid, homocysteine, cystatin C, fibrinogen, hs-CRP, total cholesterol, high-density lipoprotein cholesterol (HDL-C), LDL cholesterol (LDL-C), and apolipoprotein A and B levels were measured using a Toshiba 200FR automatic analyser (Toshiba Medical System Co., Ltd, Tokyo, Japan) according to the manufacturer’s instructions. Plasma insulin levels were determined using a MODULAR analytics
E170 module (Roche Diagnostics, Manheim, Germany) and glycosylated haemoglobin (HbA1c) levels were measured using a VARIANT II TURBO 2.0 kit (Bio-Rad Laboratories, Hercules, CA, USA), both according to the manufacturer’s instructions. Free thyroxine and TSH were measured using an automatic SR300 radioimmunoassay analyser (STRATEC Biomedical AG, Birkenfeld, Germany) and associated reagents, according to the manufacturer’s instructions.

Primary outcome measures were changes in cardiometabolic parameters, comprising blood lipids (total cholesterol, LDL-C, HDL-C, triglycerides, free fatty acids, and apolipoproteins A and B), glycaemic parameters (FPG, fasting insulin, HbA1c, and homeostatic model assessment values for insulin resistance and β-cell function [HOMA-IR and HOMA-B]), and vascular inflammation and atherosclerosis markers (uric acid, hs-CRP, fibrinogen, homocysteine, and cystatin C), according to thyroid hormone status.

Secondary outcome measures were the correlation between TSH levels and metabolic parameters, and the baseline characteristics that predicted changes in metabolic parameters. The signs and symptoms of hypothyroidism were assessed using the Zulewski score as previously described, and metabolic syndrome was defined according to the National Cholesterol Education Program (NCEP) Adult Treatment Panel III report.

**Statistical analyses**

All normally distributed continuous variables are presented as mean ± SD, and categorical variables as presented as n (%) prevalence. Student’s paired t-test or analysis of variance was used to compare continuous variables, and χ²-test was used to compare categorical variables. The relationship between changes in TSH levels and other parameters was evaluated using Pearson’s correlation coefficient. All analyses were performed using SPSS software, version 17.0 (SPSS Inc., Chicago, IL, USA), and differences with a P-value < 0.05 were considered statistically significant.

**Results**

**Baseline characteristics**

Among 50 patients who were enrolled, two patients withdrew during the study period and 48 patients completed the study. Baseline characteristics are shown in Table 1.

**Changes in metabolic parameters according to changes in thyroid hormone status**

Changes in haemodynamic and metabolic parameters according to changes in thyroid hormone status were investigated by comparing parameters immediately before levothyroxine withdrawal (Visit 1), at 4 weeks following levothyroxine withdrawal (on day of radiotherapy; Visit 2), and at 4 weeks following levothyroxine reinstitution (Visit 3; Table 2). TSH levels had
significantly increased and free thyroxine levels significantly decreased at Visit 2 (66.9 ± 30.3 mU/l and 0.19 ± 0.17 ng/dl, respectively; both $P < 0.05$ compared with Visit 1), and these changes were subsequently reversed at Visit 3 (2.4 ± 5.0 mU/l and 2.03 ± 0.35 ng/dl, respectively; both $P < 0.05$ compared with Visit 2). The mean Zulewski score increased, and mean systolic blood pressure and heart rate (HR) decreased, during the severe hypothyroid state; all changes were reversed following reinstitution of levothyroxine. Most lipid parameters (total cholesterol, LDL-C,
triglycerides, free fatty acids and apolipoprotein B levels) significantly increased following levothyroxine withdrawal, including HDL-C levels (Table 2); all of these changes were reversed by levothyroxine replacement. In addition, FPG, insulin, HOMA-B, and HOMA-IR significantly decreased following levothyroxine withdrawal, and these changes were also reversed after levothyroxine reinstitution. Among the markers of vascular inflammation and atherosclerosis, levothyroxine withdrawal was associated with decreased levels of hs-CRP, fibrinogen, and cystatin C, although serum homocysteine levels were significantly increased. All of these changes were reversed by levothyroxine reinstitution, with the exception of the decreased cystatin C levels (Table 2).

**Changes metabolic syndrome components during a severe hypothyroid state**

Most metabolic syndrome components were aggravated following levothyroxine withdrawal, with the exception of glycaemic profiles during the severe hypothyroid phase. Thus, the proportions of patients who fulfilled the metabolic syndrome criteria for each related component, based on the NCEP Adult Treatment Panel III definition of metabolic syndrome, were analysed according to changes in thyroid hormone status (Figure 2). Among the metabolic syndrome components, proportions of male and female patients with high triglyceride levels (≥150 mg/dl) increased significantly during the severe hypothyroid state (Visit 2), however, proportions of other metabolic syndrome components, such as high blood pressure, high FPG levels (among female patients), and high HDL-C levels decreased during the hypothyroid state (P < 0.05 versus Visit 1; Figure 2). The proportion of all patients who fulfilled the criteria for metabolic syndrome decreased from 29.2% (14/48) at baseline (Visit 1) to 25.0% (12/48) during the hypothyroid state (P < 0.05). There were no sex-specific differences in these changes, and the proportions returned to baseline values following reinstitution of levothyroxine.

**Correlation between TSH levels and metabolic parameters following thyroid hormone withdrawal**

The correlation between TSH levels and the metabolic parameters that changed during the severe hypothyroid state were further analysed. During the severe hypothyroid state (Visit 2) TSH levels exhibited a significant positive correlation with LDL-C levels (r = 0.3, P = 0.04) and HDL-C levels (r = 0.39, P = 0.01), and a significant negative correlation with hs-CRP levels (r = –0.32, P = 0.03) (Figure 3). TSH levels were not significantly correlated with other metabolic parameters (triglycerides, free fatty acids, uric acid, homocysteine, and fibrinogen levels).

**Baseline characteristics of patients with different metabolic responses following thyroid hormone withdrawal**

To identify characteristics that may predict significant changes in cardiometabolic parameters during a hypothyroid state, patients were divided into tertiles according to magnitude of change in lipid parameters. Patients in the upper tertile for change in triglyceride levels exhibited higher baseline levels of aspartate aminotransferase (AST)/alanine aminotransferase (ALT), triglycerides, free fatty acids, fibrinogen and uric acid, and a higher baseline proportion of metabolic syndrome, compared with the lower tertile group (P < 0.05; Table 3). Patients in the upper tertile for change in LDL-C levels exhibited a similar pattern (higher baseline body mass index, AST/ALT, total cholesterol, LDL-C, triglycerides, free fatty acids, apolipoprotein B,
Figure 2. Serial changes in the proportion of patients with metabolic syndrome components associated with withdrawal and reinstitution of thyroid hormone in patients with differentiated thyroid cancer who received radioactive iodine ablation following total thyroidectomy (n = 48). Proportion of patients with (a) waist circumference (WC) ≥ 90 cm among males and ≥ 80 cm among females; (b) blood pressure (BP) ≥ 130/85 mmHg; (c) fasting plasma glucose (FPG) ≥ 100 mg/dl; (d) triglyceride (TG) ≥ 150 mg/dl; (e) high-density lipoprotein-cholesterol (HDL-C) levels < 40 mg/dl among males and < 50 mg/dl among females; and (f) metabolic syndrome defined according to the National Cholesterol Education Program Adult Treatment Panel III report.20 Data presented as % patient prevalence. Visit 1, immediately before withdrawal of levothyroxine in preparation for radioactive iodine ablation; Visit 2, at 4 weeks following levothyroxine withdrawal (on day of radiotherapy); and Visit 3, at 4 weeks following reinstitution of levothyroxine. *P < 0.05 versus Visit 1; #P < 0.05 versus Visit 2 (χ²-test).

hs-CRP, homocysteine, fibrinogen, cystatin C, and uric acid levels and a higher baseline proportion of metabolic syndrome) compared with the lower tertile group (P < 0.05; Table 3). The severe hypothyroid state also induced an increase in HDL-C levels, and the upper tertile group for changes in HDL-C levels exhibited a significantly greater

proportion of female patients, a lower baseline proportion of patients with metabolic syndrome, a lower body mass index, and a smaller waist circumference. Furthermore, these patients exhibited lower baseline levels of FPG, hs-CRP, and uric acid ($P < 0.05$; Table 3).

**Discussion**

In the present study among patients who underwent total thyroidectomy for differentiated thyroid cancer, severe hypothyroidism due to thyroid hormone withdrawal produced noticeable changes in various cardiometabolic parameters, particularly among patients with underlying metabolic syndrome. Interestingly, these changes were fully reversed following reinstitution of thyroid hormone treatment. Furthermore, the present study revealed the direction of changes in these metabolic parameters, which have been reported with conflicting results in previous studies.\(^{15,21}\)

As expected, a severe hypothyroid state significantly aggravated the majority of lipid parameters that were evaluated in the present study, such as levels of LDL-C, triglycerides, free fatty acids and apolipoprotein B. In addition, patients who had a greater number of metabolic syndrome components prior to levothyroxine withdrawal subsequently experienced greater changes in these parameters during the severe hypothyroid state. Furthermore, changes in LDL-C levels were significantly correlated with TSH levels, although not with triglycerides and free fatty acids levels. The results of the present study concur with previously published findings. For example, differences in lipid profiles according to thyroid function have been reported\(^{15}\) with levels of total cholesterol, triglycerides, LDL-C, and apolipoprotein B increasing in patients with hypothyroidism and decreasing in patients with hyperthyroidism. TSH levels were also reported to be significantly correlated with changes in triglycerides, apolipoprotein B, and LDL-C levels,\(^{15}\) although this relationship was not observed in the present study. The discrepancy between the present and published results may be related to the fact that correlations between TSH levels and lipid parameters were examined during a severe hypothyroid state in the present study, when TSH levels were 20–125 mU/l. HDL-C levels were also elevated during the hypothyroid state in the present study, and may have resulted from decreased hepatic lipase and cholesterol-ester transport protein activity, leading to decreased HDL catabolism, reduced transfer of cholesteryl esters from HDL\(_2\) to very low- and intermediate-density lipoproteins, reduced transport of HDL\(_2\) to HDL\(_3\), and ultimately increased levels of HDL\(_2\).\(^{21}\)

Several studies have reported that thyroid hormone replacement exerts favourable effects on lipid profiles and haemodynamic factors, which may eventually reduce the risk of cardiovascular disease morbidity and mortality. Levothyroxine replacement in patients with hypothyroidism reduces body weight\(^{22}\) and improves various haemodynamic factors, such as central arterial stiffness and endothelium-dependent vasodilatation.\(^{23}\) In addition, atherogenic lipid levels (e.g., total cholesterol, LDL-C, triglycerides, and apolipoprotein B) are reported to be reduced following levothyroxine replacement in patients with overt hypothyroidism.\(^{24}\) Studies have also reported, however, that levothyroxine replacement does not affect these cardiometabolic parameters among patients with subclinical disease.\(^{24,25}\)

In the present study, levothyroxine reinsti- tution fully reversed the changes in cardiometabolic parameters that were induced by short-term levothyroxine withdrawal, although further studies are needed to determine if levothyroxine has different effects in the acute and chronic hypothyroid states.

In addition to lipid profiles, changes in atherogenic markers (i.e., homocysteine,
CRP, fibrinogen, and cystatin C levels) associated with the withdrawal and reinsti-
tution of levothyroxine were also investig-
gated in the present study. Plasma levels of
homocysteine levels were observed to be
significantly elevated during the severe
hypothyroid state, and levothyroxine
replacement reversed this elevation.
Interestingly, homocysteine is an athero-
genic factor that promotes the production
of vascular inflammatory chemokines,
reactive oxygen species, and oxidized LDL-
C.26,27 A meta-analysis has also
revealed that plasma homocysteine levels
are elevated in patients with hypothyroid-
ism, compared with those in healthy indi-
viduals, although levothyroxine replacement
can reverse this elevation.28 Another study
has suggested that these hypothyroidism-
induced elevated homocysteine levels
may induce insulin resistance and increase
the risk of cardiovascular disease.12 In the
present study, however, HOMA-IR was
significantly decreased during the hypothy-
roid state.
Although homocysteine levels and the
majority of lipid parameters exhibited
unfavourable changes during the severe
hypothyroid state in the present study,
favourable changes in blood pressure, FPG
levels, and atherosclerosis markers (e.g., hs-
CRP, fibrinogen, and cystatin C levels) were
observed during this state. Furthermore,
HOMR-B was shown to be reduced during
the severe hypothyroid state. Although sev-
eral studies have reported increased insulin
resistance in cases of hypothyroidism,12,29
the present results are consistent with find-
ings of one study that showed a 7.4%
decrease in FPG levels in cases of overt
hypothyroidism compared with cases of subclinical disease, and that the decrease
was correlated with reduced insulin resist-
ance.10 Interestingly, hypothyroidism
induces reductions in energy expenditure
and metabolic rate, which may lead to
lower levels of FPG and insulin.30
Previous studies have reported conflicting
results regarding changes in CRP, fibrino-
gen and cystatin C levels among patients
with hypothyroidism.11,13–17 These factors
are well-known inflammatory markers of
cardiovascular disease, and many of the
previous studies have focused on the
increase in these markers and their associ-
ation with the risk of cardiovascular disease
during the hypothyroid state.11,14,16 Thus,
the favourable changes in hs-CRP, fibrino-
gen, and cystatin C levels observed during
the hypothyroid state in the present study
are difficult to interpret. Nevertheless, the
authors speculate that the low-iodine diet
recommended for patients undergoing
radioactive iodine therapy could affect
these parameters, and that acute withdrawal
of levothyroxine may induce different
responses in these inflammatory markers,
compared with the responses observed
during chronic hypothyroidism.31
The present study has several clinical
implications. First, patients with hyperlipid-
aemia should be tested to determine their
thyroid function, and should be actively
treated using thyroid hormone if hypothy-
roidism is detected, as levothyroxine
reinstatement restored lipid profiles to their
baseline state within 4 weeks. Furthermore,
patients with baseline metabolic syndrome
components experienced pronounced
changes in their lipid profiles after levothyr-
oxine withdrawal in the present study, which
suggests that these patients should be care-
fully assessed before withdrawing levothy-
roxine in preparation for radioactive iodine
therapy. Given that these changes were fully
reversed following levothyroxine reinsti-
tution, however, and that several cardiometa-
bolic markers exhibited favourable changes
during the severe hypothyroid state, short-
term withdrawal of levothyroxine may not
significantly affect the development of car-
diovascular disease.
The results of the present study may be
limited by the relatively small sample size
and the fact that this was a single centre study. Further multicentre studies should be conducted, with larger sample sizes. In addition, further studies are needed to identify the long-term effects of changes in these parameters on cardiovascular morbidity and mortality in relation to thyroid disease.

In conclusion, levothyroxine withdrawal-related hypothyroidism induced pronounced changes in various cardiometabolic parameters among patients who had undergone total thyroidectomy and were preparing to undergo radioactive iodine therapy. These changes may increase the risk of atherosclerosis and cardiovascular diseases, especially among patients with metabolic syndrome components, although these changes were rapidly reversed after reinstating thyroid hormone treatment.

Declaration of conflicting interest
The authors declare that there is no conflict of interest.

Funding
This study was supported by a grant from the Korean Society of Lipidology and Atherosclerosis.
