ABSTRACT

The quasilinear mean-field theory for driven MHD turbulence leads to the result that the observed cross helicity $\langle \mathbf{u} \cdot \mathbf{b} \rangle$ may directly yield the magnetic eddy diffusivity $\eta_T$ of the quiet Sun. In order to model the cross helicity at the solar surface, magnetoconvection under the presence of a vertical large-scale magnetic field is simulated with the nonlinear MHD code NIRVANA. The very robust result of the calculations is that $\langle \mathbf{u} \cdot \mathbf{b} \rangle \simeq 2 \langle \mathbf{u} \cdot \mathbf{b} \rangle$ independent of the applied magnetic field amplitude. The correlation coefficient for the cross helicity is about 10\%. Of similar robustness is the finding that the rms value of the magnetic perturbations exceeds the mean-field amplitude (only) by a factor of five. The characteristic helicity speed $u_\eta$ as the ratio of the eddy diffusivity and the density scale height can be computed. If also the density scale is known from calculations, the ratio of the eddy diffusivity and the density scale can be used to calculate the numerical value of the eddy diffusivity for weak fields. This the more as $\langle \mathbf{u} \cdot \mathbf{b} \rangle \simeq \langle \mathbf{u} \cdot \mathbf{b} \rangle$ if the large-scale magnetic field has only a vertical component and the only vertical gradient is due to the density stratification. The correlation of the vertical components of flow and field can empirically be obtained by both Doppler measurements and spectropolarimetry.

To estimate the value of the cross helicity we assume a density scale height of 100 km and write the result in the form

$$\frac{\langle \mathbf{u} \cdot \mathbf{b} \rangle}{B_z} \simeq \frac{\eta_T}{H_\sigma} \text{ km/s},$$

where $H_\sigma = H_\sigma/100 \text{ km}$ and $\eta_T = 10^{12} \eta_T \text{ cm}^2/\text{s}$. With observations of the LHS of (1) of about 1 km/s one would find $\eta_T$ of order $10^{12} \text{ cm}^2/\text{s}$. In the present paper numerical simulations of stratified magnetoconvection and observational results are discussed and the theory will also be extended to the inclusion of a vertical stratification of the turbulence intensity. Both the simulations as well as the observations lead to very similar results for the desired magnetic eddy diffusivity for the quiet Sun exceeding the value given by (1) by a factor of (only) two.

A simple prediction of this theory is that the ratio $\eta_T$ does not depend on the sign of the mean magnetic field, i.e. it does not vary from cycle to cycle and (for a dipolar field) from hemisphere to hemisphere. As a consequence, the sign of the cross helicity $\langle \mathbf{u} \cdot \mathbf{b} \rangle$ should vary from cycle to cycle and between the hemispheres. Zhao et al. (2011) indeed found indications for a variation from hemisphere to hemisphere.
2. Mean-field electrodynamics

Let \( \mathbf{U} + \mathbf{u} \) and \( \mathbf{B} + \mathbf{b} \) be the fluctuating velocity and magnetic field with the average values \( \mathbf{U} \) and \( \mathbf{B} \). The scalar correlation between the fluctuations of flow and field, i.e., the cross helicity \( \langle \mathbf{u} \cdot \mathbf{b} \rangle \), is a pseudoscalar. In the same sense, the cross correlation tensor \( \langle u_i b_j \rangle \) is a pseudotensor. We are here only interested on its symmetric part

\[
H_{ij} = \frac{\langle u_i b_j \rangle + \langle u_j b_i \rangle}{2}.
\]

As we have shown the tensor \( H_{ij} \) can be finite in presence of a mean magnetic field \( \mathbf{B} \) and for density-stratified fluids (Rüdiger et al. 2011). Consider these quantities as small of a mean magnetic field

\[
\text{free mean flow} \quad \mathbf{U} = (U_x, U_y, U_z),
\]

the cross correlation tensor \( \langle u_i b_j \rangle \) is a pseudotensor.

The spectral tensor of the momentum density that accounts for the stratification of the turbulence to the first order terms reads

\[
\langle \hat{m}_i(z, \omega) \hat{m}_j(z', \omega') \rangle = \delta(\omega + \omega') \frac{g(k, \omega, \kappa)}{16 \pi k^2} \left( \delta_{ij} - k_i k_j / k^2 + (\kappa_i k_j - k_i k_j) / (2k^2) \right),
\]

where \( k = (z - z') / 2, \) \( \kappa = z + z' \), \( \hat{q} \) is the Fourier transform of the local spectrum,

\[
\hat{q}(k, \omega, r) = \rho^2 E(k, \omega, r) = \int \hat{q}(k, \omega, \kappa) e^{ik \cdot r} \, d\kappa,
\]

so that

\[
\langle u^2 \rangle = \int_{0}^{\infty} \int_{0}^{\infty} E(k, \omega, r) \, dk \, d\omega.
\]

Derivation of the cross correlation yields

\[
H_{ij} = \frac{1}{2} \eta_T (G_i B_j + G_j B_i) - \left( \frac{3}{10} \eta_T + \frac{1}{15} \hat{q} \right) (B_{i,j} + B_{i,j}),
\]

where \( \mathbf{G} = \nabla \log \rho \) is the gradient of density and

\[
\eta_T = \frac{1}{3} \int_{0}^{\infty} \int_{0}^{\infty} \frac{\eta k^2 E}{\omega^2 + \eta^2 k^2} \, dk \, d\omega,
\]

\[
\hat{\eta} = \int_{0}^{\infty} (\omega^2 + \eta^2 k^2)^2 \, dk \, d\omega,
\]

where \( \eta \) is the molecular magnetic diffusivity. Both quantities remain finite in the high-conductivity limit.

From the cross correlation tensor \( \langle \mathbf{u} \cdot \mathbf{b} \rangle \) the cross helicity \( \langle \mathbf{u} \cdot \mathbf{b} \rangle = \eta_T (\mathbf{G} \cdot \mathbf{B}) \) is obtained. From Eq. (10) we find the slightly more complicated expression

\[
\langle u_i b_z \rangle = \eta_T G_i B_z - \left( \frac{3}{10} \eta_T + \frac{2}{15} \hat{q} \right) \left( 2 \frac{\partial B_z}{\partial z} \right),
\]

where \( G = G_z \) is the only nonzero radial components of the density-stratification vectors. Note the negativity of \( G \). An upward divergence of the mean field would reduce the effect of density stratification but for uniform field components the result is \( \langle u_i b_z \rangle = \langle \mathbf{u} \cdot \mathbf{b} \rangle \).

A real difference, however, between the both correlation expressions is due to a possible gradient \( G' \) of the turbulence intensity \( u_{t,\text{rms}} \). One easily finds that for vertical fields the turbulence intensity gradient \( G' \) enters the expressions for the correlations such as

\[
\langle \mathbf{u} \cdot \mathbf{b} \rangle = (G + \frac{1}{2} G') \eta_T B_z, \quad \langle u_i b_z \rangle = (G + \frac{3}{10} G') \eta_T B_z.
\]

The spectral tensor of the momentum density that accounts for the stratification of the turbulence to the first order terms reads

\[
\langle \hat{m}_i(z, \omega) \hat{m}_j(z', \omega') \rangle = \delta(\omega + \omega') \frac{g(k, \omega, \kappa)}{16 \pi k^2} \left( \delta_{ij} - k_i k_j / k^2 + (\kappa_i k_j - k_i k_j) / (2k^2) \right),
\]

where \( k = (z - z') / 2, \) \( \kappa = z + z' \), \( \hat{q} \) is the Fourier transform of the local spectrum,

\[
\hat{q}(k, \omega, r) = \rho^2 E(k, \omega, r) = \int \hat{q}(k, \omega, \kappa) e^{ik \cdot r} \, d\kappa,
\]

so that

\[
\langle u^2 \rangle = \int_{0}^{\infty} \int_{0}^{\infty} E(k, \omega, r) \, dk \, d\omega.
\]

Derivation of the cross correlation yields

\[
H_{ij} = \frac{1}{2} \eta_T (G_i B_j + G_j B_i) - \left( \frac{3}{10} \eta_T + \frac{1}{15} \hat{q} \right) (B_{i,j} + B_{i,j}),
\]

where \( \mathbf{G} = \nabla \log \rho \) is the gradient of density and

\[
\eta_T = \frac{1}{3} \int_{0}^{\infty} \int_{0}^{\infty} \frac{\eta k^2 E}{\omega^2 + \eta^2 k^2} \, dk \, d\omega,
\]

\[
\hat{\eta} = \int_{0}^{\infty} (\omega^2 + \eta^2 k^2)^2 \, dk \, d\omega,
\]

where \( \eta \) is the molecular magnetic diffusivity. Both quantities remain finite in the high-conductivity limit.

From the cross correlation tensor \( \langle \mathbf{u} \cdot \mathbf{b} \rangle \) the cross helicity \( \langle \mathbf{u} \cdot \mathbf{b} \rangle = \eta_T (\mathbf{G} \cdot \mathbf{B}) \) is obtained. From Eq. (10) we find the slightly more complicated expression

\[
\langle u_i b_z \rangle = \eta_T G_i B_z - \left( \frac{3}{10} \eta_T + \frac{2}{15} \hat{q} \right) \left( 2 \frac{\partial B_z}{\partial z} \right),
\]

where \( G = G_z \) is the only nonzero radial components of the density-stratification vectors. Note the negativity of \( G \). An upward divergence of the mean field would reduce the effect of density stratification but for uniform field components the result is \( \langle u_i b_z \rangle = \langle \mathbf{u} \cdot \mathbf{b} \rangle \).

A real difference, however, between the both correlation expressions is due to a possible gradient \( G' \) of the turbulence intensity \( u_{t,\text{rms}} \). One easily finds that for vertical fields the turbulence intensity gradient \( G' \) enters the expressions for the correlations such as

\[
\langle \mathbf{u} \cdot \mathbf{b} \rangle = (G + \frac{1}{2} G') \eta_T B_z, \quad \langle u_i b_z \rangle = (G + \frac{3}{10} G') \eta_T B_z.
\]

In the bulk of the convection zone \( G' = G_z \) is positive while \( G \) is negative. Hence, \( \langle u_i b_z \rangle > \langle \mathbf{u} \cdot \mathbf{b} \rangle \) for positive \( B_z \), which is confirmed by the presented simulations (see below).

By elimination of \( G' \) one finds

\[
\frac{5}{2} \langle u_i b_z \rangle - \frac{3}{2} \langle \mathbf{u} \cdot \mathbf{b} \rangle = -\frac{\eta_T}{H_p} B_z.
\]
The magnetic eddy diffusivity can thus be determined if the LHS of (15) is calculated from magnetoconvection simulations when the density scale height $H_\rho$ is known from numerical models of the solar atmosphere. As only the correlation $(u_z b_z)$ can directly be observed one needs a numerical model for the application of the LHS of (15) to derive the eddy diffusivity at the solar surface.

3. Numerical simulations

We perform simulations for a number of different parameter combinations. These parameters include the strength of the imposed vertical field $B_z$, the viscosity $\nu$ and the magnetic diffusivity coefficient $\eta$.

The numerical simulations are done using the Nirvana code, which uses a conservative finite difference scheme (Ziegler 2004). We use Cartesian coordinates. The code solves the equation of motion, 

$$\frac{\partial (\rho u)}{\partial t} + \nabla \cdot (\rho u \mathbf{u} + (p + \frac{1}{8\pi} |B|^2) \mathbf{I} - \frac{1}{4\pi} \mathbf{B} \mathbf{B}) = \nabla \cdot \mathbf{\tau} + \rho \mathbf{f}_e,$$  

(16)

the induction equation, 

$$\frac{\partial \mathbf{B}}{\partial t} - \nabla \times (\mathbf{u} \times \mathbf{B} - \eta \nabla \times \mathbf{B}) = 0,$$  

(17)

the equation of mass conservation, 

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{u}) = 0,$$  

(18)

and the equation of energy conservation, 

$$\frac{\partial e}{\partial t} + \nabla \cdot \left[ \left( e + p + \frac{1}{8\pi} |B|^2 \right) \mathbf{v} - \frac{1}{4\pi} (\mathbf{u} \cdot \mathbf{B}) \mathbf{B} \right] = \nabla \cdot \left[ \mathbf{\tau} + \frac{\eta}{4\pi} \mathbf{B} \times (\nabla \times \mathbf{B}) - \mathbf{F}_{\text{cond}} \right] + \rho \mathbf{f}_e \cdot \mathbf{u}.$$  

(19)

In Eqs. (16) and (19) $f_e$ the (external) gravity force and 

$$\tau = \nu (\nabla \mathbf{u} + (\nabla \mathbf{u})^T) - \frac{2}{3} (\nabla \cdot \mathbf{u}) \mathbf{I}$$  

(20)

the viscous stress tensor. The total energy density is the sum of the thermal, kinetic, and magnetic energy density: 

$$e = e + \frac{\rho}{2} \mathbf{u}^2 + \frac{1}{2\mu} \mathbf{B}^2.$$  

(21)

We assume an ideal gas with a constant mean molecular weight $\mu = 1$. The thermal energy density is then 

$$e = \rho \mathbf{T} \frac{R}{\gamma - 1}.$$  

(22)

with $\gamma = c_p/c_v = 5/3$.

The gas is heated from below and kept at a fixed temperature at the top of the simulation box. Periodic boundary conditions apply at the horizontal boundaries. A homogeneous vertical magnetic field is applied. The upper and lower boundaries are impenetrable and stress-free.

The simulation volume is a rectangular box. The stratification is along the $z$-coordinate and it is piecewise polytrophic, with the polytrophic index chosen such that the hydrostatic equilibrium state is convectively stable in the lower and unstable in the upper half of the simulation box. In the following, $p$ denotes gas pressure, $\rho$ mass density, $T$ temperature, $g$ gravity, $\kappa$ thermal conductivity and $c_p$ the specific heat capacity at constant pressure.

The gas is initially in hydrostatic equilibrium, i.e. 

$$\frac{\partial p}{\partial z} + \rho g = 0,$$  

(23)

where $g = \text{const.}$, and the heat flux through the box is vertical and constant, 

$$F_0 = -\kappa \frac{\partial T}{\partial z} = \text{const.}$$  

(24)

The equation of state is that for an ideal gas and the heat conductivity is constant in the upper and lower layer, respectively, but its values differ between the two layers.

In the dimensionless units the size of the simulation box is $8 \times 8 \times 2$ in the $x$, $y$, and $z$ directions, respectively. The numerical resolution is $512 \times 512 \times 128$ grid points. The stratification of density, pressure, and temperature is piece-wise polytrophic as described in Ziegler (2002). Similar setups have been used by Cattaneo et al. (1991), Brummell et al. (1996), Brandenburg et al. (1996), Chan (2001) and Ossendrijver et al. (2001). The initial state is in hydrostatic equilibrium but convectively unstable in the upper half of the box. The $z$ coordinate is negative in our setup, with $z = 0$ at the upper boundary. The stable layer thus extends from $z = -2$ to $z = -1$, the unstable layer from $z = -1$ to $z = 0$. The density varies by a factor 5 over the depth of the box, i.e. the density scale height is 1.2.

Figure 1 shows snapshots of the fluctuations of density and temperature for $Ra = 10^5$ in a horizontal plane close to the upper boundary. The density is increased at the boundaries of the convection cells and decreased at the center. The opposite is true for the temperature, which is highest at the center of a convection cell and lowest at the boundaries. Vertical velocity is positive, i.e. upwards, at the center and negative, i.e. downwards, at the boundaries. The magnetic field is strongly concentrated in a few small patches which coincide with cell corners, where the gas horizontal flow converges and the vertical flow is downwards.

The initial magnetic field is vertical and homogeneous. We run the simulations until a quasistationary state evolves. Our control parameters are the heat conduction coefficient, $\kappa$ and the Prandtl number, $Pr = \nu/\kappa$. Convection sets in if the Rayleigh number,

$$Ra = \frac{\rho g c_p d^4}{T \kappa \nu} \left( \frac{d T}{d z} - \frac{g}{c_p} \right),$$  

(25)

with the density $\rho$, the specific heat capacity $c_p$, the gravity $g$, and the length scale $d$, exceeds a critical value. The length scale is defined by the depth of the convectively unstable layer, i.e. $d = 1$. After 11 the correlations and the mean magnetic field always have opposite signs. This has also numerically been realized. For positive values of the mean magnetic field $B_z$ the cross helicity is negative in the unstably stratified layer. If the field polarity is reversed and everything else is left unchanged the cross correlation becomes positive with the same amplitude.

The velocity field, which is measured in units of $c_m/100$, shows the asymmetry between upwards and downwards motion as it is characteristic of convection in stratified media. The downward motion is concentrated at the boundaries of the convection cells and particularly at the corners. The
Fig. 1. Fluctuations of density and temperature in the upper part of the unstable layer at \( z = -0.05 \) for \( \text{Ra} = 10^7 \) and \( B_0 = 10^{-3} \).

Fig. 2. The same as in Fig. 1 but for the fluctuations of the vertical flow and the vertical field. \( B_0 = 1 \).

Fig. 3. The numerical values for the cross helicity \( \langle u \cdot b \rangle \) (left) and the coefficient \( \langle u_z b_z \rangle \) (right) for weak magnetic field, \( B_z = 10^{-3} \). The blue lines denote individual snapshots and the red lines averages over the snapshots shown.

Fig. 4. The same as in Fig. 3 but for \( B_z = 1 \).

Fig. 5. The same as in the right part of Fig. 4 but with reduced numerical resolution of \((128 \times 128 \times 128)\) (left) and \((256 \times 256 \times 128)\) (right).

Figures 3 and 4 hold for \( \text{Ra} = 10^7 \) and for weak and strong magnetic fields. The value of both the Prandtl number and the magnetic Prandtl number is 0.1. The left diagram shows the horizontal average of the cross helicity as a function of the depth and the right diagram shows the same for the correlation of the vertical components, \( \langle u_z b_z \rangle \).

There is a difference between the two quantities, with the vertical component actually being twice the cross helicity. Equation (15) can thus be written as

\[
\frac{\langle u_z b_z \rangle}{B_z} \simeq -\frac{4}{7} u_\eta
\]

with

\[
u_\eta = \frac{\eta T}{H \rho}
\]

The correlations do not vanish abruptly at the bottom of the unstable layer because of overshoot, which affects the upper half of the stable layer. The correlations are there positive and much smaller than in the unstable layer. The results in Fig. 4 are given in arbitrary units defined by the code. Velocities are given in units of \( c_{\text{ac}}/100 \) with the isothermal speed of sound \( c_{\text{ac}} \).

With an approximate value of \( c_{\text{ac}} \approx 6.6 \) km/s at the optical depth \( \tau = 1 \) of the Sun the simulations lead to the cross correlation velocity \( \langle u_z b_z \rangle/B_z \simeq -9 \) in units of 0.066 km/s (Fig. 3 right), i.e., after (26)

\[
u_\eta \simeq 1.04 \text{ km/s.}
\]
This value depends only weakly on the magnetic field amplitude for weak fields. For the much stronger magnetic field Fig. 1 (right) yields the slightly smaller value of 0.81 km/s.

A characteristic velocity results as the cross correlation velocity

\[ U_c = \frac{|\langle u \cdot b \rangle|}{B_z}. \]  

(29)

Using the maximal values in Fig. 3 (left) we find \( U_c \approx 6 \) in units of \( c_{ac}/100 \). Hence, the simulations lead to the cross correlation velocity \( U_c \approx 0.4 \) km/s. For the \( B_z = 1 \) case (Fig. 4 left) we find \( U_c \approx 3 \) in units of \( c_{ac}/100 \) or 0.2 km/s, respectively.

It also makes sense to normalize the cross correlation in the form

\[ c_\eta = \frac{\langle u \cdot b \rangle}{B_z \sqrt{\langle u^2 \rangle}}, \]  

(30)

which is the ratio of the cross correlation velocity (29) and the rms velocity of the turbulence. Its numerical value does not depend on the internal units of the code so that \( c_\eta \) is a general and basic result of the simulations. Close to the surface the maximal numerical value is \( c_\eta \approx 0.6 \) for \( B_z = 10^{-3} \) and \( c_\eta \approx 0.3 \) for \( B_z = 1 \). Test calculations for various magnetic fields over many orders of magnitudes show this value as almost uninfluenced by the magnetic-field suppression. Resulting from the overshoot phenomenon at the bottom of the unstable layer always small negative values there appear. The correlation coefficient

\[ c = \frac{|\langle u \cdot b \rangle|}{\sqrt{\langle u^2 \rangle} \sqrt{\langle b^2 \rangle}}, \]  

(31)

for the cross helicity is much smaller than (30) as always

\[ \langle b^2 \rangle / B_z^2 \approx 50, \]  

(32)

similar to the result of Ossendrijver et al. (2001). The relation (31) proves to be true for all amplitudes of the mean magnetic field between \( 10^{-3} \) and 0.1. One finds for all calculations a characteristic correlation coefficient \( c \approx 0.1 \). The \( B_z = 1 \) case shows the beginning of the suppression of the fluctuations by the mean magnetic field which occurs at large values of \( B_z \), resulting in a smaller value of 25 for \( \langle b^2 \rangle / B_z^2 \).

During the simulations there are significant temporal fluctuations. The convective instability initially grows exponentially until its saturation when the system settles in a statistically steady state but the cross helicity still shows some variations. We therefore average over a certain number of snapshots, typically 10. To test how much the results dependend on the numerical resolution we rerun the \( B_z = 1 \) case at the lower lower resolutions of \( 256 \times 256 \times 128 \) and \( 128^3 \). Fig. 3 shows \( \langle u_z b_z \rangle \) from those runs. There is a weak dependence on resolution with higher resolution leading to larger values.

Figure 6 contains all informations about the kinetic and magnetic energies of the magnetoconvection. The rms value of the velocity is hardly influenced by the large-scale magnetic field. In physical units we find an averaged value of \( u_{rms} \approx 0.1 c_{ac} \approx 0.66 \) km/s. Contrary, the magnetic energy strongly depends on the applied magnetic field. In dimensionless units it is in both cases \( b_{rms} / u_{rms} \approx 0.6 B_z \) which leads to

\[ \frac{E_{mag}}{E_{kin}} \approx \frac{3600}{\mu_0 \rho c_{ac}^2}, \]  

(33)

in physical units. At the top of the convection zone we find very small contributions of the magnetic energy for \( B_z = 1 \) Gauss while for 1000 Gauss there is almost equipartition.

### 4. Observations

It is difficult to empirically determine the cross helicity \( (u \cdot b) \) at the solar surface, because it is hard to retrieve the horizontal flows and magnetic field components from observations. We have, however, the possibility to use the relation \( (u \cdot b) \approx 0.5 \langle u_z b_z \rangle \), known from the above numerical simulations. The vertical flow speed and magnetic field component can be determined with much better accuracy. Then using Eq. (28) we can determine the cross helicity velocity from the observations.

For this purpose we have analyses two datasets containing observations of quiet Sun at disk center, where the line-of-sight coincides with the local vertical. Data from the CRISP instrument on the Swedish 1-m Solar Telescope (SST) cover the 6302.5 Å Fe I spectral line with 12 equidistant wavelength positions at 48 mÅ steps and a continuum point. They have a pixel scale of 0′′.0592 and a total field-of-view of about 60″ × 60″. The second dataset is from the spectropolarimeter on the Solar Optical Telescope of HINODE and covers both the 6301.5 and 6302.5 Å Fe I
The HINODE observations were taken from the level 2 data and the line-of-sight velocity and magnetic field data for the HINODE observations were taken from the level 2 data products available online. Magnetic field strengths have been converted to fluxes by taking the filling factor into account. The SST data were inverted using the lilia inversion code (Socas-Navarro 2001). Velocities were calibrated accounting the SST resolution is reduced by rebinning the data.

The ratio (32) of the magnetic fluctuations to the applied magnetic field is always of the order five.

We have also shown that for density-stratified turbulence the identity \( \langle u \cdot b \rangle = \langle u_z b_z \rangle \) holds. So far observations can only measure the correlation \( \langle u_z b_z \rangle \). The numerical simulations, however, always lead to the result \( \langle u_z b_z \rangle \approx 2 \langle u \cdot b \rangle \) so that the observed value of \( \langle u_z b_z \rangle \) would overestimate the actual cross helicity by a factor of two. The reason is the vertical stratification of the turbulence intensity which at the top of the convection zone is antiparallel to the density stratification. Hence, both the correlations \( \langle u_z b_z \rangle \) and \( \langle u \cdot b \rangle \) are reduced but not by the same amount.

With \( \langle u_z b_z \rangle \approx 2 \langle u \cdot b \rangle \) the value of \( \eta \) can be computed by use of Eq. (29). The numerical simulations lead to \( \eta \approx 1 \) km/s and \( \eta \approx 0.8 \) km/s respectively for the two cases studied. This result is well confirmed by the observations which lead to values between 0.7 km/s (HINODE) and 1.3 km/s (SST). To estimate the value of the eddy diffusivity at the solar surface we shall assume a density scale height of 100 km and find values close to \( \eta_T \approx 10^{12} \) cm/s for the eddy diffusivity at the surface of the quiet Sun.

Acknowledgements. We gratefully acknowledge Axel Brandenburg (Stockholm) for motivating discussions and for numerical support.

| HINODE  | 230        | -1.03         | 2.55   | -0.41           | 0.71    |
| SST     | 115        | -1.82         | 2.54   | -0.72           | 1.26    |
| SST′    | 172        | -1.57         | 2.54   | -0.62           | 1.08    |
| SST′′   | 258        | -1.32         | 2.54   | -0.52           | 0.91    |
| SST∗    | 344        | -1.05         | 2.54   | -0.41           | 0.72    |

These data have been rebinned.

The anticorrelation (34) for density-stratified turbulence is somewhat higher than that from the HINODE data. At high-conductivity limit, i.e. for sufficiently large magnetic Reynolds numbers, has a pixel scale of 0.16 and a total (scanned) field-of-view of 164′′×328′′.

The line-of-sight velocity and magnetic field data for the HINODE observations were taken from the level 2 data products available online. Magnetic field strengths have been converted to fluxes by taking the filling factor into account. The SST data were inverted using the lilia inversion code (Socas-Navarro 2001). Velocities were calibrated using the convective blueshift determined by de La Cruz Rodríguez et al. (2011). More details on these two datasets can be found in Schnerr & Spruit (2011).

We show the results for these datasets in Table 1. The cross helicity velocity \( u_\eta \) as determined from the SST data is somewhat higher than that from the HINODE data. At least partly this is due to the lower resolution of HINODE as compared to the SST. If we rebin the SST data to a lower resolution, the cross helicity velocity decreases (see Table 1). The reason for this is that the strongest fields and flows are smoothed out.

The coefficient \( \langle B_z^2 \rangle / \langle B_z \rangle^2 \) from the HINODE and SST data are 521.3 and 163.5 respectively, which is larger than the value of 50 found in the simulations. This indicates that the effective magnetic Reynolds number in the simulations is smaller than in the solar convection zone.

5. Conclusions

We have shown that nonrotating turbulence at the top of the solar convection zone under the influence of a vertical magnetic field forms a finite cross helicity. The only condition is the existence of a vertical stratification of density and/or turbulence intensity. The effect would not appear within the Boussinesq approximation. It also exists in the high-conductivity limit, i.e. for sufficiently large magnetic Reynolds numbers.

In our understanding the cross helicity is anticorrelated to the mean radial magnetic field, i.e.

\[
\langle u \cdot b \rangle \cdot B_z < 0. 
\]

For an oscillating dipolar background field the sign of the cross helicity differs for both hemispheres and also from cycle to cycle.

The theory can also be used to measure the magnetic diffusivity if the cross helicity is known by observations. In order to find the cross helicity one has only to correlate observed flow fluctuations with observed magnetic fluctuations.

The anticorrelation (34) for density-stratified turbulence has been established by Rüdiger et al. (2011) for a model of numerically-driven turbulence. In the present paper buoyancy-driven magnetoconvection has been simulated in a box with the NIRVANA code. We find that also such a turbulence fulfills the relation (34). The correlation coefficient (30) takes the value of 0.6 for the weak magnetic field \( B_z = 10^{-3} \) and 0.3 for the stronger field \( B_z = 1 \).
