Coronavirus disease 2019 (COVID-19) has spread widely throughout the world and become a pandemic disease. In this study, we decided to investigate the chest computed tomography (CT) findings in COVID-19 patients in Hamadan, west of Iran.

Methods: This cross-sectional study was conducted on 101 patients with confirmed COVID-19 infection from February to March 2020. Demographic, clinical, laboratory, and chest CT findings of identified COVID-19 patients were assessed.

Results: The mean age of the patients was 55.21 ± 14.08 years, and 54 (53.47%) of them were male. With regard to clinical manifestations, 82.18%, 72.28% and 54.46% of COVID-19 patients had dry cough, dyspnea, and fever, respectively. The right lower lobe was the most commonly and severely involved lobe (69%), followed by left lower lobe, right middle lobe, and lingual segment; however, the anterior segment of upper lobes showed the least involvement with abnormality in the late course of the disease. The most common pattern was ground glass opacity (GGO), but atypical patterns such as round pneumonia, moderate to severe pleural effusion, and segmental lobar consolidation were seen without evidence of mediastinal adenopathy, cavitation, or nodular lesion. Chest X-ray (CXR) was not a sensitive method as the first-line imaging method because 34.65% of them were normal.

Conclusion: CXR is not a sensitive method as the first-line imaging method (34.65% normal first CXR), but chest CT is a very sensitive and nonspecific modality for diagnosis of COVID-19. The lower lobe and posterior basal segments of the lungs are the most involved sites in most cases. About 12% showed atypical chest CT findings.

Keywords: Chest CT, COVID-19, Coronavirus, Chest radiograph, Iran

Introduction

Coronavirus disease 2019 (COVID-19) infection was first detected in December 2019 in Wuhan, the capital of Hubei province of China and spread to a growing number of countries. Alongside severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS), COVID-19 is another common type of coronavirus that infects humans. COVID-19 is transmitted through direct contact from human to human, mainly through respiratory droplets, and also through contact by the same mechanism as other common cold or influenza viruses. The symptoms of COVID-19 infection appear after an incubation period; studies so far suggest a mean incubation period of 5 days (range: 0–24 days). The most common clinical symptoms of COVID-19 are fever, dry cough, dyspnea, muscle soreness, and fatigue. Some of the patients were reported to have headache or hemoptysis and some patients were relatively asymptomatic. Approximately 80% of COVID-19 infections are mild or asymptomatic, 15% are severe infections requiring oxygen, and 5% are critical infections requiring ventilation. Additionally, the mortality rate is approximately 3%. Older patients are more likely to have respiratory failure due to severe alveolar damage. Old age, male gender, and presence of comorbidities are high risk factors for poor prognosis of the disease.

Real-time polymerase chain reaction (RT-PCR) technique has high false negative rate and needs at least
48 hours for determination, while chest CT has high sensitivity and gives the results in a small fraction of the time.\textsuperscript{11,12} Therefore, chest CT plays an important role in the early detection of chest abnormality in suspected cases. These features of CT images help physicians in rapid management, planning, initiation of treatment, isolation of patients, and determination of the severity of the disease. Previous studies showed that imaging plays an important role in follow up of COVID-19 patients.\textsuperscript{13} There are few studies on imaging of COVID-19 patients and the majority of them belong to China; therefore, we conducted this study to observe the imaging characteristics of the COVID-19 patients in Iran.

Materials and Methods

Study Design And Population Under Study

This cross-sectional study was performed in Hamadan province, the west of Iran. A total of 101 patients with confirmed COVID-19 infection identified in all hospitals in the province affiliated to Hamadan University of Medical Sciences were enrolled in the study from February to March 2020 through census method. Hamadan province with an area of 19493 km\textsuperscript{2} is located in the west of Iran and have a population of 1,758,268 (according to the national census held in 2016 by Statistical Center of Iran: http://irandataportal.syr.edu/census/census-2016)

Eligibility Criteria

All patients with COVID-19 infection confirmed by RT-PCR testing on nasopharyngeal swabs and throat swabs hospitalized in Sina hospital and underwent chest CT were included in the study.

Patients with positive RT-PCR results were included in the study and assessed. It should be noted that these patients have not been included in any study.

Data Collection Procedure and Instrument Tool

A checklist including demographic, clinical, laboratory and chest CT findings of identified COVID-19 patients were used for collecting data. Demographic and clinical data, including signs, symptoms and underlying diseases history, were obtained directly from the patients and when the patient was unable to respond due to a bad physical condition, the information was obtained from the physician or patient's medical records. Biochemical blood test results were gathered by referring to the patient's medical record.

Chest images of each patient were reviewed independently. All hospitalized patients underwent chest computed tomography (CT) at the first day of admission using a 16-channel multi-detector CT scanner (Somatom Emotion; Siemens Healthcare, Erlangen, Germany). CT Scans were obtained in supine position with full inspiration and without injection of contrast media. Acquisition parameters were as following characteristics: 170–200 MAs; 110 – 120 kVp; collimation 0.625–5 mm and pitch, 1.2. Images were reconstructed with slice thickness 0.625-5 mm and reconstruction interval 1-3 mm sharp reconstruction kernel. All images were viewed with lung (width, 1500 HU; level, - 600 HU) and mediastinal window (width, 400 HU; level, 40 HU).

Two expert radiologists (with 11 and 20 years of experience in chest imaging, respectively) analyzed and reviewed all the chest radiographs and CT images on a picture archiving and communication system (PACS Marco) by consensus on controversial images. All images were evaluated for the presence of a lesion, location of the lesion, and patterns of lung abnormality such as ground glass opacity (GGO), patchy mix consolidation, reticular interlobular septal thickening, segment and lobe involvement, mostly and minimally involved lobe, presence or absence of pleural and pericardial effusion, lymphadenopathy cavitation, underlying lung disorder, presence or absence of reversed halo sign, and crazy paving appearance. GGO is defined as increased lung density without obscuration of vascular and bronchial margins due to partial filling of airspaces.\textsuperscript{14} Consolidation is increased lung density with obscuration of bronchial and vascular structure.\textsuperscript{14} Reversed halo sign is described as a central GGO surrounded by denser consolidation in the shape of a crescent or a ring. Crazy paving appearance is defined as interlobular septal thickening in the background of GGO. Peripheral pulmonary lesions are defined as lesions in the peripheral one-third of the lung in the transaxial plane.\textsuperscript{14}

Statistical Analysis

For data analysis, we used descriptive statistics including mean (SD) for describing continuous variables and frequency and percentage for describing categorical variables arranged in the frequency table and chart. Data were analyzed using Stata 14 (StataCorp, College Station, TX, USA).

Results

A total of 101 COVID-19 patients with a mean age of 55.21 ± 14.08 years (range: 27–87 years) were investigated. Fifty-four (53.47%) patients were male. The age distribution of the patients is shown in Figure 1.

Less than half of the patients (36, 35.64%) had underlying diseases, including cardiac disorder (15.84%), diabetes (8.91%), chronic obstructive pulmonary disease (3.96%), asthma (2.97%), hypertension (2.97%), and renal failure (0.99) (Figure 2).

The main clinical symptoms at the early stage of illness were dry cough in 83 cases (82.18 %), dyspnea in 73 cases (72.28%), and fever in 55 cases (54.46%). Based on the laboratory results, 45 (44.5%) had lymphopenia and in the vast majority of them, C-reactive protein level was 2 plus. Clinical and laboratory findings of investigated patients are presented in Table 1.

The most common CT features were GGO, interlobular septal thickening, and patchy consolidation in 64.35%, 33.66%, and 26.73% of the cases, respectively. Other CT features are shown in Figure 3.
Findings at initial chest CT examination in the COVID-19 patients are presented in Table 2. Of the 101 patients, 99 patients (98.02%) had bilateral involvement, while two of them had unilateral involvement. Ninety-six patients (95.05%) had asymmetrical laterality and the right lobe was involved in 68.32% of them. At the first chest CT of the patients, the right upper, middle and lower lobes were involved in 39 (32.67%), 13 (12.67%), and 69 (68.32%) cases, respectively. However, the left upper and lower lobes were involved in 33 (38.61%) and 58 (57.43%) cases, respectively. The most and least commonly involved sites were the right lower lobe and right middle lobe in 58 (57.43%) and 30 (29.70%) cases, respectively. With regard to CXR images, 35 (34.65%) patients had normal CXR at the first day of diagnosis. In relation to other radiographic features of the patients, it can be noted that 10 (9.9%) cases had mild pleural thickening, 2 patients (1.98%) had pneumothorax, 6 of them (5.94%) had mild to moderate pleural effusion, and 2 (1.98%) patients had severe pleural effusion.

Discussion

COVID-19 is a novel coronavirus disease caused by SARS-CoV-2 that spread around the world. In the present study, 101 patients were enrolled. The mean age of the patients was 55.21 ± 14.08 years, ranging from 27 to 87 years. Thirty-six percent had underlying or coexisting medical disorders including diabetes, cardiac disease, hypertension, COPD, asthma, and end-stage renal disease. This is different from influenza pneumonia which involved...
Radiological Manifestations in COVID-19

In the present study, about 35% of the patients showed normal CXR as the first-line imaging modality and 65% showed some nonspecific abnormal findings. According to the study conducted by Yoon et al., most Korean COVID-19 patients had normal chest X-ray or ambiguous findings, and chest radiographic abnormalities were seen only in 60% of Chinese COVID-19 patients. Yoon et al. also emphasized that imaging findings are milder in COVID-19 than in two other similar viral infections (SARS and MERS-CoV pneumonia), and 33% of the COVID-19 cases had abnormal initial CXR while in the SARS and MERS-CoV infections, 78.3%–82.4% and 83.6% of initial CXRs were abnormal, respectively. Therefore, all clinicians should be aware of the limitations of CXR as the first-line imaging tool in the evaluation of COVID-19 pneumonia.

In the study by Bernheim et al., 56% of the patients in the early stage (0-2 days after the onset of symptoms) had normal chest CT scan. In this study, lung abnormality was seen in all the chest CT scans (100% of cases) that were performed 2-4 days after the onset of symptoms. CT findings of the patients were generally consistent with those of COVID-19 pneumonia patients in China. In the study conducted by Bernheim et al., 20 (17%) patients had unilateral lung involvement, but the involvement of left and right lungs was separately seen in 7 and 13 patients, respectively.

The most common symptom was dry cough (83%), followed by dyspnea (73%). Only 55% of the patients had fever, and lymphopenia, anemia, and thrombocytopenia were seen in 45%, 17%, and 8% of the cases, respectively. Moreover, chest CT scan had a low rate of missed diagnosis of COVID-19 (3.9%) and should be considered as a rapid diagnostic tool.

In the study by Shan et al., the presence of ground glass opacities was reported in 15 asymptomatic patients and CT scan was suggested as a sensitive modality even in patients with false negative RT-PCR results and highly suspicious clinical findings. Considering the high false negative rate of RT-PCR and high sensitivity of CT scan (up to 98%), chest CT scan is accepted as the first screening tool for diagnosis of Covid-19 pneumonia. Another imaging modality is chest X-ray; however, it is not as sensitive as chest CT in the evaluation of lung abnormality as the first-line diagnostic tool in suspected cases. In the present study, about 35% of the patients showed normal CXR as the first-line imaging modality and 65% showed some nonspecific abnormal findings. According to the study conducted by Yoon et al., most Korean COVID-19 patients had normal chest X-ray or ambiguous findings, and chest radiographic abnormalities were seen only in 60% of Chinese COVID-19 patients. Yoon et al. also emphasized that imaging findings are milder in COVID-19 than in two other similar viral infections (SARS and MERS-CoV pneumonia), and 33% of the COVID-19 cases had abnormal initial CXR while in the SARS and MERS-CoV infections, 78.3%–82.4% and 83.6% of initial CXRs were abnormal, respectively. Therefore, all clinicians should be aware of the limitations of CXR as the first-line imaging tool in the evaluation of COVID-19 pneumonia.

Based on the results of a study on 121 chest CT scans by Bernheim et al., 56% of the patients in the early stage (0-2 days after the onset of symptoms) had normal chest CT scan. In this study, lung abnormality was seen in all the chest CT scans (100% of cases) that were performed 2-4 days after the onset of symptoms. CT findings of the patients were generally consistent with those of COVID-19 pneumonia patients in China. In the present study, two patients had unilateral right lung involvement (only in the right lower lobe), 98.02% showed bilateral lung involvement, and 95.05% of them had asymmetrical involvement. The predominant lung involvement was the right lung (69%), but in 27% of the patients, left lung involvement was dominant and 5% of them showed symmetrical abnormality in both lungs. In the study conducted by Bernheim et al., 20 (17%) patients had unilateral lung involvement, but the involvement of left and right lungs was separately seen in 7 and 13 patients, respectively.

### Table 1. Clinical and Laboratory Findings in the COVID-19 Patients

| Variables         | Characteristics | No. (%) |
|-------------------|-----------------|---------|
| Signs and symptoms|                 |         |
| Fever             |                 | 55 (54.46) |
| Dry cough         |                 | 83 (82.18) |
| Sore throat       |                 | 4 (3.96) |
| Dyspnea           |                 | 73 (72.28) |
| Lymphopenia       |                 | 45 (44.5) |
| Laboratory        |                 |         |
| Thrombocytopenia  |                 | 6 (7.92) |
| Anemia            |                 | 17 (16.83) |
| C-reactive protein|                 |         |
| Negative          |                 | 18 (17.82) |
| +                 |                 | 61 (60.40) |
| ++                |                 | 17 (16.83) |
| +++               |                 | 5 (4.95) |

Figure 3. Chest CT Patterns of Lung Involvement in the COVID-19 Patients.

older patients with further underlying disorders. The most common symptom was dry cough (83%), followed by dyspnea (73%). Only 55% of the patients had fever, and lymphopenia, anemia, and thrombocytopenia were seen in 45%, 17%, and 8% of the cases, respectively. Moreover, chest CT scan had a low rate of missed diagnosis of COVID-19 (3.9%) and should be considered as a rapid diagnostic tool.

In the study by Shan et al., the presence of ground glass opacities was reported in 15 asymptomatic patients and CT scan was suggested as a sensitive modality even in patients with false negative RT-PCR results and highly suspicious clinical findings. Considering the high false negative rate of RT-PCR and high sensitivity of CT scan (up to 98%), chest CT scan is accepted as the first screening tool for diagnosis of Covid-19 pneumonia. Another imaging modality is chest X-ray; however, it is not as sensitive as chest CT in the evaluation of lung abnormality as the first-line diagnostic tool in suspected cases. In the present study, about 35% of the patients showed normal CXR as the first-line imaging modality and 65% showed some nonspecific abnormal findings. According to the study conducted by Yoon et al., most Korean COVID-19 patients had normal chest X-ray or ambiguous findings, and chest radiographic abnormalities were seen only in 60% of Chinese COVID-19 patients. Yoon et al. also emphasized that imaging findings are milder in COVID-19 than in two other similar viral infections (SARS and MERS-CoV pneumonia), and 33% of the COVID-19 cases had abnormal initial CXR while in the SARS and MERS-CoV infections, 78.3%–82.4% and 83.6% of initial CXRs were abnormal, respectively. Therefore, all clinicians should be aware of the limitations of CXR as the first-line imaging tool in the evaluation of COVID-19 pneumonia.

Based on the results of a study on 121 chest CT scans by Bernheim et al., 56% of the patients in the early stage (0-2 days after the onset of symptoms) had normal chest CT scan. In this study, lung abnormality was seen in all the chest CT scans (100% of cases) that were performed 2-4 days after the onset of symptoms. CT findings of the patients were generally consistent with those of COVID-19 pneumonia patients in China. In the present study, two patients had unilateral right lung involvement (only in the right lower lobe), 98.02% showed bilateral lung involvement, and 95.05% of them had asymmetrical involvement. The predominant lung involvement was the right lung (69%), but in 27% of the patients, left lung involvement was dominant and 5% of them showed symmetrical abnormality in both lungs. In the study conducted by Bernheim et al., 20 (17%) patients had unilateral lung involvement, but the involvement of left and right lungs was separately seen in 7 and 13 patients, respectively.
The hallmarks of novel coronavirus infection on images are bilateral and peripheral GGO and consolidative pulmonary opacities. However, in the study conducted by Bernheim et al, 22% of patients had no ground-glass opacity or consolidation, 2 while in our study, 55% of patients showed ground-glass opacity and 36% showed mixed GGO and patchy consolidation. In the pictorial review study by Ye et al, pure GGO (14-96%) and mixed GGO and consolidative pulmonary opacities. However, there are differences in the CT manifestations of patients with influenza and COVID-19 pneumonia. Complete consolidation is less common in COVID-19 pneumonia patients. In the study by Wang et al, most patients with H7N9 pneumonia showed complete consolidation. 15

Another point about the pattern of lung involvement is that chest CT scan manifestation is altered with the course and severity of the disease. 18, 19 In the present study, in mild cases and in the early stage of disease, GGO was the predominant pattern and later with the progression of the disease, the pattern was followed by crazy paving and consolidation in chest CT. In addition, Shi et al showed progression of GGO to bilateral diffuse consolidation from the first to the second week of the infection after symptom onset and peripheral and posterior lung involvements were seen in 78% and 67% of cases, respectively. In addition, most of the lesions were ill-defined, composed of consolidation and ground glass opacities, and lower lobe predominance was also seen. Moreover, a less common nodular pattern was bronchovascular bundle. In the study on 121 chest CT by Bernheim et al, 2 there was a correlation

### Table 2. Imaging Characteristics at the Initial Chest CT in the COVID-19 Patients

| Variables                     | Characteristics | No. (%)    |
|-------------------------------|-----------------|------------|
| Lung involvement              | Unilateral      | 2 (1.98)   |
|                               | Bilateral       | 99 (98.02) |
| Laterality                    | Symmetrical     | 5 (4.95)   |
|                               | Asymmetrical    | 96 (95.05) |
| Involved lung                  | Both lobe       | 5 (4.95)   |
|                               | Right lobe      | 69 (68.32) |
|                               | Left lobe       | 27 (26.73) |
| Lung lobes involvement        | Left lower lobe | 58 (57.43) |
|                               | Left upper lobe | 33 (31.61) |
|                               | Right upper lobe| 39 (32.67) |
|                               | Right middle lobe| 13 (12.87)|
|                               | Right lower lobe| 69 (68.32) |
|                               | Lingual segment | 12 (11.88) |
|                               | All             | 52 (51.49) |
| The most commonly involved sites | None          | 1 (0.99)   |
|                               | Left lower lobe | 29 (28.71) |
|                               | Left upper lobe | 6 (5.94)   |
|                               | Right upper lobe| 9 (8.91)   |
|                               | Right middle lobe| 6 (5.94)  |
|                               | Right lower lobe| 58 (57.43) |
|                               | Lingual segment | 3 (2.97)   |
| The least commonly involved sites | None          | 6 (5.94)   |
|                               | Left lower lobe | 9 (8.91)   |
|                               | Left upper lobe | 12 (11.88) |
|                               | Right upper lobe| 18 (17.82) |
|                               | Right middle lobe| 30 (29.70)|
|                               | Right lower lobe| 3 (2.97)   |
|                               | Lingual segment | 28 (27.72) |
between the onset of clinical symptoms and the initial chest CT scans (0-2 days: early, 3-5 days: intermediate, and 3-12 days: late). Bilateral lung involvement was observed in 10 of the 36 early patients (28%), 25 of the 33 intermediate patients (78%), and 22 of the 25 late patients (88%).

Reticular thickening, also known as interlobar septal thickening, is seen due to interstitial lymphocyte infiltration. This is the second frequent lesion in COVID-19 pneumonia. In the present study, 33% of patients showed interlobar septal thickening. Another atypical and less common finding was pleural changes such as pleural thickening and pleural effusion. The former was more frequent, 32% versus 5%.

In this study, pleural thickening was seen in 10% and mild to moderate pleural effusion was seen in 6%. Two cases in the end stage of the disease showed moderate to severe pleural effusion. Reversed halo sign was seen in 5% of the patients. In the studies conducted by Bernheim et al and Yoon et al, reversed halo sign was reported in 2 and 3% of COVID-19 patients, respectively. This sign was first described as a specific finding in cryptogenic organizing pneumonia; however, recently, it was believed that this sign might indicate organizing pneumonitis due to some viral or fungal infections such as COVID-19 pneumonia.

In this study, other less frequent and atypical findings were seen as follow: 5% of the cases showed crazy paving appearance mostly in severe cases, 5% of patients had only one lobe or segment involvement, with the appearance of segmental or lobar consolidation, one case had peribronchovascular infiltration, one case showed typical round pneumonia, and one patient had mild generalized GGO in the entire lung.

There was no case with significant lymphadenopathy, cavitation, nodular lesion, or bronchiectasis. Air bronchogram was seen only in case of consolidation, and pericardial effusion was seen in 5%. Additionally, 5% had hyperaeration, and in two cases, mild unilateral pneumothorax was seen.

There are some limitations in this study such as the retrospective design of the study and lack of follow-up chest CT scans after the recovery of patients. Therefore, it is recommended that further studies should be done in the future for better evaluation of lung involvement and proper management. Moreover, follow-up chest CT after completing the treatment should be considered. In the study conducted by Shan et al, a deep learning model was developed for automatic diagnosis of the infected lobes and segments using follow-up CT scans performed every 3-5 days during management. In a study by Kay and Abbara, it is recommended that other patterns of lung involvement should be considered for accurate diagnosis and atypical features of lung involvement in chest CT.

Conclusion
CXR is not a sensitive method as the first-line imaging method in the diagnosis of COVID-19 pneumonia (35% normal CXR). Chest CT scan is very sensitive but it is nonspecific and non-characteristic. The right lower lobe, mostly posterior basal segment, is the most commonly involved lobe and the right middle lobe showed the least involvement. GGO, predominantly in the lower posterior and peripheral parts of the lungs, was the most common imaging feature which is compatible with non-specific organizing pneumonia and about 12% showed atypical imaging patterns.

Availability of Data and Materials
All supporting data is available through the corresponding author.

Ethic Approval
The protocol was approved by the Ethics Committee of Hamadan University of Medical Sciences, Iran (Ethics code: IR.UMSHA.REC.1399.001, Research ID: 9903061349). Written informed consent for the survey was obtained from all the patients.

Conflict of Interest Disclosures
The authors declared no conflict of interests.

Authors’ Contributions
FG, SHH, FK, and SK developed the original idea and the protocol, abstracted and prepared the manuscript. SK, MG, FG, and SB participated in the study design and analyzed the data. SB, FEA, FG, MM, FK, and MMM contributed to study design and data gathering. All authors drafted the work. All authors read and approved the final manuscript.

Funding
Hamadan University of Medical Sciences financially supported this study. This funding source had no role in analysis and interpretation of data, writing of the manuscript, or submitting it for publication.

Acknowledgements
The authors would like to appreciate the Vice-chancellor of Research and Technology, Hamadan University of Medical Sciences for funding the study. Additionally, we would like to thank the medical staff of public hospitals of Hamadan Province for their kind collaboration.
