ABSTRACT

We test general relativity (GR) at the effective redshift $\bar{z} \sim 1.5$ by estimating the statistic $E_G$, a probe of gravity, on cosmological scales $19 - 190 \ h^{-1}$ Mpc. This is the highest-redshift and largest-scale estimation of $E_G$ so far. We use the quasar sample with redshifts $0.8 < z < 2.2$ from Sloan Digital Sky Survey IV extended Baryon Oscillation Spectroscopic Survey (eBOSS) Data Release 16 (DR16) as the large-scale structure (LSS) tracer, for which the angular power spectrum $C^{gq}_{\ell}$ and the redshift-space distortion (RSD) parameter $\beta$ are estimated. By cross correlating with the Planck 2018 cosmic microwave background (CMB) lensing map, we detect the angular cross-power spectrum $C^{gq}_{\ell}$ signal at 12σ significance. Both jackknife resampling and simulations are used to estimate the covariance matrix (CM) of $E_G$ at 5 bins covering different scales, with the later preferred for its better constraints on the covariances. We find $E_G$ estimates agree with the GR prediction at 1σ level over all these scales. With the CM estimated with 300 simulations, we report a best-fit scale-averaged estimate of $E_G(\bar{z}) = 0.30 \pm 0.05$, which is in line with the GR prediction $E_G^{GR}(\bar{z}) = 0.33$ with Planck 2018 CMB + BAO matter density fraction $\Omega_m = 0.31$. The statistical errors of $E_G$ with future LSS surveys at similar redshifts will be reduced by an order of magnitude, which makes it possible to constrain modified gravity models.

Key words: cosmology: theory – cosmology: observations – large-scale structure of Universe – gravitation – gravitational lensing: weak – cosmic background radiation

1 INTRODUCTION

The expansion of the universe was first discovered by measuring the redshifts and relative distances of galaxies (Hubble 1929). One of the milestones in cosmology in the past decades has been the detection of a negative deceleration parameter from supernovae observations (Riess et al. 1998), i.e. the expansion of the universe is accelerating. Many theoretical models of cosmology and gravity (Silvestri & Trodden 2009) have been proposed to explain the cosmic expansion and acceleration, among which ΛCDM has been regarded as the standard model for its simplicity and success in explaining a wide range of cosmological observations, including the CMB surveys (e.g. Planck Collaboration VI 2018) and galaxy redshift surveys (e.g. Alam et al. 2017b). ΛCDM takes general relativity (GR) as the true theory for gravity on both galactic and cosmological scales, and assumes the existence of the cosmological constant ($\Lambda$), a special form of dark energy (DE) whose spatially uniform energy density does not evolve with cosmic expansion, and cold dark matter (CDM), along with ordinary (baryonic) matter. Although the expansion history can be well described by ΛCDM-GR
by fine-tuning the relative density ratios of the energy components, the nature of dark matter (DM) and DE are not well understood and their properties are hard to observe with experiments. On the other hand, some modified gravity (MG) models (see e.g. Carroll et al. 2003; Sotiriou & Faraoni 2010; Dvali et al. 2000), which can predict the same expansion history of the universe as ΛCDM-GR with or without assuming the existence of DE, have been developed to challenge GR as the true theory for gravity on cosmological scales. There have been some great reviews of the two approaches, see e.g. Peebles & Ratra (2003) for the cosmological constant and DE, Clifton et al. (2012) for MG, and Joyce et al. (2016) for a comparison.

Despite the degeneracy in predicting cosmic expansion, the growth of the DM large scale structure (LSS) predicted by MG usually differs from that by GR. Combining the gravitational lensing \( \nabla^2 (\Psi - \Phi) \) and the divergence of the peculiar velocity \( \theta \), Zhang et al. (2007) proposed a statistic \( E_G \) as a function of redshift and scale, to probe gravity on cosmological scales. Lensing is related to the underlying matter overdensity \( \delta \) through the Poisson equation which depends on the gravity model (see e.g. Hojjati et al. 2011). On linear scales, \( \theta = -f\delta \), where \( f \) is the linear growth rate. In real surveys, instead of the DM field, the direct observables are the LSS tracers, e.g. galaxies or quasars. The distribution of these tracers is connected to the underlying matter perturbation field with the clustering bias \( b \), which varies with the physical properties of the tracers that are targeted in a particular survey. Defined as the ratio between \( \nabla^2 (\Psi - \Phi) \) and \( \theta \), \( E_G \) has the advantage of being independent of \( b \) and the variance of the matter density field \( \sigma_b \).

The estimation of \( E_G \) requires data from both gravitational lensing and redshift surveys. Accurate estimates of tracers’ redshifts are necessary in order to do the 3-D clustering analysis, from which the growth of the structure can be probed. Thus spectroscopic redshift surveys are usually preferred. For photometric surveys, Giannantonio et al. (2016) proposed a statistic \( D_G \), which does not require the estimation of the growth rate. However, this quantity cannot be directly used to discriminate GR and MG models. Using galaxy-galaxy lensing and luminous red galaxies (LRGs), \( E_G \) has been measured over scales \( \lesssim 70 \, h^{-1} \) Mpc at redshifts in \( 0.2 < z < 0.7 \) (Reyes et al. 2010; Blake et al. 2015; de la Torre et al. 2017; Alam et al. 2017a; Amon et al. 2018; Singh et al. 2018). Besides tracing the lensing signal with background galaxies, Pullen et al. (2015) proposed to use the cosmic microwave background (CMB) lensing map, which allows the estimation of \( E_G \) at higher redshifts and larger scales (Pullen et al. 2016; Singh et al. 2018).

In this work, using quasars and CMB lensing, we test ΛCDM-GR on cosmological scales 19–190 \( h^{-1} \) Mpc at the effective redshift \( \bar{z} \sim 1.5 \), which is the highest-redshift and largest-scale \( E_G \) estimation so far. Quasars, also known as quasi-stellar objects (QSOs), are active galactic nuclei (AGN) with very high luminosity, which makes them good candidates to trace LSS at higher redshifts (e.g. 1 < \( z \) < 2). As part of the primary motivation of constraining \( E_G \), we also investigate the reliability of quasars as a tracer of the DM in both auto- and cross-clustering analysis. The redshift range of the quasar targets is very close to the peak of CMB lensing kernel at \( z \sim 2 \). We should expect a promising cross-correlation signal, which is usually harder to be detected than the auto-correlation. Assumptions of the cosmology and gravity models have to be made in order to do certain estimations and generate the simulations needed. So far for it is very difficult to design one blind test for various gravity models. To do a rigorous estimation of \( E_G \) based on other MG models, the corresponding changes have to be made for either simulations or analytic calculations (see e.g. Hojjati et al. 2011).

The paper is organized as follows. In Section 2, we review the \( E_G \) theory and describe the estimator we use. The quasar and CMB data, simulations and jackknife resampling for the estimation of covariance matrices are described in Section 3. Section 4 includes analytic models, estimators, systematics and calibrations for the angular power spectra. Section 5 describes our estimation of the quasar 2-point correlation function and the maximum likelihood fitting of the redshift-space distortion (RSD) parameter. We present all the estimates and our final results in Section 6 and conclude in Section 7.

For our self-consistency test of GR, wherever needed, we assume a flat ΛCDM fiducial cosmology with Planck 2018 CMB+BAO parameters (Planck Collaboration VI 2018): \( \Omega_m = 0.3111 \pm 0.0086 \), \( \Omega_b h^2 = 0.11933 \pm 0.00091 \), \( \Omega_k h^2 = 0.02242 \pm 0.00014 \), \( n_s = 0.9665 \pm 0.0038 \), \( H_0 = 67.66 \pm 0.42 \), and \( \sigma_8 = 0.8102 \pm 0.0060 \).

## 2 \( E_G \) Formalism & Estimator

In this section, we briefly review the \( E_G \) theory and describe the estimator used in this work. We assume a flat Universe described by the perturbed Friedmann-Robertson-Walker (FRW) metric in conformal Newtonian gauge,

\[
ds^2 = a(t) \left[ (1 + 2\Psi) dx^2 - (1 + 2\Phi) dx^2 \right].
\]

where \( \Psi \) and \( \Phi \) are the scalar perturbations to the time and spatial components of the metric. The statistic \( E_G \) is defined in Fourier Space (Zhang et al. 2007) as

\[
E_G(k,z) = \left[ \frac{\nabla^2 (\Psi - \Phi)}{-3H_0^2(1+z)\theta} \right]_k
\]

where \( H_0 \) is the Hubble constant and \( \theta = \nabla \cdot \vec{v} / H(z) \) is the divergence of the comoving peculiar velocity field. In linear perturbation theory, \( \theta = -f\delta \), where \( f \) is the linear growth rate and \( \delta \) is the matter perturbation. For GR, assuming no anisotropic stress (\( \Phi = -\Psi \)) and using Poisson equation \( \nabla^2 \Psi = 4\pi G\rho \), we have

\[
E_G^{GR}(z) = \frac{\Omega_{m,0}}{f(z)},
\]

where \( \Omega_{m,0} = \rho_{m,0}/\rho_{crit,0} \) is the fraction of matter density today with \( \rho_{crit,0} = 3H_0^2 / 8\pi G \), and \( f(z) \simeq \Omega_m(z)^\gamma \) with \( \gamma = 0.55 \) and

\[
\Omega_m(z) = \frac{\Omega_{m,0}(1+z)^3}{\Omega_{m,0}(1+z)^3 + (1 - \Omega_{m,0})}
\]

at late time. Notice that \( E_G^{GR}(z) \) is scale-independent and only relies on the relative fraction of matter density in the Universe. Predictions of \( E_G \) with modified gravity models can be at different values and even scale-dependent.

The angular estimator for \( E_G \) at the effective redshift \( \bar{z} \) can be constructed as (Pullen et al. 2015)

\[
E_G(\theta)_{\bar{z}} = \frac{\bar{z}^2}{3H_0^2} \left( \frac{C_L^{\ell q}}{C_L^0} \right)^{1/2} \Gamma(\bar{z})^{C_L^{\ell q}} \left( \frac{C_L^{\ell q}}{\bar{C}_L^{\ell q}} \right)^{1/2}
\]

where \( C_L^{\ell q} \) is the angular power spectrum at \( \ell \) for \( q \) realizations. At large scales, it is expected to be correlated with the angular position of the quasar samples, whereas at smaller scales, it is expected to be uncorrelated with the position of the quasar samples.
where \( c \) is the speed of light, \( \kappa \) and \( q \) denote the CMB lensing convergence and quasar overdensity respectively. \( C_{\ell} \)'s are the angular power spectra, \( B \) is the RSD parameter, and \( \Gamma \) is an analytic factor,

\[
\Gamma(z) = \frac{2c}{3H_0^2} \frac{H(z)f_q(z)}{1 + z} W(z),
\]

where \( f_q(z) \) is the normalized redshift distribution of the quasar sample at the effective redshift and \( W(z) \) is the CMB lensing kernel. \( f_q(z) \) and \( W(z) \) work as the radial projection kernels for \( q \) and \( \kappa \) fields when we transform the 3-D power spectra \( P(k, z) \) into angular \( C_{\ell} \)'s, as shown in Eq. 17 and Eq. 19. To convert \( C_{\ell}^{mq} \) to the directly measurable \( C_{\ell}^{Gq} \), the approximation made in Eq. 5 which includes the substitution of a certain redshift-dependent factor with the effective value at \( \bar{z} \) is not perfect. This can cause a systematic bias around 5% to our \( E_G \) estimation. Following Pullen et al. (2016) and assuming a scale-independent linear bias \( b(z) \), we introduce the calibration factor

\[
C_G = \frac{c}{2} \frac{W(z)(1 + \bar{z})}{H(z)f_q(z)} C_{\ell}^{mq},
\]

where

\[
C_{\ell}^{mq} = \int_{z_1}^{z_2} dz_x \frac{1}{2} \frac{H(z)}{c} f_q^2(z) b(z) P_m \left( \ell + 1/2, \frac{\chi(z)}{\chi(x)} \right),
\]

and

\[
Q_{\ell}^{mq} = \frac{1}{2} \int_{z_1}^{z_2} dz_x \frac{H(z)}{c} f_q^2(z) b(z) P_m \left( \ell + 1/2, \frac{\chi(z)}{\chi(x)} \right),
\]

where \( \chi(z) \) is the radial comoving distance at redshift \( z \). \( P_m \) is the matter power spectrum and Limber approximation \( 4k_x \simeq \ell + 1/2 \) has been used. Due to the limited size of the quasar sample, it is hard to study the redshift evolution of the bias by cutting the redshift range into a few smaller bins. Here we just take a constant bias at the effective redshift, i.e. \( b(z) \approx b(z) \). We also tried an eBOSS quasar bias model presented in Laurent et al. (2017), and the difference is negligible considering that the systematic bias calibrated by \( C_G \) is only around 5% of the \( E_G \) signal. Another systematic bias concern is the non-linear quasar bias and the imperfect connection between quasars and the matter field at small scales, which is hard to model and needs to be corrected with N-body simulations. However, for the scales (\( \gtrsim 18 h^{-1} \text{Mpc} \)) we are considering, this systematic bias should be negligible (Pullen et al. 2016; Singh et al. 2018).

The correspondence between multipoles \( \ell \) and linear scales \( \chi_\perp \) at a certain redshift is given by \( \chi_\perp = 2\pi \chi(z)/\ell \). With Eq. 5, we can estimate \( \hat{E}_G(\ell) \) for a range of multipoles. These multipoles are binned into a few bandpowers in practice, with more details discussed in the estimation of \( C_G \)'s (Section 4.2). In the end, we need to find the best-fit \( E_G \) with \( \hat{E}_G(\ell) \) over scales in order to compare with the GR prediction. To make the discussion coherent, we present our fitting method along with our estimates of the covariance matrix for \( E_G(\ell) \) in Section 6.4.

3 DATA & COVARIANCES

In this section, we describe the quasar and CMB lensing data used in this work. We also discuss the simulations and the jackknife resampling method used to estimate the covariance matrices.

Figure 1. The overlapped mask of Planck 2018 CMB lensing and eBOSS DR16 quasar NGC (upper) and SGC (lower) clustering catalogs. NGC (SGC) covers about 2929 (1815) deg^2. The orientation of the regions are shown in J2000 coordinates. For jackknife resampling, NGC and SGC are divided into 56 and 35 equally-weighted regions respectively.

3.1 Quasar catalogs

We use the quasar sample for clustering analysis from the fourth phase of the Sloan Digital Sky Survey (SDSS-IV) (Blanton et al. 2017) extended Baryon Oscillation Spectroscopic Survey (eBOSS) (Dawson et al. 2016) Data Release 16 (DR16) (Ahumada et al. 2019), which is observed with the Sloan Foundation 2.5-meter Telescope located at the Apache Point Observatory (Gunn et al. 2006) with double-armed spectrographs (Smee et al. 2013). The construction of these eBOSS DR16 clustering catalogs for quasars from the complete SDSS DR16 quasar (DR16Q) catalog (Lyke et al. 2020) is described in Ross et al. (2020), along with the catalogs for luminous red galaxies (LRGs) and emission line galaxies (ELGs). The quasar sample comprises the north galactic cap (NGC) and the south galactic cap (SGC), which correspond to two separate regions on the sky. Since jackknife resampling is used for covariance estimation (see Section 3.3), we only use the sky region covered by both the quasar and CMB lensing surveys (Fig. 1). The sky coverage fraction and number of quasars are shown in Table 1. This overlapped coverage masks out around 3.4% quasars in NGC and 7.4% quasars in SGC. Even without jackknife resampling, using this total mask is still reasonable since the removed quasars do not have the corresponding lensing signal anyway.

Using the HEALPix (Górski et al. 2005) pixelization, we construct the quasar overdensity map with

\[
\delta_q = \frac{n_q}{\bar{n}} - 1,
\]
Table 1. The overlapped sky coverage fraction of eBOSS DR16 quasar catalogs and Planck 2018 CMB lensing, and the corresponding number of quasars. The (weighted) mean and median redshifts agree with each other (see text), denoted as $\bar{z}$. The last column shows the number of quasars in the original catalogs but not covered by the total mask.

| Cap | $f_{sky}$ (%) | # quasars | $\bar{z}$ | # masked |
|-----|---------------|-----------|----------|---------|
| NGC | 7.1           | 210881    | 1.51     | 7328    |
| SGC | 4.4           | 116249    | 1.52     | 9250    |

Figure 2. Number density redshift distribution of eBOSS DR16 quasar clustering catalogs (with the overlapped sky coverage with CMB lensing applied, see text). NGC has a higher number density than SGC, which results in lower shot noise.

where $i$ is the pixel index, $n_i = \sum q \in i w_q$ is the weighted number count of quasars for each pixel and $\bar{n}$ is the the average over all covered pixels. The weight for each quasar is given by $w_q = w_{\text{sys}} \cdot w_{\text{cp}} \cdot w_{\text{pz}}$, where $w_{\text{cp}} \cdot w_{\text{pz}}$ corrects for the spectroscopic completeness due to close pairs and redshift failures across fibers, and $w_{\text{sys}}$ accounts for the imaging systematics. Additionally, for the estimation of the correlation function, $w_{\text{KP}}$ is also applied to optimize the clustering statistics (Feldman et al. 1994). The determination of all these weights is described in detail in Ross et al. (2020).

The redshift distribution of the two catalogs are shown in Fig. 2, where we see that NGC has a higher number density than SGC. So the shot noise due to the Poisson distribution of the quasars, which is inversely proportional to the number density, is lower for NGC than SGC. The quasars are observed in redshift bin $0.8 < z < 2.2$, for which we need to determine the effective redshift for our angular analysis. The recommended definition of the effective redshift in eBOSS DR16 clustering analysis is given by

$$z_{\text{eff}} = \frac{\sum_{i,j} w_i w_j (z_i + z_j) / 2}{\sum_{i,j} w_i w_j},$$

(11)

which is proposed for the measurement of the 2-point correlation function and the summation is conducted over pairs with separation distance $25 \leq s \leq 120 \text{ Mpc}^{-1} h$. With this definition, Hou et al. (2020) find $z_{\text{eff}} \approx 1.48$ for the full clustering quasar sample. For both NGC and SGC quasar samples used in this work, we find that the mean, weighted mean ($\sum_i w_i z_i / \sum_i w_i$) and median redshifts agree with each other, with the value shown as $\bar{z}$ in Table 1. Although the overlapped mask removes some quasars, these redshift values almost remain the same. The tiny difference in the definitions of the effective redshift is completely negligible compared with the statistical accuracy. Thus for simplicity, in this work, we take the effective redshift at $z = 1.5$ for both NGC and SGC.

3.2 CMB lensing map

The gravitational lensing convergence ($\kappa$) map used is the minimum-variance estimate with CMB temperature and polarization measurements (Planck Collaboration VIII 2018), reconstructed and provided as part of the Planck 2018 data release (Planck Collaboration I 2018). The map covers about 70 percent of the sky and is provided in spherical harmonics $\kappa_{\ell m}$’s up to $\ell = 4096$. However, in this work, we only use the multipoles in $8 \leq \ell \leq 2048$. We do not use the multipoles $\ell > 2048$ due to the significant reconstruction noise at those very small scales. Since we are only considering well-defined linear scales $100 \leq \ell \leq 1000$ for our angular power spectra and $E_G$ estimation, contributions from those much smaller and non-linear scales should be negligible compared with the statistical errors.

3.3 Covariance matrices

Covariance matrices (CMs) are needed for constructing the likelihood functions used in the posterior distribution sampling of the parameters, e.g. RSD parameters and scale-averaged $\bar{E}_G$. Like any other statistics, an accurate estimation of the CM relies on a large number of samples. In this work, we estimate the CMs in two ways. One is using simulations, and the other is jackknife resampling, which only depends on the data itself.

For simulations, we run all of them through the same data analysis pipeline as we do for the real data, with which we can then construct the CM for any statistical quantity in the procedure. We use 300 simulated $\kappa$ maps with Planck 2018 CMB lensing analysis (Planck Collaboration VIII 2018), in which the lensing reconstruction noise is included. For the eBOSS quasar sample, Zhao et al. (2020) generated 1000 effective Zel’dovich mock catalogs (EZ mocks, Chuang et al. 2015). The fiducial cosmology for generating the mocks is flat ΛCDM with parameters: $\Omega_m = 0.307115$, $\Omega_b = 0.048206$, $\sigma_8 = 0.8225$, and $n_s = 0.9611$. These are slightly different from the Planck 2018 CMB+BAO parameters we are assuming, but the influence on the CMs should be negligible. Combining these simulated $\kappa$ maps and EZ mocks, we have 300 sets of independent simulations for our $E_G$ analysis. These lensing maps and quasar mocks are not correlated, which results in zero mean signal and lower error estimates (Eq. 20) for the cross correlation $\ell$. As discussed in Section 6.2, the contribution of $C^{\ell}_{\ell} \kappa$ signal to the error distribution of itself is negligible compared with the noise level in the auto correlation of the current surveys. However, the $C^{\ell}_{\ell}$ signal is important in the CM estimation for functions of it like $E_G$, which can be seen from the Gaussian error propagation. We discuss our approach to fix this issue in Section 6.4, where the estimates of CMs for $E_G(\ell)$ are presented. Although using realistic simulations is a promising way to estimate CMs since we can run as many simulations as needed (with enough computing resources), it should still be reiterated that simulations depend on the fiducial model, where extra consideration is necessary for the purpose of testing different models on the data.

Another CM estimation method which only relies on the data sample is jackknife resampling. In this work, we divide the overlapped sky coverage of quasar and CMB lensing into $N$ equally weighted regions and make leave-one-out jackknife samples by taking one region out each time. This process leaves us $N$ correlated
re-samples of the original full data. We do the analysis for each of these jackknife samples, with each result denoted as a vector \( \mathbf{x} \), e.g. the correlation function or power spectrum. Then the covariance matrix of \( \mathbf{x} \) is given by

\[
\text{Cov}(x_i, x_j) = \frac{N-1}{N} \sum_{k=1}^{N} \left( \hat{x}_i^{(k)} - \bar{x}_i \right) \left( \hat{x}_j^{(k)} - \bar{x}_j \right),
\]

where \( \bar{x} \) is the mean of all the jackknife estimates, which are labeled with index \( k \). Compared with the normal unbiased sample CM estimation, a factor of \( (N-1)^2/N \) is multiplied, which corresponds to the fact that the jackknife samples are not independent. Jackknife resampling has the advantage of being dependent only on the data, which hence naturally includes all the systematics and the noise in the observations. However, the maximum number of jackknife samples is limited by the largest scale to be probed. In this work, by requiring the linear scale of each region to be at least two times the largest scale we are interested in, we are able to use 56 (35) jackknives for NGC (SGC) (Fig. 1). We make sure that jackknife resampling is unbiased by comparing the mean of all the jackknife estimates with the estimate using the full data sample. It turns out that for the statistics in this work, they are always consistent. However, the number of jackknives used may not be enough to give us accurate estimates of the CMs, especially the off-diagonal terms (i.e. cross correlations between different scales), whose relative strength compared with variances (diagonal terms) can be quantified with the correlation matrix,

\[
\text{Corr}(C)_{ij} = \frac{C_{ij}}{\sqrt{C_{ii}C_{jj}}},
\]

where \( C \) denotes the CM.

The estimated \( \hat{C} \) for a multivariate Gaussian vector with a limited number of samples follows the Wishart distribution, which is an unbiased estimate of the true CM, \( C \). However, \( \hat{C}^{-1} \), the inverse of \( \hat{C} \), which obeys the inverse Wishart distribution, is a biased estimate of \( C^{-1} \) due to the error in \( \hat{C} \). This can be corrected with a simple factor (Hartlap et al. 2007),

\[
\hat{C}^{-1}_{\text{unbiased}} = \left( 1 - \frac{N_d - 1}{N_d} \right) \hat{C}^{-1},
\]

where \( N_d \) is the size of the data vector and \( N_d \) is the number of samples. Furthermore, the error in \( \hat{C} \) propagates to the CM of the model parameters in the maximum likelihood fitting (Dodelson & Schneider 2013). This can be corrected by multiplying the factor

\[
M = \frac{1 + B(N_d - N_p)}{1 + A + B(N_p + 1)}
\]

to the CM of the parameters (Percival et al. 2014), where \( N_p \) is the number of parameters and

\[
A = \frac{2}{(N_d - N_d - 1)(N_s - N_d)},
\]

\[
B = \frac{N_s - N_d - 2}{(N_s - N_d)(N_s - N_d - 4)}.
\]

It should be noticed that the above corrections are derived for independent samples like the simulations, which may not be the proper solution for jackknife samples (Taylor et al. 2013). However, more detailed discussion is out of the scope of this paper, which we leave for future work. Specifically in this work, two CMs are used for fitting purposes. One is for the 2-point correlation function of quasars in RSD fitting and the other is for the fitting of \( E_{\text{CM}}(\ell) \) over scales.

4 ANGULAR POWER SPECTRA

In this section, we describe the theoretical models and estimators for the angular power spectra. We also discuss the influence of systematics and the corresponding calibrations applied.

4.1 Theory

The analytic expressions for the angular power spectra can be derived by integrating the 3-D power spectra \( P(k, z) \) over the wavenumber \( k \), with proper radial projection kernels \( F(\ell) \) applied. For high \( \ell \)'s (e.g. \( \ell > 10 \)) it is good enough for the wide redshift bin of the quasar sample, the spherical Bessel functions \( j_{\ell}(kz) \) vary fast compared with \( F(\ell) \), which picks out the scale \( k = (\ell + 1/2)/\chi(z) \). Based on this, the Limber approximation replaces the \( j_{\ell} \) with the Dirac delta function, which significantly speed up the numerical evaluation of the integral. In what follows, this approximation is always applied.

The CMB lensing \( \times \) quasar cross-power spectrum reads

\[
C_{\ell}^{Q} = \frac{3 \Omega_{m,0} H_0^2}{2c^2} \int_{z_1}^{z_2} dz \chi^{-2}(z) W(z) f_g(z) P_{\psi q / \eta q}(\ell/\chi(z)),
\]

where \( \chi(z) \) is the radial comoving distance at redshift \( z \), \( W(z) = \chi(z) [1 - \chi(z)/\chi_{\text{CMB}}] \) is the CMB lensing kernel with \( \chi_{\text{CMB}} \approx 1100 \), \( f_g(z) = 1 + \frac{dN(z)}{dz} \) is the normalized quasar redshift distribution and \( P_{\psi q / \eta q}(k, z) \) is the 3-D cross-power spectrum of the two fields. Assuming GR and using the Poisson equation to replace the lensing convergence with matter perturbation, Eq. 17 can be written as

\[
C_{\ell}^{Q} = \int_{z_1}^{z_2} dz \chi^{-2}(z) H(z)/c \int_{z_1}^{z_2} dz \chi^{-2}(z) \left( \ell + 1/2 \right)/\chi(z),
\]

Similarly, the quasar auto-power spectrum is given by

\[
C_{\ell}^{Q} = \int_{z_1}^{z_2} dz \chi^{-2}(z) H(z)/c \int_{z_1}^{z_2} dz \chi^{-2}(z) P_q q(\ell/\chi(z)),
\]

where \( H(z) \) is the Hubble parameter at redshift \( z \). On linear scales, the quasar overdensity field \( q(k, z) \) is connected to the underlying matter perturbation \( m(k, z) \) with a local bias, \( b(k, z) = b(z)m(k, z) \), where \( b(z) \) is the linear bias of the quasar sample at redshift \( z \), which we assume to be scale-independent. It is worth mentioning that our estimators of the angular power spectra (Section 4.2 below) do not directly rely on these theoretical predictions, and a redshift dependent \( b(z) \) model may only matter in the \( C_{\ell} \) calibration, as discussed below Eq. 7.

Later in our analysis it will be useful to have analytic expressions for statistical errors of \( C_{\ell}^{Q} \) and \( C_{\ell}^{Q} \). Assuming \( X \) and \( Y \) to be Gaussian fields, the sample variance of \( C_{\ell}^{Q} \) can be approximated as

\[
\sigma^2(C_{\ell}^{Q}) = \frac{1}{(2\ell + 1)F_{\text{sky}}^2} \left[ (C_{\ell}^{Q})^2 + (C_{\ell}^{Q} + N_{\delta}^{Q}) (C_{\ell}^{Q} + N_{\delta}^{Q}) \right]
\]

\[
= (r_{\ell}^2 + 1)/(2\ell + 1)F_{\text{sky}}^2 (C_{\ell}^{Q} + N_{\delta}^{Q}) (C_{\ell}^{Q} + N_{\delta}^{Q}),
\]

where \( r_{\ell} \equiv C_{\ell}^{Q} / (C_{\ell}^{Q} + N_{\delta}^{Q}) (C_{\ell}^{Q} + N_{\delta}^{Q}) )^{1/2} \) is known as the cross-correlation coefficient, \( N_{\delta}^{Q} \) is the lensing reconstruction
noise, $N_q^{\text{sky}}$ is the shot noise and $f_{\text{sky}}^{\text{sky}}$ is the overlapped sky coverage fraction of the surveys. Similarly, we have the variance for $C_{\ell}^{qq}$.

$$\sigma^2(C_{\ell}^{qq}) = \frac{2}{(2\ell + 1)f_{\text{sky}}^{\text{sky}}} (C_{\ell}^{qq} + N_q^{\text{sky}})^2. \quad (21)$$

When the multipoles $\ell$’s are averaged into bandpowers $p$’s (as discussed below) weighted by inverse variance (i.e. minimum variance average of Gaussian random vectors assuming no covariances), the uncertainty for the binned signal is given by

$$\sigma(C_p) = \left[ \sum_p \sigma^{-2}(C_p) \right]^{-1/2}. \quad (22)$$

These analytic uncertainties, which include the well known lensing reconstruction and shot noise, have been widely used in doing forecasts. So it would be useful to have them as references and compared to the statistical errors estimated with simulations and jackknife resampling.

### 4.2 Estimators

Due to the noise and computational complexity, it is neither necessary nor possible to estimate $C_{\ell}$ for each multipole. Thus we bin the multipoles into bandpowers, denoted with subscript $p$. Here we briefly describe the estimators we use for $C_{\ell}^{qq}$ and $C_p^{qq}$.

We estimate $C_{\ell}^{qq}$ with the Pseudo-$C_{\ell}$ (PCL) estimator,

$$\hat{C}_{\ell}^{qq} = \sum_p \left[ M^{-1} \right]_{pp} \hat{D}_p^{qq}, \quad (23)$$

where $M$ is the binned mode coupling matrix computed with the masks of the two fields and $\hat{D}_p^{qq}$ is the binned cross-power spectrum of the masked full sky maps,

$$\hat{D}_p^{qq} = \sum_{\ell \in p} w_{\ell} \frac{1}{2\ell + 1} \sum_{m=\ell}^{\ell} \kappa_m^q q_m, \quad (24)$$

where $w_{\ell}$ is the normalized weight of each multipole inside the bin, $\kappa_m^q$ and $q_m$ are the harmonics of the masked (i.e. with pixel values set to 0 if not covered) $\kappa$ and $q$ maps. We use the fast implementation NAMASTER \footnote{https://github.com/LSSTDESC/NaMaster} (Alonso et al. 2019) to do the computation. For the maps used in this work, the results of this more complicated PCL estimator are consistent with the results given by the simpler version $\hat{C}_{\ell}^{qq} \approx D_{\ell}^{qq} / f_{\text{sky}}^{\text{sky}}$, where the couplings between modes due to the geometry of the masks are ignored.

For the cross correlation, the noise in the two maps from separate surveys are usually uncorrelated and only contributes to the statistical error without causing systematic bias. However, the situation is more complicated for the auto correlation because the noise may not be correlated to the signal but is obviously correlated with itself and hence can significantly bias the signal. Thus for the estimation of $C_p^{qq}$, instead of the PCL estimator, we use the optimal quadratic minimum variance (QMV) estimator which marginalizes over the noise (Tegmark 1997). We denote the pixelated quasar overdensity map with an 1-D vector $x$ and the corresponding covariance matrix with $C$. Defining the quadratic vector

$$\hat{Q}_p = \frac{1}{2} x^T C^{-1} \frac{\partial C}{\partial C_p} C^{-1} x, \quad (25)$$

and the Fisher matrix

$$F_{pp'} = \frac{1}{2} \text{Tr} \left( C^{-1} \frac{\partial C}{\partial C_p} C^{-1} \frac{\partial C}{\partial C_{p'}} \right), \quad (26)$$

the estimator can be constructed as

$$\hat{C}_p^{qq} = \sum_{p'} [F^{-1}]_{pp'} \hat{Q}_{p'}. \quad (27)$$

The shot noise is properly fitted and marginalized in the estimation. In this work, $x$ includes ~ 10^6 pixels, which makes it computationally impossible to invert $C$ directly. We use the conjugate gradient method to iteratively evaluate $C^{-1}x$ and the trace for the Fisher matrix. This optimal QMV estimator has been used in previous CMB and galaxy power spectra analysis, and we refer our readers to the references (Padmanabhan et al. 2001, 2003; Padmanabhan et al. 2007; Hirata et al. 2004, 2008; Ho et al. 2008) for more details.

### 4.3 Systematics & calibrations

Compared with the theoretical predictions in Eq. 18 and 19, the estimated power spectra can be biased due to several aspects, most of which are hard to be corrected in the estimators above and hence extra calibrations might be needed. For the quasars, the observed flux and measured redshift from the photometric and spectroscopic surveys are distorted due to the foreground density perturbation and RSD. There can also be bias due to redshift smearing. For the CMB survey, the temperature map can be contaminated by foregrounds, e.g. dust emission and point sources. Here we mainly focus on the bias caused by the distortion of quasar catalogs. The possible systematics due to contamination in CMB are discussed in Appendix A, where it is shown that the bias to $\hat{C}_p^{qq}$ is negligible.

Our observed targets are distorted by the gravitational lensing of the foreground density perturbations. First, compared with the intrinsic value, the flux of an individual source can be either increased or decreased by lensing. This can cause bias to the flux or magnitude based target selection of the clustering catalog. Also, the observed angular distribution of the targets can be magnified. These effects can be quantified by the magnification bias $s$ (Liu et al. 2014; Hui et al. 2007), which can be measured with the slope of the cumulative apparent magnitude function,

$$s = \frac{d \log \bar{n}_q(m < m_*)}{dm} \bigg|_{m=m_*}, \quad (28)$$

where $m_*$ is the faint magnitude limit of the survey and $n_q(m < m_*)$ is the number of quasars that are apparently brighter than the survey limit. Depending on the value of $s$ and the linear bias $b$, our estimates of the power spectra can be more or less biased (Dizgah & Durrer 2016). Following Yang & Pullen (2018) (see Section 2 and Appendix A therein for the expressions with Limber approximation), we do the calibration by adding correction terms $\Delta C_p^{qq}$ and $\hat{C}_{\ell}^{qq}$ to our estimates from Eq. 23 and Eq. 27. Besides $s$ and $b$, these corrections also depend on the measured CMB lensing auto-power spectrum $C_{\ell}^{qq}$. The target selection for eBOSS quasars includes the magnitude cutoff for two frequency bands, $g < 22 OR r < 22$ (Myers et al. 2015). Looking into the apparent point spread function (PSF) magnitudes, we find that the overall cutoff is mainly dominated by the $r$ band. With Eq. 28, we get $s \approx 0.1$ for both NGC.
and SGC. The corrections are around 13% for \( C_{\ell}^{eq} \) and 7% for \( C_{\ell}^{qq} \), which results in about 5% calibrations in \( E_G(\ell) \).

The impact of RSD on the angular power spectra results from the flow of quasars due to peculiar velocities at the cutoff boundaries of the redshift bin. Starting from the additional RSD component in the flow of quasars due to peculiar velocities at the cutoff boundaries,

\[
C_{\ell}^{eq,r} = \frac{3\Omega_0 H_0^2}{2c^2} \int_{z_{1}}^{z_{2}} \frac{cdz}{H(z)} K(\ell, \chi) f(z) \chi^{-2} W(z) P_m \left( \frac{\ell + 1/2}{\chi}, z \right),
\]

(29)

where \( f(z) \) is the linear growth rate and

\[
K(\ell, \chi) = \frac{2\ell^2 + 2\ell - 1}{(2\ell - 1)(2\ell + 3)} \phi(\chi) - \frac{\ell(\ell - 1)}{\sqrt{2\ell - 3}(2\ell - 1)\sqrt{2\ell + 1}} \delta_0 - \frac{(\ell + 1)(\ell + 2)}{\sqrt{2\ell + 1}(2\ell + 3)\sqrt{2\ell + 5}} \delta_2,
\]

(30)

where \( \delta_0(\chi) = f_0(z) H(z) \) is the normalized quasar redshift distribution as a function of the comoving distance. Similarly, the bias on \( C_{\ell}^{qq} \) can be described with two extra terms,

\[
C_{\ell}^{qq,r} = \int_{z_{1}}^{z_{2}} \frac{cdz}{H(z)} K(\ell, \chi) \frac{H(z)}{c} \chi^{-2} f(z) P_m \left( \frac{\ell + 1/2}{\chi}, z \right)
\]

(31)

and

\[
C_{\ell}^{qq,rr} = \int_{z_{1}}^{z_{2}} \frac{cdz}{H(z)} K^2(\ell, \chi) \frac{H(z)}{c} \chi^{-2} f^2(z) P_m \left( \frac{\ell + 1/2}{\chi}, z \right).
\]

(32)

For the multipoles we are considering, \( 100 \leq \ell \leq 1000 \), we find \( C_{\ell}^{eq,r}/C_{\ell}^{eq} < 10^{-4} \), \( C_{\ell}^{qq,r}/C_{\ell}^{qq} < 10^{-4} \), and \( C_{\ell}^{qq,rr}/C_{\ell}^{qq} < 10^{-8} \), where \( C_{\ell}^{eq} \) and \( C_{\ell}^{qq} \) are the true power spectra in Eq. 17 and Eq. 19. So the bias due to RSD is completely negligible. This is expected since the redshift bin 0.8 < \( z < 2.2 \) for the quasar sample is wide, while the distortion only happens around the edges of the bin. Similarly, the bias due to redshift smearing error from the redshift fitting pipeline should also be negligible for these angular power spectra.

5 REDSHIFT-SPACE DISTORTION

We estimate the RSD parameter \( \beta \) of the quasar sample at the effective redshift by fitting an analytic model to the monopole and quadrupole of the configuration space 2-point correlation function (2PCF).

5.1 Two point correlation function

The 2PCF is estimated with the standard Landy & Szalay estimator (Landy & Szalay 1993),

\[
\xi = \langle DD \rangle - 2 \langle DR \rangle + \langle RR \rangle,
\]

(33)

where \( D \) is the data catalog, \( R \) is the random catalog and \( \langle \cdot \rangle \) denotes the normalized pair count between two catalogs. We sample the pair counts in (\( s, \mu \)) bins, where \( s \) is the separation distance and \( \mu \) is the cosine of the angle between the line-of-sight (LOS) and separation vectors. We use a bin size of 5 h^{-1}Mpc for \( s \) and 0.01 for \( \mu \). The multipoles are extracted by expanding the 2PCF in Legendre polynomials,

\[
\xi(s, \mu) = \sum_\ell \xi_\ell(s)L_\ell(\mu),
\]

(34)

where

\[
\xi_\ell(s) = \frac{2\ell + 1}{2} \int_{-1}^{1} \xi(\mu, s)L_\ell(\mu)d\mu.
\]

(35)

The two lowest order even multipoles, monopole \( \xi_0(s) \) and quadrupole \( \xi_2(s, \mu) \), are used in the following fitting process. The non-zero quadrupole results from the peculiar velocity due to gravity and contains the information about the growth of the structure and RSD. For jackknife resampling, the pair count process is optimized to get the results for all samples in one run. For the large number of mocks, we count the pairs with Corrfunc 4 (Sinha & Garrison 2020).

5.2 CLPT-GS model

The analytic model of the 2PCF we use is a combination (Wang et al. 2013) of the Convolution Lagrangian Perturbation Theory (CLPT) (Carlson et al. 2012) and the Gaussian Streaming (GS) model (Reid & White 2011). In the GS model, the correlation function in redshift space is given by

\[
1 + \xi(s, \mu) = \int ds \frac{1 + \xi(r)}{2\pi r^12(r, \mu)} \exp \left\{ \frac{(\mu y - \nu_{12}(r))^2}{2\sigma_{12}^2(r, \mu)} \right\},
\]

(36)

where the real space correlation function \( \xi(r) \), pairwise velocity \( v_{12}(r) \) and velocity dispersion \( \sigma_{12}^2(r, \mu) \) are outputs from CLPT modified by the growth rate \( f \) and the first and second-order Lagrangian bias, \( F' \) and \( F'' \). On linear scales, the (Eulerian) bias and RSD parameter are given by \( b = 1 + F' \) and \( \beta = f/b \) respectively. \( F' \) and \( F'' \) can also be constrained with a single overdensity parameter \( \nu \) through peak-background split (White 2014),

\[
F' = \frac{1}{\delta_{c}} \left[ av^2 - 1 + \frac{2p}{1 + (av)^2} \right],
\]

(37)

\[
F'' = \frac{1}{\delta_{c}} \left[ a^2 v^4 - 3 av^2 + 2p(2av^2 + 2p - 1) \right],
\]

where \( a = 0.707 \) and \( p = 0.3 \) with the Sheth-Tormen mass function (Sheth & Tormen 1999), and \( \delta_{c} = 1.686 \) is the linear critical overdensity of spherical collapse. To account for the finger-of-god (FoG) effect and redshift smearing error, \( \sigma_{12}^2 \) is modified by adding a nuisance term \( \sigma_{12}^0 = \sigma_{Fog}^2 + \sigma_{z}^2 \), where \( \sigma_{Fog} \) and \( \sigma_{z} \) are degenerate in this model. CLPT takes the matter power spectrum as an input, which is calculated using CAMB 5 (Lewis et al. 2000) with our fiducial cosmological parameters. This CLPT-GS model has been used in the RSD analysis of CMASS galaxies in 0.43 < \( z < 0.7 \) (Alam et al. 2015), BOSS DR12 galaxies in 0.2 < \( z < 0.7 \) (Sapathy et al. 2017), and eBOSS DR14 quasars in 0.8 < \( z < 2.2 \) (Zarrouk et al. 2018).

4 https://github.com/manodeep/Corrfunc
5 https://camb.info
5.3 Parameters distribution sampling

Given the data and analytic model of the 2PCF, we construct a multivariate Gaussian likelihood function,

$$L(\theta | \hat{\xi}) \propto \exp \left[ -\frac{1}{2} (\hat{\xi} - \hat{\xi} )^T \tilde{C}^{-1} (\hat{\xi} - \hat{\xi} ) \right],$$

where $\hat{\xi}$ is the data vector consists of $\hat{\xi}_0$ and $\hat{\xi}_2$, $\tilde{C}$ is the estimated covariance matrix of $\hat{\xi}$, and $\hat{\xi}(\theta)$ is the output of the CLPT-GS model described above with the set of free parameters denoted as $\theta$. We estimate $\tilde{C}$ with 1000 EZ mocks and do the correction as described in Section 3.3. As a comparison, $\tilde{C}$ is also estimated with jackknife resampling. We plot the correlation matrices of $\hat{\xi}$ with both methods and the ratio of the statistical errors in Fig. 3. We can see that compared with the mocks, jackknife resampling tends to overestimate the statistical errors and the relative strength of the covariances (i.e. the off-diagonal terms). Considering that the number of jackknives we are using is not very large, which hence may not be able to give us well-constrained estimates, here we use the simulated $\tilde{C}$ in the likelihood function. The set of free parameters $\theta$ includes the RSD parameter $\beta$, the overdensity parameter $\nu$ and a nuisance velocity dispersion term $\sigma_{\text{nu}}$. Flat priors are used for these parameters and the posterior distribution is sampled using Markov Chain Monte Carlo (MCMC) with emcee 6 (Foreman-Mackey et al. 2013).

6 https://github.com/dfm/emcee

6. RESULTS

In this section, we first discuss the methods of combining NGC and SGC. Then we present our estimates of the angular power spectra $C_\ell^{qq}$ and $C_\ell^{qG}$ and the RSD parameter $\beta$. These are then combined into $E_G(\ell)$ at the 5 handpowers, with which we find the best-fit scale-independent $\tilde{E}_G$ estimate.

6.1 Combination of NGC and SGC

As mentioned in Section 3.1, the quasar sample comprises two catalogs, which correspond to two separate regions on the sky, namely NGC and SGC. A proper combination of the two caps, which we denote as NS, should give us better constrained estimates. Throughout the data analysis pipeline in this work, this process can be conducted at several stages.

First, at the raw data level, the simplest approach is to put the two caps together before doing any estimation. For the quasar overdensity map, we may simply use all the quasars in the two catalogs to make one map or merge the two overdensity maps into one. For the estimation of the correlation function, we may combine the pair counts in the Landy & Szalay estimator. However, we do not do the combination at this data level since NGC and SGC are observed with different photometric calibrations and have different number densities (Fig. 2), which result in different shot noise and other possible systematics. For the estimation of $C_\ell^{qq}$, where the shot noise contributes much more than the signal at smaller scales, this simple combination of two maps with different shot noise is not optimal.

Instead of combining the data of the two caps directly, we measure $C_\ell$’s and $\beta$ separately for the two caps, which are then averaged to get the estimates for NS. This process is conducted for the full data sample, simulations and jackknife samples. Assuming no cross correlation between the two caps, the average is weighted with inverse variances, which are estimated with the 300 simulations. For jackknife resampling, $91 = 56 + 35$ jackknife estimates for NS are constructed by averaging each of the jackknife estimates from one cap with the full estimate from the other cap. It is worth mentioning that the jackknife estimates for NS are not constructed by simply stacking NGC and SGC estimates together, since the 91 jackknives should make up a complete sample from which one jackknife region is left out each time. This also requires that we are using equal weights when making jackknife regions for NGC and SGC separately in order to make sure that they are statistically equivalent. Adhering to the advantage of being dependent only on the data, the variances used in these averages are also estimates from jackknife resampling instead of simulations or analytic uncertainties. These variances for jackknives should also be rescaled with the ratio of $\chi_{\text{sky}}$’s between the leave-one-out jackknife mask and the full mask, while the difference is negligible.

At last, we may also do the average with estimates of $E_G(\ell)$ or $\tilde{E}_G$ for the two caps. As long as the error distributions of $C_\ell$’s, $\beta$ and $E_G$ are approximately Gaussian, this should be consistent with the method above.

6.2 $C_\ell^{qq}$ and $C_\ell^{qG}$

We consider the multipoles $100 \leq \ell \leq 1000$ for our analysis of the angular power spectra and $E_G(\ell)$. This corresponds to the linear scales $19 < \chi_{\text{sky}} < 190 h^{-1}$ Mpc with the radial comoving distance $\chi(z = 1.5) = 3029 h^{-1}$ Mpc given our fiducial cosmology. We do
Figure 4. CMB lensing convergence $\kappa$ × quasar overdensity $q$ angular cross-power spectra. The crosses are estimates using *Planck* 2018 CMB lensing map and eBOSS DR16 quasar clustering catalogs. We shifted the data points of NGC and SGC horizontally in the plot for reading convenience. For reference, we also plot the analytic model (Eq. 18) with a linear bias $b = 2.32$ fitted from $C_{\ell}^{qq}/C_{\ell}^{\kappa q}$. The statistical 1 $\sigma$ errors are estimated with 300 simulations. The middle panel includes the comparison of error estimates for NS using simulations and jackknife resampling with the analytic uncertainties (Eq. 20). Individual and cumulative SNRs for NS over the bandpowers are shown in the lower panel, where the cumulative SNR starts from the smallest scale (i.e. highest $\ell$) and the covariances between scales are included (Eq. 39).

Figure 5. Quasar overdensity angular auto-power spectra, with similar information as Fig. 4. The shaded area denotes the average and 1 $\sigma$ error bar of estimates from 300 EZ mocks. The analytic model in Eq. 19 is plotted for reference, with the same bias used in Fig. 4. The analytic uncertainty is computed with Eq. 21.

not consider smaller scales since $E_G$ is well defined only on linear scales. The largest scale that can be probed is limited by the spatial size of the sample and the trade-off between the number of jackknives. These multipole are binned into 5 evenly spaced bandpowers on the log scale. We do not use narrower bins because the low SNR of $C_{\ell}^{qq}$ bandpowers at small scales could result in outliers in the $E_G(\ell)$ estimates with the 300 simulations, whose error distribution would no longer be appropriate for estimating the Gaussian covariance matrix. Also, $E_G$ as a ratio of noisy quantities can be biased, hence using wider bins with smaller errors is preferable.

The estimates of $C_{\ell}^{qq}$ and $C_{\ell}^{q\kappa}$ are shown in the upper panels in Fig. 4 and Fig. 5 respectively, with the statistical 1 $\sigma$ errors given by simulations. For reference, we also plot the analytic models discussed in Section 4.1, with a linear bias $b$ fitted from $C_{\ell}^{qq}/C_{\ell}^{q\kappa}$. It is worth noticing that for $C_{\ell}^{qq}$ estimates with quasar mocks, NGC and SGC are not very well consistent on the largest-scale bandpower. This might be caused by some other systematics besides the shot noise. A better understanding requires more simulations with different possible systematics applied, which we leave for future work. We do not have $C_{\ell}^{q\kappa}$ signals with simulations since as mentioned, our simulated $\kappa$ maps and quasar mocks are not correlated. Besides simulations, the statistical errors are also estimated with jackknife resampling. In the middle panels, we show the comparison of the error estimates from both methods with the analytic uncertainties in Eq. 20 and 21, where the quasar bias and shot noise are derived from data. As expected, the error estimates are mostly higher than the analytic uncertainties where only the lensing reconstruction and shot noise are considered. Even though our simulated $\kappa$ maps and quasar mocks are not correlated, the underestimation in $\sigma(C_{\ell}^{qq})$ is negligible due to the low cross correlation coefficient $r_\ell < 0.2$ (see Eq. 20). We measure the marginalized SNR over scales with the full covariance matrix

$$\text{SNR}(C_{\ell}) = \left(\sum_{\ell,\ell'} C_{\ell,\ell'}^{-1} C_{\ell'}\right)^{1/2}$$

(39)

to quantify the overall strength of the signal. The individual SNR for each bandpower and the cumulative SNRs starting from the highest-$\ell$ band are shown in the lower panels. For $C_{\ell}^{qq}$, both methods give similar errors and hence comparable SNRs. While for $C_{\ell}^{q\kappa}$, jackknife resampling errors are higher than that from simulations. We are not doing any fittings with these angular power spectra, so more comparisons between the two methods are discussed in Section 6.4, where the covariance matrices for $E_G(\ell)$ are presented. With the simulated covariance matrices, we get overall SNR($C_{\ell}^{qq}$) = 12.5 and SNR($C_{\ell}^{q\kappa}$) = 14.0 for NS. Although the SNR for each band depends on our binning scheme, the overall value should remain roughly the same.

6.3 RSD parameter

We show the estimated monopole and quadrupole of the 2PCF of the quasar catalogs in Fig. 6, along with the best-fit CLPT-GS model and the 1000 EZ mocks. Data points with separation distances $30 \leq s \leq 135 \ h^{-1}\text{Mpc}$ are included in the RSD fitting. We do not
Figure 6. The monopole and quadrupole of the 2PCF with the best-fit CLPT-GS model. The crosses are estimates using eBOSS DR16 quasar NGC (upper) and SGC (lower) clustering catalogs. The gray shaded area denotes the mean and 1 std error of the 1000 EZ mocks used to estimate the covariance matrix in Eq. 38. Notice that the overall sky mask with CMB lensing has been applied on both the data and EZ mock catalogs. The two vertical dashed lines enclose the data points used in RSD fitting, with separation distances $30 \leq s \leq 135 \ h^{-1}\text{Mpc}$.

The posterior distributions with flat priors (i.e. likelihood functions) of the RSD parameter $\beta$, the overdensity parameter $\nu$ and the nuisance velocity dispersion parameter $\sigma_{\text{tot}}$ are shown in Fig. 7. For $\beta$ and $\nu$, while slight skewness is observed, the distributions are approximately Gaussian around the maximum likelihood estimates. This skewness might be caused by the strong cross correlation with $\sigma_{\text{tot}}$ at large values, as we can tell from the banana-shaped contours. These covariances with velocity dispersion might be better constrained with an optimized modelling that breaks the degeneracy between the FoG effect and the redshift smearing effect. For $\sigma_{\text{FoG}}$, a scale-dependent analytic model would be more accurate. The constraint on $\sigma_z$ could also be improved by constructing an informative prior based on redshifts measured with different methods. The best-fit estimates for the marginalized distribution of each parameter along with the confidence intervals are summarized in Table 2. Though the confidence intervals inferred from posterior distributions are quoted for reference, these are not propagated to the error estimation of $E_G(t)$. As mentioned in Section 3.3, to estimate the full covariance matrix for $E_G(t)$, we also need to run all the simulations through the data analysis pipeline, including the RSD fitting process. For the 300 EZ mocks, the average along with the standard deviation of the best-fit estimates are $f \sigma_8 = 0.380 \pm 0.055$ for NGC and $f \sigma_8 = 0.366 \pm 0.067$ for SGC, which are consistent with the fiducial value $f \sigma_8 = 0.381$ given the cosmological parameters used in the EZ mock simulation. The analysis of MCMC chains including the plots and statistics is conducted with the usage of ChainConsumer 7 (Hinton 2016).

For our consistency test of ΛCDM-GR on the data, we are allowed to fix the fiducial cosmological parameters in this RSD fitting process since the Planck 2018 results are measured to very high accuracy, and a flat prior based on this will not really change the marginalized distribution of the RSD parameters given the statistical accuracy. If the true parameters are statistically different from Planck results or ΛCDM-GR is not a proper model, we should be able to see the deviation of $E_G(t)$ estimates from the ΛCDM-GR prediction with Planck parameters. From $\beta$ and $\nu$, we can also infer the posterior distribution of the linear growth rate, which gives $f \sigma_8 = 0.424^{+0.064}_{-0.047}$ for NGC and $f \sigma_8 = 0.430^{+0.058}_{-0.057}$ for SGC. Our estimates are consistent with the eBOSS DR16 consensus result

Figure 7. Posterior distributions of the parameters in RSD fitting, sampled with MCMC. The properties of the marginalized distributions of individual parameters are summarized in Table 2.

Table 2. The maximum likelihood estimates of the RSD parameters with flat priors, where the 68.3% confidence intervals are quoted with $\mathcal{L}(\theta) = \mathcal{L}(\theta_0)$.

| Parameter | Prior | $\beta$ | $\nu$ | $\sigma_{\text{tot}}$ |
|-----------|-------|--------|-------|------------------|
| NGC       | [0, 1] | 0.469$^{+0.091}_{-0.063}$ | 2.04$^{+0.056}_{-0.072}$ | $7.2^{+2.1}_{-4.3}$ |
| SGC       | [0, 16] | 0.474$^{+0.091}_{-0.082}$ | 1.99$^{+0.081}_{-0.089}$ | $0.63^{+3.89}_{-0.58}$ |

7 https://github.com/samreay/ChainConsumer
of the quasar sample, \( f \sigma_{\text{eff}}^2 (z_{\text{eff}} = 1.48) = 0.462 \pm 0.045 \), which is a combination of the configuration space (Hou et al. 2020) and Fourier space (Neveux et al. 2020) analysis. The possible sources of difference include the overlapped mask with CMB lensing, fixed Alcock-Paczyński (AP; Alcock & Paczyński 1979) parameters and a different analytic model used in this work. The combination of \( \xi(s) \) and \( P(k) \) analysis could also help reduce the systematics in the consensus result (Smith et al. 2020). A more detailed discussion of models and systematics in RSD fitting is out of the scope of this work, thus we refer our readers to the series of papers presenting the eBOSS final data release (eBOSS Collaboration et al. 2020). In the RSD analysis of eBOSS DR14 quasar catalog using the same CLPT-GS model (Zarrouk et al. 2018), a shift on the linear bias \( \Delta b_{gS} = 0.037 \) was observed when \( F'' \) was set free instead of fixed. So besides the main analysis using \( \nu \) and background split, we also do a test by running the RSD fitting with free \( F' \) and \( F'' \) parameters on the data sample. For the RSD parameter we are interested in, we get \( \beta = 0.445 \pm 0.090 \) for NGC and \( \beta = 0.458 \pm 0.069 \) for SGC, which are consistent with the values in Table 2.

### 6.4 \( E_G \) estimates

We combine our estimates of \( \epsilon^q \), \( C_{\ell \ell}^q \) and \( \beta \) into \( E_G(\ell) \) following Eq. 5, with the calibration in Eq. 7 applied, which shifts the \( E_G(\ell) \) signals lower for about 5%. We find the factor \( \Gamma (z = 1.5) \approx 0.74 \) for both caps and NS. The \( E_G(\ell) \) estimates for the bandpowers are shown in Fig. 8, where the 1 \( \sigma \) statistical errors for individual bins are determined using simulations. These errors are also estimated using jackknife resampling, with the comparison shown in the middle panel. We see that \( E_G(\ell) \) estimates at all the 5 bandpowers agree with the GR prediction at 1 \( \sigma \) level. As discussed in Section 6.1, to get \( E_G(\ell) \) estimates for NS, we can combine NGC and SGC at either the \( \{\epsilon^q, \beta \} \) level or \( E_G(\ell) \) level. The NS signals shown in Fig. 8 are derived using the first method, which are consistent with that using the second method. For the scale-averaged \( E_G \) discussed below, besides fitting \( E_G(\ell) \) of NS, we can also do the fitting for NGC and SGC separately and then combine the results to get \( E_G \) for NS. We have tried all these methods, and the results are consistent in 3%, which is expected as for all the statistical quantities, the error distributions are approximately Gaussian and the two spatially separated caps should not be correlated for the scales we are considering.

To test GR, which predicts a scale-independent \( E_G \), we infer the best-fit value \( \hat{E}_G \) of \( E_G(\ell) \) over scales (i.e. bandpowers) by maximizing the multivariate Gaussian likelihood function,

\[
\mathcal{L}(\hat{E}_G) \propto \exp \left\{ -\frac{1}{2} \left( \hat{E}_G(\ell) - E_G(\ell) \right)' C^{-1} \left( \hat{E}_G(\ell) - E_G(\ell) \right) \right\},
\]

where \( C \) is the estimated covariance matrix of \( E_G(\ell) \). For this linear fitting model, the max-\( \mathcal{L} \) point can be analytically written as

\[
\hat{E}_G = \frac{\sum_{\ell, \ell'} C_{\ell \ell'}^{-1} \hat{E}_G(\ell')}{\sum_{\ell, \ell'} C_{\ell \ell'}^{-1}}.
\]

with the statistical error

\[
\sigma (\hat{E}_G) = M \times \left( \sum_{\ell, \ell'} C_{\ell \ell'}^{-1} \right)^{-1/2},
\]

where the indices denote the bandpowers, \( C_{\ell \ell'}^{-1} \) is the \( \ell, \ell' \) element of \( \hat{C} \) inverse with the correction in Eq. 14 applied, and \( M \) is the calibration factor in Eq. 15. As discussed in Section 3.3, we estimate \( \hat{C} \) with both jackknife resampling and simulations. One defect of the simulations is that the simulations are correlated. This can be caused by the fact that the simulations were correlated. The correlation matrices (Eq. 13) of \( \hat{C} \) from both methods are shown in Fig. 9, and the square root of the diagonal terms is shown in the middle panel in Fig. 8.

In this issue, we shift the center of the error distribution of the 300 simulated \( C_{\ell \ell}^q \)'s from zero to the expected signal with a fiducial quasar bias measured from the data. By doing this, the distribution of the simulated \( C_{\ell \ell}^q \)'s should be roughly equivalent to what we would get if the simulations were correlated. The correlation matrices (Eq. 13) of \( \hat{C} \) from both methods are shown in Fig. 9, and the square root of the diagonal terms is shown in the middle panel in Fig. 8. We see that \( \hat{C} \)'s given by both methods include non-negligible cross correlations between scales. This can be caused by the fact that we are using one scale-independent \( \beta \) estimate for all bandpowers, which introduces the same variation for all of them and hence contributes to the covariances. To test if \( \hat{C} \)'s are well constrained with both methods, we take another approach of estimating \( \hat{E}_G \) by fitting the ratio \( R_F \equiv C_{\ell \ell}^q / \sqrt{C_{\ell \ell}^q} \) over scales first, instead of that for \( E_G(\ell) \). \( \hat{C} \) for \( R_F \) is estimated. More details are included in Appendix B. It is shown that the covariances of \( R_F \) are much weaker (Fig. B2) than that of \( E_G(\ell) \) (Fig. 9), which is expected without the same \( \beta \) variation for all bins. The two approaches give consistent final results with \( \hat{C} \)'s given by simulations. While with jackknife resampling, the final \( \hat{E}_G \) estimates are more different, especially for SGC. One reason might be that the numbers of jackknives, with only 35 samples for SGC, are not enough to get converged estimates.
Also, for the two caps, the observational systematics in the imaging used to target quasars are different, which may result in different unknown bias. The poor constraint on \( C \) for either or both of \( E_G(\ell) \) and \( R_\ell \) can then bias our fitting for \( E_G \).

We summarize our best-fit estimates of the scale-averaged \( E_G \) in Table 3. Considering the result of the test above and the fact that the simulations we are using are designed to be as realistic as possible, i.e. including all the known systematics, we take the estimates with simulated \( C \) as our primary results. Although the signals are different, the statistical errors given by the two methods are almost the same. We report a best-fit \( E_G(z \approx 1.5) = 0.295 \pm 0.054 \) estimate for NS, which is about 0.74 \( \sigma \) lower than the \( \Lambda \)CDM-GR prediction with \( \Omega_{m,0} = 0.3111 \) are also presented. The last row includes the best-fit estimates using \( C \) from jackknife resampling, which are not reported as our final results due to the possible poor constraints on the covariance matrices (see text).

Table 3. \( E_G \) estimates at the effective redshift \( z = 1.5 \) averaged over scales \( 19 \leq \ell \leq 190 \) h\(^{-1}\)Mpc with \( \text{Planck} \) 2018 CMB lensing map and eBOSS DR16 quasar clustering catalogs. Best-fit results for NGC, SGC and the combination NS with simulated \( C \) are quoted with 1\( \sigma \) statistical errors. The deviations from \( \Lambda \)CDM-GR prediction \( E_G(z \approx 1.5) = 0.3346 \) with \( \Omega_{m,0} = 0.3111 \) are also presented. The last row includes the best-fit estimates using \( C \) from jackknife resampling, which are not reported as our final results due to the possible poor constraints on the covariance matrices.

| Cap | NS | NGC | SGC |
|-----|----|-----|-----|
| \( E_G \) | 0.295 ± 0.054 | 0.309 ± 0.068 | 0.272 ± 0.087 |
| Deviation | 0.74 \( \sigma \) | 0.38 \( \sigma \) | 0.72 \( \sigma \) |
| \( E_G \) with \( C_{jk} \) | 0.253 ± 0.050 | 0.283 ± 0.066 | 0.214 ± 0.076 |

Figure 9. Estimated correlation matrices (Eq. 13) of \( E_G(\ell) \) with jackknife resampling (upper) and 300 simulations (lower) for NGC, SGC and the combination NS. The number of jackknife samples is 56 for NGC, 35 for SGC and 91 for NS.

Figure 10. Likelihood functions of scale-averaged \( E_G \), with covariance matrices estimated using simulations. The green line with shaded area corresponds to the \( \Lambda \)CDM-GR prediction with the \( \text{Planck} \) 2018 CMB+BAO matter density and 1\( \sigma \) uncertainty, \( \Omega_{m,0} = 0.3111 \pm 0.0056 \).

Figure 11. Some previous \( E_G \) estimates and the results of this work. For reading convenience, some results are slightly shifted horizontally. For the results in this work, the NS is plotted at the effective redshift \( z = 1.5 \). The data points with white marker face color are estimated using CMB lensing while others are estimated with galaxy-galaxy lensing. The solid line is the \( \Lambda \)CDM-GR prediction (Eq. 3) with \( \Omega_{m,0} \) from \( \text{Planck} \) 2018 CMB+BAO cosmological parameters.

7 CONCLUSIONS

\( E_G \) is a promising probe of gravity on cosmological scales by combining gravitational lensing and LSS, with the advantage of being independent of the tracer bias and \( \sigma_8 \). In this work, we estimate \( E_G \) at the effective redshift \( z \sim 1.5 \) over scales \( 19 \sim 190 \) h\(^{-1}\)Mpc with the \( \text{Planck} \) 2018 CMB lensing convergence map and SDSS eBOSS DR16 quasar clustering catalogs. This is the highest redshift and largest scale where \( E_G \) has been estimated so far. We show that quasars are promising DM LSS tracers for both auto correlation clustering analysis and cross correlation with the weak gravitational lensing signal reconstructed from CMB. Our results are in line with the \( \Lambda \)CDM-GR prediction within 1\( \sigma \) confidence interval. Some previous estimates of \( E_G \) at lower redshifts and results in this work are summarized in Fig. 11. The statistical errors are still too large to discriminate between different gravity models. This work extends the redshift baseline of testing GR with \( E_G \), while there is still a gap between \( z \approx 0.6 \) and \( z \sim 1.5 \), where \( E_G \) has not been explored mainly due to the lack of promising LSS tracers considering the drop in the CMB lensing kernel.
There are still a few concerns which can be improved in the future with larger data samples. First, the redshift range 0.8 < z < 2.2 of the quasar sample in this work is wide, and the effective redshift description may not be perfect. We tried to split the sample into smaller redshift bins, and study the redshift evolution of all the quantities. However, limited by the size of the sample, the SNRs are too low to give us reliable estimates. Second, we used both jackknife resampling and simulations to estimate the covariance matrix for $E_G(\ell)$, with the latter taken for the final result reported. However, we know that both these two methods have limitations. Although the simulations are designed to be realistic, it is still possible that there are unknown systematics that contribute to the covariances. For future surveys with a larger sky area, a larger number of jackknives would serve as a reliable comparison. At last, so far the statistical error bars are still very large, which make it difficult to do a selection of different gravity models. Also, a rigorous self-consistency test of any gravity model requires the corresponding fiducial cosmology and simulations. Besides, it is necessary to have simulated CMB lensing maps and galaxy/quasar mocks that are truly correlated for future surveys where lensing reconstruction and shot noise will be lower and the contribution to the covariance matrix from cross correlation will no longer be negligible.

*Planck* has been a very successful CMB survey which gives the best constraints on the cosmological parameters so far. The next stage CMB surveys, e.g. *CMB-S4 (CMB-S4 Collaboration 2016)* and Simons Observatory (SO; SO Collaboration 2019), will produce even more accurate maps with higher resolution and lower noise. BOSS and eBOSS in SDSS has made the largest catalogs of LSS tracers in the Universe. While DR16 is the last data release of the series, more and larger LSS surveys are in progress. In the coming few years, the Dark Energy Spectroscopic Instrument (DESI; DESI Collaboration 2016) survey will target about 17 million ELGs in the redshift range 0.6 ≤ z ≤ 1.6, which will be able to fill the gap in Fig. 11. Redshifts of 1.7 million quasars with z < 2.1 as LSS tracers will also be measured over a sky area of 14000 deg$^2$, which corresponds to $f_{sky} \approx 34\%$. Compared with the eBOSS sample used in this work, the sky coverage and angular number density are increased by a factor of 3 and 1.7 respectively. Some analytic forecasts of constraining $E_G$ with future CMB and LSS surveys are discussed in Pullen et al. (2015), where we can see that the SNR in this work can be improved by an order of magnitude with the DESI quasar sample. With all these promising future surveys, modern cosmology will be able to explore the origin and evolution of the Universe with higher and higher precision.

Here we take a slightly different approach on fitting $E_G(\ell)$ over scales (i.e., the 5 bandpowers) for the scale-averaged $E_G$, which also serves as a test on the reliability of estimating the covariance matrices (CMs) with simulations and jackknife resampling. With our $E_G(\ell)$ estimator given by Eq. 5 and assuming a scale-independent RSD parameter $\beta$, $E_G(\ell)$ could be scale-dependent only through the ratio of the angular power spectra,

$$R = C^{qq}_\ell / C^{cc}_\ell.$$  \hfill (B1)

**APPENDIX B: TEST ON FITTING $E_G(\ell)$ OVER SCALES**

We use the galactic dust emission map constructed in Schlegel et al. (1998). For point sources, we make angular maps for several Planck point source catalogs, including galactic cold clumps (GCC; Planck Collaboration XXVIII 2016), Sunyaev-Zeldovich (SZ; Sunyaev & Zeldovich 1980) sources (Planck Collaboration XXVII 2016) and compact sources (CS; Planck Collaboration XXVI 2016) at 100, 143 and 217 GHz. Following Pullen et al. (2016), we estimate the biases to $C^{\kappa\kappa}_\ell$ by these possible sources

$$\Delta C^{\kappa\kappa}_\ell = \frac{\hat{C}^{\kappa\kappa}_\ell}{C^{\kappa\kappa}_\ell}.$$  \hfill (A1)

where $c$ is any of the contamination maps, and the errors are given by

$$\sigma^2 \left( \Delta C^{\kappa\kappa}_\ell \right) = \left( \Delta C^{\kappa\kappa}_\ell \right)^2 \frac{\sigma^2 \left( C^{\kappa\kappa}_\ell \right)}{C^{\kappa\kappa}_\ell} + \frac{\sigma^2 \left( \hat{C}^{\kappa\kappa}_\ell \right)}{C^{\kappa\kappa}_\ell}.$$  \hfill (A2)

The estimates are shown in Fig. A1. We find that the biases are consistent with zero, with statistical errors that are much lower than our $C^{\kappa\kappa}_\ell$ signal (Fig. 4). This is expected since the most foreground-contaminated area of the dust emission map, i.e. the Galactic plane, and the sky regions of many point sources have already been masked out in the Planck maps. Compared with the previous analysis for cross-correlating CMASS galaxies (Pullen et al. 2016) with Planck 2015 CMB lensing map, the removal of the contamination has been improved for Planck 2018 data release. A similar analysis has also been conducted for eBOSS DR14 quasars (Han et al. 2019).
Figure A1. The estimated bias $\Delta C_{\kappa q}$ to the CMB lensing $\times$ quasar cross-power spectrum caused by possible contamination sources in the CMB temperature map.

Table B1. Scale-averaged $E_G$ estimates, similar as Table 3 but with the approach discussed in Appendix B.

| Cap   | NS   | NGC  | SGC  |
|-------|------|------|------|
| $E_G$ with $\hat{C}_{\text{sim}}$ | 0.294 ± 0.057 | 0.308 ± 0.073 | 0.272 ± 0.092 |
| $E_G$ with $\hat{C}_j$  | 0.267 ± 0.045 | 0.291 ± 0.062 | 0.240 ± 0.066 |

Thus fitting $E_G(\ell)$ as discussed in Section 6.4 should be equivalent to fitting $R_\ell$ over scales first, whose best-fit estimate is then combined with $\beta$ into $\bar{E}_G$. The Gaussian likelihood function and best-fit value are in the same form as that for $E_G(\ell)$ (Eq. 40 and 41), with $E_G(\ell)$ replaced by $R_\ell$. The key point is that the corresponding $\hat{C}$ is now the CM for $R_\ell$. We present the estimates and the correlation matrices of $R_\ell$ in Fig. B1 and B2. Compared with that for $E_G(\ell)$ (Fig. 9), the cross correlations between scales are weaker, which is expected since using the same scale-independent $\beta$ value for all bins of $E_G(\ell)$ introduces covariances. With the $C_T$ (Eq. 7, which are almost the same value for the 5 bins) calibration factor applied, we summarize the final scale-independent $\bar{E}_G$ estimates with this second approach in Table B1. Compared with the results in Table 3, the estimates with simulated CMs are well consistent while that with jackknife resampling CMs are more or less different, especially for SGC. This disagreement in jackknife resampling can be caused by the small number of samples, which may not be enough to give us accurate CMs for either or both of $E_G(\ell)$ and $R_\ell$. On the other hand, for simulations, the consistency between the two approaches indicates that the CMs should be well constrained.

This paper has been typeset from a \LaTeX\ file prepared by the author.
Figure B2. Estimated correlation matrices, similar as Fig. 9 but for $R_\ell$ (Eq. B1).
