Abstract
Background: Cardiac rhabdomyoma are the most common cardiac tumour in childhood and are associated with Tuberous Sclerosis Complex (TSC) up to 96% of infant cases. They classically manifest in the fetal and neonatal period, undergo spontaneous regression in the first years of life and are associated with arrhythmia in part due to interruption of normal conduction pathways by the tumour.

Case summary: We present a case of a 3-year-old boy with a long-standing history of atrial ectopy who was incidentally found to be in atrial flutter due to a new, rapidly growing cardiac rhabdomyoma impacting ventricular function. The boy was later confirmed with further investigation and TSC1 gene test to have TSC.

Discussion: Cardiac Rhabdomyoma does not always present in the infantile period. Any ongoing or new cardiac concern in patient with TSC, even if seemingly minor, should warrant more frequent cardiac evaluation and investigation.

**Keywords:** pediatric cardiology, cardiac rhabdomyoma, tuberous sclerosis complex, atrial flutter, case report
Learning Points

1. De novo Cardiac Rhabdomyoma growth occurs outside of the fetal and neonatal period and can be the presenting feature of TSC.

2. More frequent surveillance for rhabdomyoma should take place if there are ongoing or new cardiac concerns.

| 4 years old (+1 year post surgical excision) | Asymptomatic. Normal echocardiography  |
**Introduction**

Cardiac rhabdomyoma are the most common cardiac tumour in childhood and are associated with Tuberous Sclerosis Complex (TSC) up to 96% of infant cases (1). These benign hamartomas classically manifest in the fetal and neonatal period and undergo spontaneous regression in the first years of life often with resolution (2). They are associated with arrhythmia in part due to interruption of normal conduction pathways by the tumour, creating abnormal atria-ventricular connections and ectopic electrical foci (3). We present a case of a 3-year-old boy with longstanding atrial ectopy who presented with a new, right atrial tumour causing sustained atrial arrhythmia and impacting ventricular function. Following surgical resection the diagnosis of cardiac rhabdomyoma was made and the patient later found to have the TSC1 gene mutation.

**Case**

A healthy 3-year-old male presented for routine pediatric cardiology follow-up. He was initially referred due to the presence of atrial ectopy during a hospital admission for left orchidopexy at 6 months of age. Otherwise, his history was unremarkable with an uneventful antenatal course and normal 20-week anomaly scan. There was no family history of cardiac disease or TSC and no other parental concerns during follow-up except for mild speech delay. At 9 and 18 months, 12 lead EKG were normal and 24-hour Holter monitoring noted sinus rhythm with a combined ectopy burden of 11%. Isolated atrial ectopy accounted for 7% of beats and ventricular ectopy 4%. There were no runs of ventricular tachyarrhythmia and the longest run of premature atrial contractions was 3 beats at 158 bpm. Echocardiograms performed at the same time as these Holter recordings were normal.

Although clinically very well, at this appointment he was in atrial flutter on his 12 lead EKG. His examination was unremarkable with normal heart sounds and no murmurs heard.
Dermal, respiratory, urinary, and visual systems were normal as well. Echocardiogram revealed a severely dilated right atrium with a new large mass (6.4x3.1cm) in the right atrium attached to the interatrial septum (see Figure 1). The mass was prolapsing through the tricuspid valve into the right ventricle during diastole causing no significant obstruction to inflow but with moderate tricuspid regurgitation through multiple jets. The right ventricular function was reduced (ejection fraction = 39%) but left ventricular function preserved (ejection fraction=61%). The conventional blood work (including liver enzymes and cardiac biomarkers) was unremarkable. A sedate cardiac MRI demonstrated a heterogenous, multilobulated right atrial mass but was not able to refine the differential to a single diagnosis. There were few cystic and myxomatous components, no brisk intense early enhancement and no evidence of infiltrative disease. (see Figure 2).

Given the potential obstruction to inflow, reduced ventricular function and persistent arrhythmia he underwent surgical excision. At the time of surgery, the mass was found to originate from the superior vena cava and right atrial junction (see Figure 3A) which were consequently reconstructed in addition to a tricuspid valve annuloplasty.

His post-operative course was uncomplicated. The echocardiogram on post-operative day 3 showed a good result with a good biventricular systolic function and no residual mass. From a rhythm perspective, the flutter immediately resolved following excision of the mass and he remained in sinus rhythm with no significant ectopy noted on subsequent 24-hour Holter monitoring at discharge.

Histology of the tumour revealed large rounded polygonal cells with pathognomonic spider cells confirming the tumour to be a cardiac rhabdomyoma (see Figure 3B).

He underwent a brain MRI which revealed multiple cortical and subcortical tubers together with calcified subependymal nodules (see Figure 3C). Abdominal ultrasound demonstrated
bilateral renal angiolipomas. Subsequent genetic testing confirmed a likely pathogenic variant 
*TSC1* gene (TSC1.c.1641_1642delAC (p.Pro548Lysfs*15)) according to the ACMG 2015 
variant classification guidelines (4).

Cardiac follow-up at 1 year confirmed good ventricular function on echocardiogram with no 
recurrence or new tumour growth. Three 24 hour Holter monitors throughout the year 
demonstrated no arrhythmia. He was referred to the TSC clinic at our institution for ongoing 
follow-up. Routine EEG showed epileptiform discharges from the centro-parietal head 
regions but he has not had any clinical seizures and did not require seizure medication.

**Discussion**

We present a case of TSC with cardiac rhabdomyoma growing in size in the first years of life. 
From the singular history of this patient who had a regular cardiological follow-up for 
clinically insignificant ectopy, we have confirmation that this cardiac rhabdomyoma appeared 
de novo after 18 months of life and grew significantly during the 3rd year of life of this 
patient.

The current International Tuberous Sclerosis Consensus Group guidelines concerning 
echocardiographic surveillance for cardiac rhabdomyoma recommend fetal scanning if there 
is high suspicion of TSC with imaging later in gestation as tumours can enlarge in the third 
trimester. At least one postnatal echocardiogram is proposed due to reported hemodynamic 
compromise after birth. In the absence of inflow/outflow obstruction and ventricular 
dysfunction, follow-up echocardiography is not recommended in the first year of life but may 
be considered between 1-3 years to document regression. Currently, no further follow-up is 
recommended once this has occurred unless prompted by new cardiac concerns (5).

The association between cardiac rhabdomyoma and TSC is due to the mutations in the *TSC1* 
or *TSC2* genes, leading to disruption of mTOR signalling pathway with resultant
tumorigenesis secondary to loss of inhibition of cell growth and proliferation (1). Recently, exogenous mTOR inhibitors have been used to reduce the size of cardiac rhabdomyomas in hemodynamically significant lesions (6) and there is suggestion that long term therapy with these medications may alleviate the clinical manifestations of TSC (7). The predominance of growth of cardiac rhabdomyoma in the fetal period is believed to be due to propagation by trans-placental oestrogen, with regression occurring after this influence dissipates (8). But it is a misconception that growth is limited to the infantile years. A large multi-national natural history study of TSC found the mean age of cardiac rhabdomyoma diagnosis to be 3.1 years (9) and a previously published literature review observed 20% of diagnoses are made over the age of 6 years, though it is unclear whether these tumours had stabilized since the infant period or presented as de-novo childhood growth (11). Although they are the only cardiac tumour known to spontaneously regress (1), it is incorrect to think regression is the definitive rule. In congruence with other studies, a prospective cohort of 154 TSC patients with cardiac rhabdomyoma noted complete regression in only 18% and partial regression in 50% of patients (8). Additionally, de-novo growth outside of the neonatal period does occur with a recent case highlighting a new, rapidly growing cardiac rhabdomyoma in a 2-year-old patient following previous surgical resection and documented regression of multiple ventricular rhabdomyomas (10). Interestingly this new, solitary tumour was located in the right atrium, an uncommon site of origin but the same as our case report.

The theoretical hormonal influence on growth is further supported by the appearance of de-novo tumours, albeit small and without hemodynamic consequence, in 4% of TSC patients around the time of puberty. Jozwiak et al’s cohort demonstrated new tumour growth in 6 patients aged 10-15 years, 3 of which had no prior history of cardiac rhabdomyoma and 5 of which were female (8). However, this pathophysiological theory is not applicable in our case due to the patient’s atypical age. Another unusual characteristic of this tumour is the
demonstration of rapid growth more in keeping with a true neoplasm rather than hamartoma. Such expansile growth is seen in adult cellular cardiac rhabdomyomas which demonstrate cellular proliferation not seen in childhood hamartoma (12). However, these tumours differ histologically with smaller cell size and fewer vacuolated spider cells which are abundant in childhood cardiac rhabdomyoma. Histology in our case was highly typical of cardiac rhabdomyoma seen in childhood.

**Summary**

Clinicians must counsel appropriately on the basis of the natural course of any disease. Cardiac rhabdomyomas associated with TSC do not always occur in the fetal and neonatal period, do not universally regress or maintain a stable size, and there is potential for new tumour growth outside of the first years of life. This case highlights the importance of surveillance echocardiography in not only all new TSC diagnoses but throughout childhood and adolescence for all confirmed TSC with even seemingly minor cardiac concerns.
