{roiel, dwajc}@cs.cmu.edu

Abstract

We study streaming submodular maximization subject to matching/b-matching constraints (MSM/MSbM), and present improved upper and lower bounds for these problems. On the upper bounds front, we give primal-dual algorithms achieving the following approximation ratios.

- $3 + 2\sqrt{2} \approx 5.828$ for monotone MSM, improving the previous best ratio of 7.75.
- $4 + 3\sqrt{2} \approx 7.464$ for non-monotone MSM, improving the previous best ratio of 9.899.
- $3 + \epsilon$ for maximum weight b-matching, improving the previous best ratio of $4 + \epsilon$.

On the lower bounds front, we improve on the previous best lower bound of $\frac{\epsilon}{\epsilon - 1} \approx 1.582$ for MSM, and show ETH-based lower bounds of $\approx 1.914$ for polytime monotone MSM streaming algorithms.

Our most substantial contributions are our algorithmic techniques. We show that the (randomized) primal-dual method, which originated in the study of maximum weight matching (MWM), is also useful in the context of MSM. To our knowledge, this is the first use of primal-dual based analysis for streaming submodular optimization. We also show how to reinterpret previous algorithms for MSM in our framework; hence, we hope our work is a step towards unifying old and new techniques for streaming submodular maximization, and that it paves the way for further new results.
1 Introduction

In this paper we study streaming maximum submodular matching (MSM) and related problems.

Submodular function maximization has a long history. For example, it has been known since the 70s that the greedy algorithm yields an $e/(e - 1) \approx 1.582$ approximation for monotone submodular maximization subject to a cardinality constraint [52]. This is optimal among polytime algorithms with value oracle access [51], or assuming standard complexity-theoretic conjectures [17, 21, 48]. The same problem for non-monotone submodular functions is harder; it is hard to approximate to within a 2.037 factor [54]. Much work has been dedicated to improving the achievable approximation [9, 10, 18, 24, 33, 44, 54, 59]; the best currently stands at 2.597 [9].

Closer to our work is the study of submodular maximization subject to matching constraints. For this problem, the greedy algorithm has long been known to be 3-approximate for monotone functions [27]. Improved approximations have since been obtained [25, 33, 43, 45], with the current best being $(2 + \epsilon)$ and $(4 + \epsilon)$ for monotone and non-monotone MSM respectively [25]. The papers above studied rich families of constraints (e.g. matroid intersection, matchoids, exchange systems), some of which were motivated explicitly by matching constraints (see [25]). Beyond theoretical interest, the MSM problem also has great practical appeal, since many natural objectives exhibit diminishing returns behavior. Applications across different fields include: machine translation [47], Internet advertising [16, 42], combinatorial auctions more broadly [11, 46, 58], and any matching problem where the goal is a submodular notion of utility such as diversity [2, 3].

The proliferation of big-data applications such as those mentioned above has spurred a surge of interest in algorithms for the regime where the input is too large to even store in local memory. To this end, it is common to formulate problems in the streaming model. Here the input is presented element-by-element to an algorithm that is restricted to use $\tilde{O}(S)$ memory, where $S$ is the maximum size of any feasible solution. We study MSM in this model.

For our problem when the objective is linear, a line of work [14, 19, 22, 29, 49, 55] has shown that a $(2 + \epsilon)$-approximation is possible in the streaming model [29, 55]. Meanwhile, for submodular objectives under cardinality constraints (which are a special case of MSM in complete bipartite graphs), a separate line of work [4, 6, 13, 23, 41, 50] has culminated in the same $(2 + \epsilon)$ approximation ratio, for both monotone and non-monotone functions (the latter taking exponential time, as is to be expected from the lower bound of [54]); moreover, this $(2 + \epsilon)$ bound was recently proven to be tight [4, 26, 53]. On the other hand, for fully general MSM, the gap between known upper and lower bounds remain frustratingly large. Chakrabarti and Kale [12] gave a 7.75-approximate algorithm for MSM with monotone functions. For non-monotone functions, Chekuri et al. [13] gave a $(12 + \epsilon)$-approximate algorithm, later improved by Feldman et al. [23] to $5 + 2\sqrt{6} \approx 9.899$. The only known lower bound for monotone MSM is $\frac{e}{e-1} \approx 1.582$ for streaming or polytime algorithms, implied respectively by [40] and [21, 51]. For non-monotone functions, [54] implies a hardness of 2.037. Closing these gaps, especially from the algorithmic side, seems to require new ideas.

1.1 Our Contributions

We present a number of improved results for streaming maximum submodular matching (MSM) and related problems.

Our first result is an improvement on the 7.75 approximation of [12] for monotone MSM.
Theorem 1.1. There exists a deterministic linear-time streaming MSM algorithm for monotone functions which is $3 + 2\sqrt{2} \approx 5.828$ approximate.

We complement the algorithm with an instance on which our analysis is tight.

Our algorithm extends in various ways: First, it yields the same approximation ratio for submodular $b$-matchings, where each node $v$ can be matched $b_v$ times, improving on the previous best 8-approximations [13, 23]. For the special case of linear functions (MWM), our algorithm—with appropriate parameters—recovers the $(2 + \epsilon)$-approximate algorithm of [55]. For weighted $b$-matching (MWBM), a slight modification of our algorithm yields a $(3 + \epsilon)$-approximate algorithm, improving on the previous best $(4 + \epsilon)$-approximation [14].

Next, we improve on the $5 + 2\sqrt{6} \approx 9.899$ approximation of [23] for non-monotone MSM.

Theorem 1.2. There exists a randomized linear-time streaming MSM algorithm for non-monotone functions which is $4 + 2\sqrt{3} \approx 7.464$ approximate.

Our non-monotone MSM algorithm’s approximation ratio is better than the previous state-of-the-art 7.75-approximate monotone MSM algorithm [12]. Moreover, when applied to monotone functions, the algorithm of Theorem 1.2 yields the same approximation ratio as the deterministic algorithm of Theorem 1.1.

We turn to proving hardness for monotone MSM. As stated before, the previous best lower bounds for this problem were $\frac{e}{e-1} \approx 1.582$. These lower bounds applied to either space-bounded [40] or time-bounded algorithms [21, 51]. We show that the problem becomes harder for algorithms which are both space bounded and time bounded. This answers an open problem posed in the Bertinoro Workshop on Sublinear Algorithms 2014 [1], at least for time bounded algorithms.¹

Theorem 1.3. No polytime streaming MSM algorithm for monotone functions is better than 1.914 approximate.

Finally, to demonstrate that our techniques have the potential for wider applicability, we also use them to provide an alternative and unified proof of the results of Chakrabarti and Kale [12] and Feldman et al. [23] for MSM, in Appendix A.

1.2 Our Techniques and Overview

Our starting point is the breakthrough result of Paz and Schwartzman [55] for a special case of our problem—maximum weight matching (MWM). They gave a $(2 + \epsilon)$-approximate streaming algorithm by extending the local-ratio technique [7]. Subsequently, Ghaffari and Wajc [29] simplified and slightly improved the analysis of [55], by re-interpreting their algorithm in terms of

¹We note briefly that such a bound does not follow from space lower for cardinality constrained submodular maximization [26, 53] in a stream (a special case of our setting, with a complete bipartite graph on $n$ and $k$ nodes), since a bound for that problem cannot be superlinear in $n$. 

2
the primal-dual method. The primal-dual method is ubiquitous in the context of approximating linear objectives. In this paper, we show that this method is also useful in the context of streaming submodular optimization, where to the best of our knowledge, it has not yet been used. For our primal-dual analysis, we rely on the concave-closure extension for submodular functions which has a “configuration LP”-like formulation. In particular, using this extension, we find that a natural generalization of the MWM algorithm of [55] (described in Section 3) yields improved bounds for monotone MSM and its generalization to b-matchings. Our primal-dual analysis is robust in the sense that it allows for extensions and generalizations, as we now outline.

**Our approach in a nutshell** (Sections 3+4). Our approach is to keep monotone dual solutions (initially zero), and whenever an edge arrives, discard it if its dual constraint is already satisfied. Edges whose dual constraint is not satisfied are added to a stack \( S \), and relevant dual variables are increased, so as to satisfy their dual constraint. Finally, we unwind the stack \( S \), constructing a matching \( M \) greedily. The intuition here is that the latter edge in the stack incident on a common edge have higher marginal gain than earlier such edges in the stack. More formally, we show that this matching \( M \) has value at least some constant times the dual objective cost. Weak LP duality and the choice of LP imply that \( f(M) \geq \frac{1}{\alpha} \cdot f(S \cup OPT) \) for some \( \alpha > 1 \), which implies our algorithm is \( \alpha \)-approximate for monotone MSM.

**Extension 1** (Section 5). Extending our approach, which gives \( f(M) \geq \frac{1}{\alpha} \cdot f(S \cup OPT) \), to non-monotone functions \( f \) seems challenging, since for such functions \( f(S \cup OPT) \) can be arbitrarily smaller than \( f(OPT) \). To overcome this challenge, we note that our dual updates over-satisfy dual constraints of edges in \( S \). We can therefore afford to randomly discard edges whose dual is not satisfied on arrival (and not add them to \( S \)), resulting in these edges’ dual constraints holding in expectation. This allows us to argue, via a generalization of the randomized primal-dual method of Devanur et al. [15] (on which we elaborate in Section 2), that \( \mathbb{E}[f(M)] \geq \frac{1}{\alpha} \cdot \mathbb{E}[f(S \cup OPT)] \). As \( S \) contains each element with probability at most some \( q \), a classic lemma of [10] allows us to show that \( \mathbb{E}[f(S \cup OPT)] \geq (1 - q) \cdot f(OPT) \), from which we get our results for non-monotone MSM. Given the wide success of the randomized-primal dual method of [15] in recent years [20, 31, 34, 35, 36, 37, 38, 56], we believe that our extension of this method in the context of submodular optimization will likely find other applications.

**Extension 2** (Section 6). For maximum weight b-matching (MWM), the dual updates when adding an edge to the stack are not high enough to satisfy this edge’s dual constraint. However, since we do cover each edge outside the stack \( S \), weak duality implies that a maximum-weight b-matching \( M \) in the stack \( S \) has value at least as high as \( f(M) \geq \frac{1}{\alpha} \cdot f(OPT \setminus S) \), and trivially at least as high as \( f(M) \geq f(OPT \cap S) \). Combining these lower bounds on \( f(M) \) imply our improved \((3 + \epsilon)\) approximation ratio for MWM. This general approach seems fairly general, and could find uses for other sub-additive objectives subject to downward-closed constraints.

**Unifying Prior Work** (Appendix A). To demonstrate the usefulness of our primal-dual analysis, we also show that this (randomized) primal-dual approach gives an alternative, unified way to analyze the MSM algorithms of [12, 23].

---

A form of equivalence between local-ratio and primal-dual was established in [8], but not for the extension of the local ratio technique given in [55].

Incidentally, for monotone functions, for which \( \mathbb{E}[f(M)] \geq \frac{1}{\alpha} \cdot \mathbb{E}[f(S \cup OPT)] \geq \frac{1}{\alpha} \cdot f(OPT) \), this algorithm is \( \alpha \)-approximate. This is somewhat surprising, as this algorithm runs an \( \alpha \)-approximate monotone algorithm (and this analysis is tight, by Appendix B) on a random \( q \)-fraction of the input, suggesting an \( \alpha/q \) approximation. Nonetheless, we show that for \( q \) not too small in terms of \( \alpha \), we retain the same approximation ratio even after this sub-sampling.
Lower bound (Section 7). Our lower bound instance makes use of two sources of hardness: computational hardness under ETH ([17, 21]) and information-theoretic hardness resulting form the algorithm not knowing the contents or order of the stream in advance ([30]). In particular, our proof embeds a submodular problem (specifically, set cover) in parts of the linear instance of [30], and hence exploits the submodularity in the MSM objective. Interestingly, our lower bound of 1.914 is higher than any convex combination of the previous hardness results we make use of, both of which imply a lower bound no higher than $e/(e-1)$.

2 Preliminaries

A set function $f : 2^N \to \mathbb{R}$ is submodular if the marginal gains of adding elements to sets, denoted by $f_S(e) := f(S \cup \{e\}) - f(S)$, satisfy $f_S(e) \geq f_T(e)$ for $e \notin T$ and $S \subseteq T \subseteq N$. We say $f$ is monotone if $f(S) \leq f(T)$ for all $S \subseteq T \subseteq N$. Throughout this paper we require only oracle access to the submodular function. The maximum submodular matching (MSM) problem is defined by a non-negative submodular function $f : 2^E \to \mathbb{R}_{\geq 0}$, where $E$ is the edge-set of some $n$-node graph $G = (V,E)$, and feasible sets are matchings in $G$. The more general maximum submodular b-matching (MSbM) problem, has as feasible sets subgraphs in which the degree of each vertex $v$ does not exceed $b_v$, for some input vector $\vec{b}$. Our objective is to design algorithms with low approximation ratio $\alpha \geq 1$, that is algorithms producing solutions $M$ such that $\mathbb{E}[f(M)] \geq \frac{1}{\alpha} \cdot f(OPT)$ for the smallest possible value of $\alpha$.

For streaming MSM, edges of $E$ are presented one at a time, and we are tasked with computing a matching in $G$ at the end of the stream, using little memory. Since any matching’s size is at most $n/2$, we restrict our algorithms to using the bare minimum space, $O(n)$ (while the entire graph can have size $\Omega(n^2)$). On a technical note, we will only allow the algorithm to query the value oracle for $f$ on subsets currently stored in memory. As is standard (see e.g., [32, 60]), we assume the range of $f$ is polynomially bounded. More precisely, we assume that $\frac{\max_{e \in S} f_S(e)}{\min_{e \in S} f_S(e)} = n^{O(1)}$, where the max and min are taken over $e, S$ for which $f_S(e) \neq 0$. This implies in particular that we can store values of the form $f_S(e)$ using $O(\log n)$ bits.

Useful Notation Throughout this paper we will rely on the following notation. First, we denote by $e^{(1)}, e^{(2)}, \ldots$, the edges in the stream, in order. For edges $e = e^{(i)}, e' = e^{(j)}$, we write $e < e'$ if and only if $i < j$, i.e., if $e$ arrived before $e'$. Similarly to [13, 23], we will also use $f(e : S) := f_{S \setminus \{e' < e\}}(e)$ as shorthand for the marginal gain from adding $e$ to the set of elements which arrived before $e$ in $S$. One simple yet useful property of this notation is that $\sum_{e \in S} f(e : S) = f(S)$ ([13, Lemma 1].) Other properties of this notation we will make use of, both easy consequences of submodularity, are $f(e : S) \leq f_S(e)$, as well as monotonicity of $f(e : S)$ in $S$, i.e., $f(e : A) \geq f(e : B)$ for $A \subseteq B$.

2.1 The Primal-Dual Method in Our Setting

As discussed in Section 1.2, the main workhorse of our algorithms is the primal-dual method. In this method, we consider some linear program (LP) relaxation, and its dual LP. We then design an algorithm which computes a (primal) solution of value $P$, and a feasible solution of value $D$, and show that $P \geq \frac{1}{\alpha} \cdot D$, which implies an approximation ratio of $\alpha$, by weak duality, since

$$P \geq \frac{1}{\alpha} \cdot D \geq \frac{1}{\alpha} \cdot f(OPT).$$
For linear objectives, the first step of the primal-dual method—obtaining an LP relaxation—is often direct: write some integer linear program for the problem and drop the integrality constraints. For submodular objective functions, which are only naturally defined over vertices of the hypercube, \( \vec{x} \in \{0, 1\}^E \), and are not defined over fractional points \( \vec{x} \in [0, 1]^E \setminus \{0, 1\}^E \), the first step of defining a relaxation usually requires extending \( f \) to real vectors. For this, we use the concave closure (see e.g. [57] for a survey of its history and further properties).

**Definition 2.1.** The concave closure \( f^+ : [0, 1]^E \rightarrow \mathbb{R} \) of a set function \( f : 2^E \rightarrow \mathbb{R} \) is given by

\[
f^+(\vec{x}) := \max \left\{ \sum_{T \subseteq E} \alpha_T \cdot f(T) \mid \sum_{T \subseteq E} \alpha_T = 1, \alpha_T \geq 0 \forall T \subseteq E, \sum_{T \ni e} \alpha_T = x_e \forall e \in E \right\}.
\]

In words, the concave closure is the maximum expected \( f \)-value of a random subset \( T \subseteq E \), where the maximum is taken over all distributions matching the marginal probabilities given by \( \vec{x} \). This is indeed an extension of set functions (and in particular submodular functions) to real-valued vectors, as this distribution must be deterministic for all \( \vec{x} \in \{0, 1\}^E \). Consequently, for any set \( P \subseteq [0, 1]^E \) containing the characteristic vector \( \vec{x}_{\text{OPT}} \) of an optimal solution \( \text{OPT} \), we have that \( \max_{\vec{x} \in P} f^+(\vec{x}) \geq f^+(\vec{x}_{\text{OPT}}) = f(\text{OPT}) \).

Now, to define an LP relaxation for submodular maximization of some function \( g \) subject to some linear constraints \( A\vec{x} \leq \vec{c} \), we simply consider \( \max \{ g^+(\vec{x}) \mid A\vec{x} \leq \vec{c} \} \). For MSbM, we obtain the primal and dual programs given in Figure 1.

| Primal \((P)\) | Dual \((D)\) |
|---|---|
| \[ \text{max} \sum_{T \subseteq E} \alpha_T \cdot g(T) \] subject to \[ \forall T \subseteq E: \sum_{T \ni e} \alpha_T = x_e \] \[ \forall v \in V: \sum_{e \ni v} x_e \leq b_v \] \[ \forall e \in E, T \subseteq E: x_e, \alpha_T \geq 0 \] | \[ \text{min} \mu + \sum_{v \in V} b_v \cdot \phi_v \] subject to \[ \forall T \subseteq E: \mu + \sum_{e \in T} \lambda_e \geq g(T) \] \[ \forall v \in E: \sum_{v \in T} \phi_v \geq \lambda_e \] \[ \forall v \in V: \phi_v \geq 0 \] |

Figure 1: The LP relaxation of the MSbM problem and its dual

### 2.2 Non-Monotone MSM: Extending the Randomized Primal-Dual Method

To go from monotone to non-monotone function maximization, we make use of our dual updates resulting in dual solutions which over-satisfy (some) dual constraints. This allows us to randomly sub-sample edges with probability \( q \) when deciding whether to insert them into \( S \), and still have a dual solution which is feasible in expectation over the choice of \( S \). This is akin to the randomized primal-dual method of Devanur et al. [15], who introduced this technique in the context of maximum cardinality and weighted matching. However, unlike in [15] (and subsequent work [20, 31, 34, 35, 36, 37, 38, 56]), for our problem the LP is not fixed. Specifically, we consider a different submodular function in our LP based on \( S \), denoted by \( g^S(T) := f(T \cup S) \). This results in random primal and dual LPs, depending on the random set \( S \). We show that our (randomized) dual solution is feasible for the obtained (randomized) dual LP in expectation over \( S \). Consequently, our expected
solution’s value is at least as high as some multiple of an expected solution to the dual LP, implying
\[ \mathbb{E}_S[f(M)] \geq \frac{1}{\alpha} \cdot \mathbb{E}_S[D] \geq \frac{1}{\alpha} \cdot \mathbb{E}_S[f(S \cup \text{OPT})]. \] (1)

Equation (1) retrieves our bound for monotone functions, for which \( \mathbb{E}_S[f(S \cup \text{OPT})] \geq f(\text{OPT}) \).

To obtain bounds for non-monotone functions, we show that \( \mathbb{E}_S[f(S \cup \text{OPT})] \geq (1 - q) \cdot f(\text{OPT}) \), by relying on the following lemma, due to Buchbinder et al. [10, Lemma 2.2].

**Lemma 2.2** ([10]). Let \( h : 2^N \to \mathbb{R}_{\geq 0} \) be a non-negative submodular function, and let \( B \) be a random subset of \( N \) containing every element of \( N \) with probability at most \( q \) (not necessarily independently), then \( \mathbb{E}[h(B)] \geq (1 - q) \cdot h(\emptyset) \).

### 3 Our Basic Algorithm

In this section we describe our monotone submodular \( b \)-matching algorithm, which we will use with slight modifications and different parameter choices in coming sections. The algorithm maintains a stack of edges \( S \), initially empty, as well as vertex potentials \( \vec{\phi} \in \mathbb{R}^{|V|} \).

When an edge \( e \) arrives, we compare the marginal value of this arriving edge with respect to the stack to the sum of vertex potentials of the edge’s endpoints times a slack parameter \( C \). If \( C \cdot \sum_{v \in e} \phi_v^{(t-1)} \) is larger, we continue to the next edge. Otherwise, with probability \( q \) we add the edge to the stack and increment the endpoint vertex potentials. At the end of the stream, we construct a \( b \)-matching greedily by unwinding the stack in reverse order. The pseudocode is given in Algorithm 1.

**Algorithm 1** The MSbM Algorithm

**Initialization**
1. \( S \leftarrow \text{emptystack} \)
2. \( \forall v \in V : \phi_v^{(0)} \leftarrow 0 \)

**Loop**
3. for \( t \in \{1, \ldots, |E|\} \) do
4.   \( e \leftarrow e^{(t)} \)
5.   \( \forall v \in V : \phi_v^{(t)} \leftarrow \phi_v^{(t-1)} \)
6.   if \( C \cdot \sum_{v \in e} \phi_v^{(t-1)} \geq f(e : S) \) then
   7.     continue \( \triangleright \) skip edge \( e \)
   8.   else
   9.     with probability \( q \) do
10.    \( S.\text{push}(e) \)
11.    for \( v \in e \) do
12.       \( w_{ev} \leftarrow \frac{f(e : S) - \sum_{b_v} \phi_v^{(t-1)}}{b_v} \)
13.     for \( v \in e \) do
14.       \( \phi_v^{(t)} \leftarrow \phi_v^{(t-1)} + w_{ev} \)

**Post-Processing**
15. \( M \leftarrow \emptyset \)
16. while \( S \neq \text{emptystack} \) do
17.   \( e \leftarrow S.\text{pop}() \)
18.   if \( |M \cap N(e)| < b_v \) for all \( v \in e \) then
19.     \( M \leftarrow M \cup \{e\} \)
20. return \( M \)

Algorithm 1 clearly outputs a feasible \( b \)-matching. In subsequent sections we analyze this algorithm for various instantiations of the parameters \( C \) and \( q \). Before doing so, we note that this algorithm when run with \( C = 1 + \Omega(1) \) is indeed a streaming algorithm, and in particular uses space \( \tilde{O}(\sum_v b_v) \).
Lemma 3.1. For any constant $\epsilon > 0$, Algorithm 1 run with $C = 1 + \epsilon$ uses $\tilde{O}(\sum_v b_v)$ space.

The proof broadly relies on the observation that every edge incident on vertex $v$ inserted to the stack increases $\phi_v$ by a multiplicative factor of $(C - 1)/b_v$, coupled with the fact that the minimum and maximum non-zero values which $\phi_v$ can take are polynomially bounded in each other, due to $f$ being polynomially bounded. See Appendix C for the complete proof.

We further note that as Algorithm 1 only evaluates $f$ a constant number of times per edge arrival, followed by an algorithm with time $O(|S|) \leq O(|E|)$, this algorithm runs in time linear in $|E|$, times the time to evaluate $f$.

Lemma 3.2. Algorithm 1 requires $O(1)$ operations and function evaluations per arrival, followed by $O(|E|)$ time post-processing.

4 Monotone MSbM

In this section we will consider a deterministic instantiation of Algorithm 1 (specifically, we will set $q = 1$) in the context of monotone submodular $b$-matching.

To argue about the approximation ratio, we will fit a dual solution to this algorithm. Define the auxiliary submodular functions $g^S : 2^E \to \mathbb{R}^+$ to be $g^S(T) := f(S \cup T)$. We will work with the dual LP $(D)$ for the function $g^S$, and consider the following dual solution.

$$
\mu := f(S) = g^S(\emptyset),
\phi_v := C \cdot \phi_v^{(|E|)}
\lambda_e := \begin{cases} 
    f(e : S) & e \not\in S \\
    0 & e \in S.
\end{cases}
$$

We start by showing that the above is indeed dual feasible.

Lemma 4.1. The dual solution $(\mu, \phi, \lambda)$ is feasible for the LP $(D)$ with function $g^S$.

Proof. To see that the first set of constraints is satisfied, note that by submodularity of $f$

$$
\sum_{e \in T} \lambda_e = \sum_{e \in T \setminus S} f(e : S) \geq \sum_{e \in T \setminus S} f(S(e)) \geq f(S(T \setminus S)) = f(S \cup T) - f(S) = g^S(T) - \mu.
$$

For the second set of constraints, note that an edge $e = e^{(t)}$ is not added to the stack if and only if the check at Line 6 fails. Therefore, since $\phi_v^{(t)}$ values increase monotonically with $t$, we have

$$
\sum_{v \in e} \phi_v = C \cdot \sum_{v \in e} \phi_v^{(|E|)} \geq C \cdot \sum_{v \in e} \phi_v^{(t-1)} \geq f(e : S) = \lambda_e.
$$

It remains to relate the value of the solution $M$ to the cost of this dual. We first prove an auxiliary relationship that will be useful:

Lemma 4.2. The $b$-matching $M$ output by Algorithm 1 satisfies

$$
f(M) \geq \frac{1}{2} \cdot \sum_{e \in S} \sum_{v \in e} b_v \cdot w_{ev}.
$$
Proof. We first note that for any edge \( e = e^{(t)} \) and \( v \in e \), since \( \phi_v^{(t-1)} = \sum_{e' \ni v, e < e} w_e \), we have that

\[
    f(e : S) = b_v \cdot w_{ev} + \sum_{u \in e} \phi_{u}^{(t-1)} \geq b_v \cdot w_{ev} + \phi_v^{(t-1)} = b_v \cdot w_{ev} + \sum_{e' \ni v, e < e} w_{e'v}.
\]

Combined with submodularity of \( f \), the above yields the following lower bound on \( f(M) \),

\[
    f(M) = \sum_{e \in M} f(e : M) \geq \sum_{e \in M} f(e : S) \geq \sum_{e \in M} \sum_{v \in e} (b_v \cdot w_{ev} + \sum_{e' \ni v, e < e} w_{e'v}).
\]

On the other hand, the greedy manner in which we construct \( M \) implies that any edge \( e' \in S \setminus M \) must have at least one endpoint \( v \) with \( b_v \) edges \( e > e' \) in \( M \). Consequently, the term \( w_{e'v} \) for such \( e \) and \( v \) is summed \( b_v \) times in the above lower bound for \( f(M) \). On the other hand, \( b_v \cdot w_{ev} = b_u \cdot w_{eu} \) for \( e = (u, v) \), by definition. From the above we obtain our desired inequality.

\[
    f(M) \geq \sum_{e \in M} \sum_{v \in e} b_v \cdot w_{ev} + \frac{1}{2} \sum_{v \in S \setminus M} \sum_{e \in M} b_v \cdot w_{ev} \geq \frac{1}{2} \sum_{v \in S} \sum_{e \in e} b_v \cdot w_{ev}.
\]

We can now bound the two terms in the dual objective separately with respect to the primal, using the following two corollaries of Lemma 4.2.

Lemma 4.3. The \( b \)-matching \( M \) output by Algorithm 1 satisfies \( f(M) \geq \frac{1}{2C} \sum_{v \in V} b_v \cdot \phi_v \).

Proof. Since \( \phi_v = C \cdot \phi_v^{(|E|)} \), and \( w_{ev} = \phi_v^{(t)} - \phi_v^{(t-1)} \) for all \( v \in e = e^{(t)} \), Lemma 4.2 implies that

\[
    f(M) \geq \frac{1}{2} \sum_{v \in V} \sum_{e^{(t)}} b_v \cdot w_{ev} = \frac{1}{2} \sum_{v \in V} \sum_{t=1}^{|E|} b_v \cdot (\phi_v^{(t)} - \phi_v^{(t-1)}) = \frac{1}{2} \sum_{v \in V} b_v \cdot \phi_v^{(|E|)} = \frac{1}{2C} \sum_{v \in V} b_v \cdot \phi_v.
\]

Lemma 4.4. The \( b \)-matching \( M \) output by Algorithm 1 satisfies \( f(M) \geq (1 - \frac{1}{C}) \mu \).

Proof. We note that \( w_e > 0 \) for an edge \( e = e^{(t)} \) if and only if \( f(e : S) \geq C \cdot \sum_{v \in e} \phi_v^{(t-1)} \). Hence,

\[
    b_v \cdot w_{ev} = f(e : S) - \sum_{v \in e} \phi_v^{(t-1)} \geq \left( 1 - \frac{1}{C} \right) f(e : S).
\]

Combining the above with Lemma 4.2, and again recalling that for \( e = (u, v) \), we have that \( b_v \cdot w_{ev} = b_u \cdot w_{eu} \), by definition, we obtain the desired inequality.

\[
    f(M) \geq \frac{1}{2} \sum_{e \in E} b_v \cdot w_{ev} \geq \left( 1 - \frac{1}{C} \right) \sum_{e \in E} f(e : S) = \left( 1 - \frac{1}{C} \right) f(S).
\]

Combining the above two corollaries and Lemma 4.1 with LP duality, we can now analyze the algorithm’s approximation ratio.

Theorem 4.5. Algorithm 1 run with \( q = 1 \) and \( C \) on a monotone MSbm instance outputs a \( b \)-matching \( M \) of value

\[
    \left( 2C + \frac{C}{C - 1} \right) \cdot f(M) \geq f(OPT).
\]

This is optimized by taking \( C = 1 + \frac{1}{\sqrt{2}} \), which yields a \( 3 + 2 \sqrt{2} \approx 5.828 \) approximation.
Proof. By weak LP duality and Lemma 4.1, together with monotonicity of \( f \), we have that
\[
C \cdot \sum_v b_v \cdot \phi_v + \mu \geq \max_T g^S(T) = \max_T f(S \cup T) \geq f(S \cup \text{OPT}) \geq f(\text{OPT}).
\]
Combining Lemma 4.3 and Lemma 4.4 and rearranging, we get the desired inequality,
\[
\left( 2C + \frac{C}{C-1} \right) \cdot f(M) \geq C \cdot \sum_v b_v \cdot \phi_v + \mu \geq f(\text{OPT}). \tag*{\Box}
\]

In Appendix B we show that our analysis of Algorithm 1 is tight.

We note that our analysis of this section required monotonicity, as we lower bounded \( f(M) \) by (a multiple of) \( f(S \cup \text{OPT}) \geq f(\text{OPT}) \), where the last step crucially relies on monotonicity. In the next section, we show how the use of randomness (namely, setting \( q \neq 1 \)) allows us to obtain new results for non-monotone MSM.

5 Non-Monotone MSM

In this section we consider MSM (so, \( b_v = 1 \) for all \( v \) in this section), for non-monotone functions.

To extend our results to non-monotone MSM, we make use of the freedom to choose \( q \notin \{0, 1\} \), resulting in a randomized algorithm. This will allow us to lower bound \( \mathbb{E}_S[f(S \cup \text{OPT})] \) in terms of \( f(\text{OPT}) \). But first, we show that for appropriately chosen \( q \), the output matching \( M \) has high value compared to \( \mathbb{E}_S[f(S \cup \text{OPT})] \). The analysis of this fact will follow the same outline of Section 4, relying on LP duality, but with a twist.

For our dual fitting, we use the same dual solution as in Section 4. However, this time this dual solution will only be feasible in expectation, in the following sense. Since we now have \( q \notin \{0, 1\} \), Algorithm 1 is now a randomized algorithm, \( S \) is a random set, \( g^S \) is a random submodular function, and thus (D) is a random LP. Let \( \mathbb{E}[(D)] \) denote this LP, which is (D) with the submodular function \( g(T) := \mathbb{E}_S[g^S(T)] \). We now show that our dual solution’s expectation is feasible for \( \mathbb{E}[(D)] \).

Lemma 5.1. For \( q \in [1/(2C+1), 1/2] \), the expected dual solution \( (\mathbb{E}[\mu], \mathbb{E}[\bar{\phi}], \mathbb{E}[\bar{\lambda}]) \) is feasible for the expected LP \( \mathbb{E}[(D)] \).

Proof. The first set of constraints is satisfied for any realization of the randomness. Indeed, as in the proof of Lemma 4.1, for any realization of \( S \), by submodularity of \( f \), we have
\[
\sum_{e \in T} \lambda_e = \sum_{e \in T \setminus S} f(e : S) \geq \sum_{e \in T \setminus S} f_S(e) \geq f_S(T \setminus S) = f(S \cup T) - f(S) = g^S(T) - \mu.
\]
Consequently, taking expectation over \( S \), we have that indeed, \( \mathbb{E}_S[\mu] + \sum_{e \in T} \mathbb{E}_S[\lambda_e] \geq \mathbb{E}_S[g^S(T)] \).

We now turn to proving the second set of constraints, which will only hold in expectation.

Fix an edge \( e = e^{(t)} \), and define the event \( A_e := [f(e : S) \leq C \cdot \sum_{v \in V} \phi_v^{(t-1)}] \). Then, by definition of \( A_e \) and monotonicity of \( \phi_v^{(t)} \), we have that
\[
\mathbb{E} \left[ \sum_{e \in e} \phi_v \mid A_e \right] \geq \mathbb{E} \left[ C \cdot \sum_{v \in e} \phi_v^{(t-1)} \mid A_e \right] \geq \mathbb{E}[f(e : S) \mid A_e] = \mathbb{E}[\lambda_e \mid A_e]. \tag*{(2)}
\]

We now prove the same inequality holds when conditioning on the complement, \( \overline{A_e} \).
Fix a realization of the randomness $R$ for which $\overline{A_e}$ holds. Then, $e = e(t)$ fails the test in Line 6, and so with probability $q$, we have $\sum_{v \in e} \phi_v^{(t)} = \sum_{v \in e} \phi_v^{(t-1)} + w_e = 2 \cdot f(e : S) - \sum_{v \in e} \phi_v^{(t-1)}$, and with probability $(1 - q)$, we have $\sum_{v \in e} \phi_v^{(t)} = \sum_{v \in e} \phi_v^{(t-1)}$. Hence, in this case, as $q \leq \frac{1}{2}$, we have

$$\mathbb{E} \left[ \sum_{v \in e} \phi_v^{(t)} \bigg| R \right] = 2q \cdot f(e : S) + (1 - 2q) \cdot \sum_{v \in e} \phi_v^{(t-1)} \geq 2q \cdot f(e : S).$$

Now, since $\phi_v \geq C \cdot \phi_v^{(t)}$, and $q \geq 1/(2C + 1)$ and since $\lambda_e$ is set to $f(e : S)$ if $e$ is not added to $S$ (with probability $1 - q$) and set to zero otherwise, the above implies that

$$\mathbb{E} \left[ \sum_{v \in e} \phi_v \bigg| R \right] \geq 2qC \cdot f(e : S) \geq (1 - q) \cdot f(e : S) = \mathbb{E} [\lambda_e \big| R].$$

By the law of total expectation, taken over all $R \subseteq \overline{A_e}$, we have

$$\mathbb{E} \left[ \sum_{v \in e} \phi_v \bigg| \overline{A_e} \right] \geq \mathbb{E} [\lambda_e \big| \overline{A_e}]. \quad (3)$$

Combining inequalities (2) and (3) with the law of total expectation gives the desired inequality,

$$\mathbb{E} \left[ \sum_{v \in e} \phi_v \right] \geq \mathbb{E} [\lambda_e]. \quad \square$$

To bound the performance of this section’s randomized variant of Algorithm 1, we can reuse corollaries 4.3 and 4.4, since these follow from Lemma 4.1, which holds for every realization of the random choices of the algorithm. We now use these corollaries, LP duality and Lemma 5.1, together with Lemma 2.2, to analyze this algorithm.

**Theorem 5.2.** Algorithm 1 run with $q = 1/(2C + 1)$ and $C$ on a non-monotone MSM instance outputs a matching $M$ of value

$$\left( \frac{4C^2 - 1}{2C - 2} \right) \cdot f(M) \geq f(OPT).$$

This is optimized by taking $C = 1 + \frac{\sqrt{3}}{2}$, resulting in an approximation ratio of $4 + 2\sqrt{3} \approx 7.464$. Moreover, the same algorithm is $2C + C/(C - 1)$ approximate for monotone MSM.

**Proof.** First, by Lemma 4.3 and Lemma 4.4, for every realization of the algorithm, we have

$$\left( 2C + \frac{C}{C - 1} \right) \cdot f(M) \geq \sum_{v} \phi_v + \mu,$$

and thus this relationship holds in expectation as well.

$$\left( 2C + \frac{C}{C - 1} \right) \cdot \mathbb{E} [f(M)] \geq \mathbb{E} \left[ \sum_{v} \phi_v + \mu \right]. \quad (4)$$

10
On the other hand, by Lemma 5.1, the expected dual LP solution is feasible for $\mathbb{E}[(D)]$. Therefore, by weak LP duality, we have

$$\mathbb{E}\left[\sum_v \phi_v + \mu\right] \geq \max_T \mathbb{E}[g(T)] = \max_T \mathbb{E}[f(S \cup T)] \geq \mathbb{E}[f(S \cup \text{OPT})].$$ (5)

The result for monotone MSM follows from equations (4) and (5), together with monotonicity implying $\mathbb{E}[f(S \cup \text{OPT})] \geq f(\text{OPT})$.

For non-monotone MSM, let us define the additional auxiliary function $h : 2^E \to \mathbb{R}^+$, with $h(T) := h(\text{OPT} \cup T)$. Now note that by our sampling procedure, $S$ is a random subset of $E$ containing every edge with probability at most $q$. Hence, by Lemma 2.2, we have

$$\mathbb{E}[f(S \cup \text{OPT})] = \mathbb{E}[h(S)] \geq (1-q) \cdot h(\emptyset) = (1-q) \cdot f(\text{OPT}).$$ (6)

Combining equations (4), (5) and (6), together with our choice of $q = 1/(2C + 1)$, the desired inequality follows by rearranging terms. \qed

Having explored the use of Algorithm 1 for submodular matchings, we now turn to analyzing this algorithm in the context of streaming linear objectives.

6 Linear Objectives

In this section we address the use of Algorithm 1 to matching and b-matching with linear objectives, i.e., MWM and MWBM, using a deterministic variant, with $q = 1$.

For MWM, this algorithm with $C = 1 + \epsilon$ is essentially the algorithm of [55], and so it retrieves the state-of-the-art $(2 + \epsilon)$-approximation for this problem, previously analyzed in [29, 55]. We therefore focus on MWBM, for which a simple modification of Algorithm 1 yields a $3 + \epsilon$ approximation, improving upon the previous best $4 + \epsilon$ approximation due to [14].

The modification to Algorithm 1 which we consider is a natural one: instead of computing $M$ greedily, we simply compute an optimal MWBM $M$ in the subgraph induced by $S$, using a polytime linear-space offline algorithm (e.g., [5, 28]). Trivially, the b-matching $M$ has weight at least

$$w(M) \geq w(\text{OPT} \cap S).$$ (7)

Moreover, this b-matching has weight no lower than the greedily-constructed b-matching of lines 15-20. We use LP duality to show that this modified algorithm with $C = 1 + \epsilon$ outputs a b-matching $M$ of weight at least $w(M) \geq \frac{1}{2+\epsilon} \cdot w(\text{OPT} \setminus S)$.

Lemma 6.1. Let $M$ be a MWBM in the stack $S$ obtained by running Algorithm 1 with $C = 1 + \epsilon/2$ and $q = 1$ until Line 15. Then, we have $w(M) \geq \frac{1}{2+\epsilon} \cdot w(\text{OPT} \setminus S)$.

Proof. Consider the matching $M'$ obtained by greedily unwinding the stack, as in Algorithm 1. Clearly, $w(M) \geq w(M')$. So, by Lemma 4.3, we have $w(M) \geq \frac{1}{2+\epsilon} \cdot \sum_{v \in V} \phi_v$, for $\phi_v = C \cdot \phi_v^{(|E|)}$.

To relate $\sum_{v \in V} \phi_v$ to $w(\text{OPT})$, we show that the dual solution $(0, \phi, \bar{w})$ is dual feasible for the LP $(D)$ with function $w$.

The first set of constraints are trivially satisfied, due to linearity of $w$, as $0 + \sum_{e \in T} w_e = w(T)$. 

11
For the second set of constraints, note that an edge \( e = e(t) \) is not added to the stack if and only if the check at Line 6 fails. Therefore, since \( \phi_v^{(t)} \) values increase monotonically with \( t \), we have

\[
\sum_{v \in e} \phi_v = C \cdot \sum_{v \in e} \phi_v^{(0)} \geq C \cdot \sum_{v \in e} \phi_v^{(t-1)} \geq f(e : S) = w_e.
\]

Therefore, by weak LP duality, we have \( w(M) \geq 0 + \frac{1}{2 + \epsilon} \cdot \sum_{v \in V} \phi_v \geq \frac{1}{2 + \epsilon} \cdot w(OPT). \)

We are now ready to analyze the approximation ratio of this MWbM algorithm.

**Theorem 6.2.** For any \( \epsilon \geq 0 \), Algorithm 1 run with \( C = 1 + \epsilon/2 \) and \( q = 1 \) until Line 15, followed by a linear-space offline MWbM algorithm run on \( S \) to compute a solution \( M \) is a \((3 + \epsilon)\)-approximate streaming MWbM algorithm.

**Proof.** To see that this is a streaming algorithm, we recall that \( |S| = \tilde{O}(\sum_v b_v) \), by Lemma 3.1. Since we compute \( M \) by running an offline linear-space algorithm on the subgraph induced by \( S \), therefore using \( O(|S|) \) space for this last step, the desired space bound follows.

To analyze the algorithm’s approximation ratio, let \( \alpha \in [0, 1] \) be the weighted fraction of \( OPT \) in \( S \). That is, \( w(OPT \cap S) = \alpha \cdot w(OPT) \), and by linearity, \( w(OPT \setminus S) = (1 - \alpha) \cdot w(OPT) \). Therefore, by Equation (7) and Lemma 6.1 we have the following.

\[
w(M) \geq w(OPT \cap S) = \alpha \cdot w(OPT).
\]

\[
w(M) \geq \frac{1}{2 + \epsilon} \cdot w(OPT \setminus S) = \frac{1 - \alpha}{2 + \epsilon} \cdot w(OPT).
\]

We thus find that the approximation ratio of this algorithm is at most \( 1/\min\{\alpha, \frac{1 + \alpha}{2 + \epsilon}\} \leq 3 + \epsilon. \)

**Remark.** We note that this approach—dual covering constraints for elements outside of the algorithm’s memory \( S \), and solving the problem optimally for \( S \)—is rather general. In particular, it applies to matching under any sub-additive (not just submodular) set function \( f \), for which \( f(OPT) \leq f(OPT \setminus S) + f(OPT \cap S) \). Moreover, this approach extends beyond matchings, to any downward-closed constraints, for which \( OPT \setminus S \) and \( OPT \cap S \) are both feasible solutions. So, it seems like this approach could find applications to streaming algorithms for other objectives and constraints, provided dual feasibility can be guaranteed using a dual solution of value bounded by that of the output solution.

### 7 Lower Bound for MSM

Previous work shows that beating a \( \frac{\epsilon}{e - 1} \approx 1.582 \) approximation for MSM in the streaming model is impossible for quasilinear space bounded algorithms [40], or polytime bounded algorithms [17, 21, 48]. In this section, we show that assuming the exponential time hypothesis (ETH), whereby \( \text{NP} \notin \text{TIME}(2^{o(n)}) \) [39], beating 1.914 is impossible for any algorithm that is both space and time bounded. In particular, we will rely on seminal hardness of approximation results Set Cover from [17]. Recall:

**Definition 7.1.** A Set Cover instance consists of a set system \((U, S)\), with \( S \subseteq 2^U \). The goal is to pick the smallest number \( k \) of sets \( S_1, \ldots, S_k \) such that \( \bigcup_{i \in [k]} S_i = |U| \). We use \( K \) to denote the size of minimal cover for the instance \((U, S)\), and \( N = |U| + |S| \) to denote the description size.
Lemma 7.2 (Extension of Corollary 1.6 of [17]). Assuming ETH, every algorithm achieving an approximation ratio \((1 - \alpha) \ln |\mathcal{U}|\) for Set Cover runs in time strictly greater than \(2^{N^{\gamma}}\) for some \(\gamma > 0\). Furthermore, this holds even under the assumptions that \(|S| \leq K^{1/(\gamma \alpha)}\) and \(|\mathcal{U}| \leq |S|^{1/(\gamma \alpha)}\).

See Appendix D for a proof that the hardness holds even under the extra assumptions. To describe the instance, we will also use some extremal graph theory results from [30].

Definition 7.3. An \(\alpha\)-Ruzsa-Szemerédi graph (\(\alpha\)-RS graph) is a bipartite graph \(G = (P, Q, E)\) with \(|P| = |Q| = n\) that is a union of induced matchings of size exactly \(\alpha n\).

Theorem 7.4 (Lemma 53 of [30]). For any constant \(\epsilon > 0\), there exists a family of balanced bipartite \((1/2 - \epsilon)\)-RS graphs with \(n^{1+\Omega(1/\log \log n)}\) edges.

In what follows we will show a randomized reduction from Set Cover to streaming MSM. Specifically, we will show that if there is a polytime streaming algorithm for MSM achieving ratio better than 1.914, then there is an algorithm for Set Cover violating Lemma 7.2. We proceed to describing our reduction.

The Reduction. The input is a Set Cover instance \((\mathcal{U}, S)\) for which the minimal cover contains \(K\) sets. Fix \(n = 2^{k^{1/d}}\) for a degree \(d\) to be determined later.

We create an underlying bipartite graph \(G = (L, R, E)\) with \(n \log \log n\) vertices as follows. The left/right vertex sets are partitioned into \(L = P \cup P', R = Q \cup Q'\). We let \(|P| = |Q| = 2n\), and we let \(|P'| = |Q'| = n \cdot |S|/K\).

The edge set \(E\) arrives in two phases. In phase 1, all the edge of a set \(E_1\) arrive, in phase 2 the edges of \(E_2\) arrive. To define \(E_1\), let \(G_0\) be a fixed \((1/2 - \epsilon)\)-RS graph with \(m = \Omega (n^{1+1/\log \log n})\) edges between \(P\) and \(Q\), and let this graph be the union of the matchings \(M_1, \ldots, M_t\). Let \(M'_t\) be a random subset of \(M_t\) of size \((1/2 - \epsilon) n\) for a parameter \(\epsilon < \delta < 1/4\) and let \(E_1 = M'_1 \cup \ldots \cup M'_t\).

Choose one index \(r \in [k]\) uniformly at random, and call \(M'_t\) the distinguished matching. Note that the index \(r\) is unknown to the algorithm.

Define \(E_2\) as follows. Let \(P_1 \cup P_2 \cup \ldots \cup P_{n/K}\) and \(Q_1 \cup Q_2 \cup \ldots \cup Q_{n/K}\) be partitions of the vertices of \(P\) and \(Q\) respectively not matched by \(M_r\) into subsets of size \(K\). Similarly, let \(P'_1 \cup P'_2 \cup \ldots \cup P'_{n/K}\) and \(Q'_1 \cup Q'_2 \cup \ldots \cup Q'_{n/K}\) be partitions of \(P'\) and \(Q'\) into subsets of size \(|S|\).

Let \(F_i\) be the edges of the complete bipartite graph between \(P_i\) and \(Q'_i\), and let \(G_i\) be the edges of the complete bipartite graph between \(Q_i\) and \(P'_i\). Finally, set \(E_2 = \bigcup F_i \cup G_i\). See Figure 2.

It remains to describe the submodular function \(f\). First, define the set function \(f_1(E) = |E \cap E_1|\). Next, we define the function \(f_2\) which is parametrized by the Set Cover instance. We identify each set of vertices \(P'_i\) and \(Q'_i\) with a disjoint copy of \(S\). For every edge \(e \in E_2\), let \(\phi(e)\) denote the set with which the endpoint of \(e\) in \(P' \cup Q'\) is associated. Now, for some parameter \(\eta > 0\) to be determined later, we define

\[
f_2(E) := \frac{\eta K}{|\mathcal{U}|} \cdot \left| \bigcup_{e \in E} \phi(e) \right|.
\]

Finally, set \(f := f_1 + f_2\). Note that \(f\) is submodular since it the sum of a scaled coverage function and a linear function. On a technical note, since we assume that \(|\mathcal{U}|\) is polynomially bounded in \(|S|\), we can represent the values of this function with \(\log \log n\) bits.

Some intuition. Intuitively, we can imagine that all edges of \(E_1\) are worth 1. We imagine that each edge of \(E_2\) is a set in one of the copies of the instance \((S, \mathcal{U})\), and we let the value of all
Figure 2: Illustration of lower bound instance.

Red edges represent the edges of the distinguished matching \( M_r \) in \( E_1 \), purple edges represent other edges in \( E_1 \), green edges represent edges of \( E_2 \). The red and purple edges together form the \((1/2 - \epsilon)\)-RS graph \( G_0 \), subsampled.

edges selected in the second phase be the coverage of all the associated sets (scaled by \( \eta K/|U| \)).

First we will argue that the algorithm can output almost none of the edges of \( M'_r \), since it after phase 1 it has no information as to which matching is the distinguished one. Hence the majority of the edges it uses from phase 1 must be from \( E_1 \setminus M'_r \). However, each edge the algorithm chooses from \( E_1 \setminus M'_r \) precludes it from taking between 1 and 2 edges of \( E_2 \). Furthermore, maximizing the value of edges of \( E_2 \) amounts to solving a hard MAX \( k \)-COVER__ instance. The coverage is scaled by the parameter \( \eta \), and as a result, the algorithm is incentivized to take some \( k := cK \) edges from each of the bipartite graphs \((P_i, Q'_i)\) (and \((Q_i, P'_i)\)) of \( E_2 \) and the remaining edges from \( E_1 \setminus M'_r \). Meanwhile, \( OPT \) can take the distinguished matching edges \( M'_r \) as well as the edges of \( E_2 \) maximizing the coverage instance. Our bound will follow by setting \( \eta \) to maximize the ratio between these.

To start, we show that no streaming algorithm can “remember” more than a \( o(1) \) fraction of the edges of the distinguished matching \( M_r \). Since phase 1 of our construction is identical to the one in Appendix H of [30] which shows a \( 3/2 \) semi-streaming lower bound for max weight matching., we can reuse their result here.

**Lemma 7.5** (Appendix H.1 of [30]). For any constants \( \gamma, \delta \in (0, 1/4) \), let \( A \) be an algorithm that at the end of phase 1, with constant probability, outputs at least \( \gamma n \) of the the edges of \( M'_r \). Then \( A \) uses \( \Omega(E_1) \geq n^{1+\Omega(1/\log \log n)} \) bits of space.

We reproduce a version of the proof in Appendix D for completeness. With this, we are finally ready to prove the main theorem of the section.
Theorem 7.6. Assuming ETH, there exists a distribution over MSM instances such that any deterministic algorithm achieving an 1.914 approximation must use either $n^{1+\Omega(1/\log \log n)}$ space or $2^{(\log n)^{1+\epsilon}}$.

Proof. Our proof is a randomized polytime reduction from Set Cover to streaming MSM. We will show that if there is a randomized streaming algorithm achieving ratio better than 1.914 for MSM, then there is an algorithm for Set Cover achieving approximation ratio $(1 - \alpha) \ln(\lvert \mathcal{U} \rvert)$ for constant $\alpha > 0$ that only requires polynomial extra overhead. We then argue that Lemma 7.2 implies that the streaming MSM algorithm must run in super polynomial time, assuming ETH.

Fix a deterministic algorithm $A$ for streaming MSM. Now, given an instance of Set Cover $(\mathcal{U}, \mathcal{S})$ with minimum cover size $K$ and description size $N = |\mathcal{U}| + |\mathcal{S}|$, create a random instance of streaming MSM according to the reduction described in this section. For each bipartite graph $(P_i, Q_i')$ (or $(Q_i, P_i')$), if the algorithm $A$ chooses $cK$ edges from this graph, it can select at most $2(1 - c)K$ edges from $E_1$ that are adjacent to $P_i$ (or $Q_i$). Suppose WLOG that it can always achieve the $2(1 - c)K$ bound. In this case we can also assume WLOG the algorithm chooses the same number $c \cdot K$ of edges from each such graph, and furthermore that it selects the same sets in the set system $(\mathcal{S}, \mathcal{U})$. Otherwise it can locally improve its solution by copying the solution for the best index $i$.

Suppose this solution achieves coverage of $(1 - e^{-c} + \gamma) \cdot |\mathcal{U}|$. Since the matchings $M_1, \ldots, M_t$ are induced, and by Lemma 7.5 w.h.p. the algorithm can only output $o(n)$ edges of $M_i'$ after phase 1, the algorithm can only select $o(n)$ edges not incident to some $P_i$ or $Q_i$. Thus the total value achieved by the algorithm is at most:

$$\left[2(1 - e^{-c} + \gamma) \cdot \eta \cdot K + 2(1 - c) \cdot K\right] \cdot \frac{n}{K} + o(n)$$

$$\leq 2(1 - e^{-c} + \gamma) \cdot \eta n + 2(1 - c) \cdot n + o(n)$$

$$\leq (2\eta - 2\ln(\eta) + 2\gamma) \cdot n + o(n),$$

where the last step follows since the expression is maximized at $c = \ln \eta$. On the other hand, the optimal solution can select the distinguished matching edge $M_i''$, as well as $K$ edges adjacent to each set $P_i$ corresponding to the minimum Set Cover solution. Thus the total value of $OPT$ is at least:

$$(1 - \delta + 2\eta) \cdot n.$$

Thus the ratio between the maximum value achievable by the algorithm and the optimal value is bounded by:

$$\frac{1 + 2\eta - \delta}{2\eta - 2\ln(\eta) + 2\gamma + o(1)}.$$

Finally, we set $\eta = 2.09$ and let $\delta \to 0$. If this ratio converges to a value strictly below 1.914, then we can conclude that $\gamma = \Omega(1)$ and $\gamma > 0$.

We have shown that $A$ can be used to pick $cK$ sets with coverage $(1 - e^{-c} + \gamma) \cdot |\mathcal{U}|$. To finish the proof, we now show that this can be used to recover an approximation algorithm $B$ for Set Cover. For convenience, set constant $\gamma'$ such that $(1 - e^{-c - \gamma'}) := (1 - e^{-c} + \gamma)$. Then, guess $K$, and repeat algorithm $A$ recursively $\lceil \ln |\mathcal{U}|/(c + \gamma') \rceil \leq \ln |\mathcal{U}|/(c + \gamma') + 1$ times, each time on the residual uncovered set system. Each call to $A$ covers $(1 - e^{-c - \gamma'})$ of the elements remaining, so after this number of iterations, the fraction of uncovered elements is less than $1/|\mathcal{U}|$, i.e. all elements are
therefore follows from Theorem 1.2 and Yao’s minimax principle \[7.6\] show that their algorithms also work more broadly for \(k\)-matchoid and \(k\)-set system constraints.

In [12], Chakrabarti and Kale presented a reduction from MSM to MWM, by showing how to use a subclass of MSM algorithms to solve MSM. We now introduce the algorithm of [12] instantiated with the MWM algorithm of McGregor [49]. The algorithm is a natural and elegant one: when an edge \(e\) arrives, we consider its marginal gain with respect to the current matching. If this marginal gain is higher than some slack parameter \(C\) times the marginal gains of the currently blocking edges \(e' \in N(e) \cap M\), we preempt those edges and add \(e\) to the matching.

In anticipation of our analysis of the algorithm of [23] in Appendix A.2, we generalize the algorithm’s description and allow the algorithm to preempt with some probability \(q \in [0, 1]\). The full pseudo-code is given in Algorithm 2.

This algorithm only ever adds an edge \(e\) to \(M\) upon its arrival. After adding an edge to \(M\), this edge can be preempted, i.e., removed from \(M\), after which it is never added back to \(M\). Thus we note that this algorithm is not only a streaming algorithm, but also a so-called preemptive algorithm: it only stores a single matching in memory and therefore trivially requires \(\tilde{O}(n)\) space.

For convenience, we let \(M^{(t)}\) denote the matching \(M\) at time \(t\), and let \(S := \bigcup_{t} M^{(t)}\) denote the set of edges ever added to \(M\). For an edge \(e\) let \(B^{(t)}(e) = \sum_{e' \in N(e) \cap M^{(t)}} f(e') : M^{(t)}\). We will also denote by \(P := S \setminus M\) the set of preempted edges.

### A.1 The Framework of [12], Applied to the Algorithm of [49]

In this section we analyze the deterministic algorithm obtained by applying the framework of Chakrabarti and Kale [12] to the MWM algorithm of McGregor [49], corresponding to Algorithm 2 run with \(q = 1\).

To argue about the approximation ratio, we will again fit a dual solution to this algorithm. Define the auxiliary submodular functions \(g^S : 2^S \to \mathbb{R}^+\) to be \(g^S(T) := f(S \cup T)\). Similarly to our
Algorithm 2 The MSM Algorithm of [12] and [23]

**Initialization**
1: $M \leftarrow \emptyset$

**Loop**
2: for $t \in \{1, \ldots, |E|\}$ do
3: $e \leftarrow e^{(t)}$
4: $B(e) \leftarrow \sum_{e' \in N(e) \cap M} f(e' : M)$
5: if $f(e : M) \leq C \cdot B(e)$ then
6: continue ⊲ skip edge $e$
7: else
8: with probability $q$ do
9: $M \leftarrow (M \setminus N(e)) \cup \{e\}$
10: return $M$

analysis of Algorithm 1, we define the following dual.

$\mu := f(S) = g^S(\emptyset)$,

$\phi_v := C \cdot \max\{f(e : M^{(t)}) \mid t \in [|E|], \ v \in e \in M^{(t)}\}$,

$\lambda_e := \begin{cases} 
    f(e : S) & e \notin S \\
    0 & e \in S.
\end{cases}$

Note the difference here in the setting of $\phi_v$ from the algorithms of Sections 4 and 5. We start by showing that this is a dual feasible solution to the LP (D) for the function $g^S$.

**Lemma A.1.** The dual solution $(\vec{\lambda}, \vec{\phi}, \mu)$ is feasible for the LP (D) with function $g^S$.

**Proof.** To see that the first set of constraints are satisfied, note that by submodularity of $f$,

$$\sum_{e \in T} \lambda_e = \sum_{e \in T \setminus S} f(e : S) \geq \sum_{e \in T \setminus S} f_S(e) \geq f_S(T \setminus S) = f(S \cup T) - f(S) = g^S(T) - \mu.$$ 

For the second set of constraints, we note that if $e = e^{(t)} \notin S$, then by the test in Line 5 and submodularity, we have that

$$\lambda_e = f(e : S) \leq f(e : M^{(t-1)}) \leq C \cdot B^{(t-1)}(e) \leq \sum_{v \in e} \phi_v.$$

It remains to relate the value of the solution $M$ to the cost of this dual. For this, we introduce the following useful notation. For any edge $e \in S$, we define the weight of $e$ to be

$$w_e := \begin{cases} 
    f(e : M) & e \in M \\
    f(e : M^{(t)}) & e \in M^{(t-1)} \setminus M^{(t)} \subseteq P.
\end{cases}$$

In words, the weight of an edge in the matching is $f(e : M)$, and the weight of a preempted edge is frozen to its last value before the edge was preempted. One simple consequence of the definition of the weights $w_e$ is the following relationship to $f(M)$. 

17
Observation A.2. \( f(M) = \sum_{e \in M} f(e : M) = \sum_{e \in M} w_e = w(M) \).

We now show that the preempted edges’ weight is bounded in terms of the weight of \( M \).

Lemma A.3. The weights of \( P \) and \( M \) satisfy \( w(P) \leq w(M) \cdot \frac{1}{C-1} \).

Proof. For any edge \( e \), we define the following set of preempted edges which are preempted in favor of \( e \) or in favor of an edge (recursively) preempted due to \( e \). First, for an edge \( e = e^{(t)} \), we let the set \( P^1(e) := N(e) \cap M^{[t-1]} \) denote the edges preempted when \( e \) is added to \( M \). For any \( i \geq 1 \), we let \( P^i(e) := P^1(P^{i-1}(e)) \) be the set of edges preempted by an edge with a trail of preemptions of length \( i - 1 \) from \( e \). By Line 6, we have that any edge \( e \in S \) has weight at least \( w_e \geq C \cdot P^1(e) \). By induction, this implies that \( w_e \geq C \cdot w(P^{(i-1)}(e)) \geq C^i \cdot w(P^i(e)) \). Now, since each preempted edge \( e' \in P \) belongs to precisely one set \( P^i(e) \) for some \( i \geq 1 \) and \( e \in M \), we find that indeed,

\[
  w(P) = \sum_{e \in M} \sum_{i \geq 1} w(P^i(e)) \leq \sum_{e \in M} \sum_{i \geq 1} \frac{1}{C^i} \cdot w_e = w(M) \cdot \left( \frac{1}{C} + \frac{1}{C^2} + \frac{1}{C^3} + \ldots \right) = w(M) \cdot \frac{1}{C-1}. \quad \square
\]

Using Lemma A.3, we can now relate the value of the primal solution \( M \) to the cost of the dual solution, \( \mu + \sum_v \phi_v \). We start by bounding \( \mu \) in terms of \( f(M) \).

Lemma A.4. The matching \( M \) output by Algorithm 2 satisfies \( f(M) \geq (1 - \frac{1}{C}) \cdot \mu \).

Proof. By submodularity of \( f \), Lemma A.3, and Observation A.2 we obtain the desired inequality,

\[
  \mu = f(S) = f(M \cup P) \leq f(M) + \sum_{e \in P} f(e : M) = w(M) + w(P) \leq \left( 1 + \frac{1}{C-1} \right) \cdot f(M). \quad \square
\]

We next bound \( \sum_v \phi_v \) in terms of \( f(M) \).

Lemma A.5. The matching \( M \) output by Algorithm 2 run with \( C > 1 \) satisfies

\[
  f(M) \geq \frac{1}{2C + C/(C-1)} \cdot \sum_{v \in V} \phi_v.
\]

Proof. Fix a vertex \( v \) and edge \( e \in M^{(t-1)} \setminus M^{(t)} \subseteq P \) preempted at time \( t \) in favor of edge \( e' = e^{(t)} \ni v \). For this edge \( e \), by monotonicity in \( t' \) of \( f(e' : M^{(t')}) \), the test of Line 5, non-negativity of \( f(e'' : M^{(t-1)}) \) for any edge \( e'' \in M^{(t-1)} \) and \( C > 1 \) we have that

\[
  w_{e'} \geq f(e' : M^{(t-1)}) \geq C \cdot B^{(t-1)}(e') \geq C \cdot f(e : M^{(t-1)}) = C \cdot w_e > w_e.
\]

Consequently, again relying on monotonicity in \( t' \) of \( f(e' : M^{(t')}) \), we have that for any edge \( e \in P \), there is at most one vertex \( v \in e \) such that \( w_e = f(e : M^{(t-1)}) \) is equal to \( \phi_v = \max\{f(e' : M^{(t')}) \mid v \in e' \in M^{(t')}\} \). Edges \( e \in M \), on the other hand, clearly have \( w_e = f(e : M) \) equal to \( \phi_v = \max\{f(e' : M^{(t-1)}) \mid v \in e' \in M^{(t-1)} \setminus M^{(t)}\} \) for at most two vertices \( v \in e \). Combined with Lemma A.3 and Observation A.2, this yields the desired inequality,

\[
  \sum_{v \in V} \phi_v \leq C \cdot \left( 2 \sum_{e \in M} w_e + \sum_{e \in P} w_e \right) \leq \left( 2C + \frac{C}{C-1} \right) \cdot w(M) = \left( 2C + \frac{C}{C-1} \right) \cdot f(M). \quad \square
\]

\(^4\)In [22, 49], these sets are referred to by the somewhat morbid term “trail of the dead”.

18
Equipped with the above lemmas, we can now analyze Algorithm 2’s approximation ratio.

**Theorem A.6.** Algorithm 1 run with $C > 1$ and $q = 1$ on a monotone MSM instance outputs a matching $M$ of value
\[
\left(2C + \frac{2C}{C - 1}\right) \cdot f(M) \geq f(OPT).
\]
This is optimized by taking $C = 2$, resulting in an approximation ratio of 8.

**Proof.** By weak LP duality and Lemma A.1, together with monotonicity of $f$, we have that
\[
C \cdot \sum_v \phi_v + \mu \geq \max_T g^S(T) = \max_T f(S \cup T) \geq f(S \cup OPT) \geq f(OPT).
\]
Combining Lemma A.5 and $f(M) = \mu$ by definition and rearranging, we get the desired inequality,
\[
\left(2C + \frac{2C}{C - 1}\right) \cdot f(M) \geq C \cdot \sum_v \phi_v + \mu \geq f(OPT).
\]

As with our algorithm of Section 4, our analysis of Algorithm 2 relied on monotonicity, crucially using $f(S \cup OPT) \geq f(OPT)$. To extend this algorithm to non-monotone MSM, we again appeal to Lemma 2.2, setting $q = \frac{1}{2C + 1}$. This is precisely the algorithm of Feldman et al. [23], which we analyze in the following section.

### A.2 The Algorithm of Feldman et al. [23]

In [23], Feldman et al. showed how to generalize the algorithm of [12] to non-monotone function maximization. Here we show an analysis of their algorithm in our primal dual framework. Our proof is an extension of the one in Appendix A.1 in a way that is analogous to how Section 5 extends Section 4.

We reuse the same dual from Appendix A.1, only this time, both our dual object and the function $g^S$ are random variables. The proof of expected dual feasibility for this variant of the algorithm of Appendix A.1 is analogous to that of Lemma 5.1, so we only outline the differences here.

We start with expected feasibility.

**Lemma A.7.** The dual solution $(E[\lambda], E[\phi], E[\mu])$ is feasible for the expected LP $E[(D)]$.

**Proof (Sketch).** The first set of constraints is satisfied for any random realization. Indeed, as in the proof of Lemma A.1, for any realization of $S$, by submodularity of $f$, we have
\[
\sum_{e \in T} \lambda_e = \sum_{e \in T \setminus S} f(e : S) \geq \sum_{e \in T \setminus S} f_S(e) \geq f_S(T \setminus S) = f(S \cup T) - f(S) = g^S(T) - \mu.
\]
Consequently, taking expectation over $S$, we have that indeed, $E_S[\mu] + \sum_{e \in T} E_S[\lambda_e] \geq E_S[g^S(T)]$.

For the second set of constraints, the proof is nearly identical to that of Lemma 5.1, where we show that
\[
E\left[\sum_{v \in e} \phi_v\right] \geq E[\lambda_e].
\]
This is proved by taking total probability over the event \( A_e := \{ f(e : S) \leq C \cdot \sum_{v \in V} \phi_v^{(t-1)} \} \) and its complement. The key inequality to prove here is that for any realization of randomness \( R \) for which \( A_e \) holds, we have that

\[
\mathbb{E} \left[ \sum_{v \in e} \phi_v^{(t)} \right| R \right] = 2q \cdot f(e : S) + (1 - 2q) \cdot \sum_{v \in e} \phi_v^{(t-1)} \geq 2q \cdot f(e : S).
\]

And indeed, conditioned on \( R \), the edge \( e = e^{(t)} \) fails the test in Line 5, and so with probability \( q \), we have \( \sum_{v \in e} \phi_v^{(t)} = 2 \cdot f(e : S) \). To see this, note that if \( e \) is added to the matching, then for both \( v \in e \), by definition \( \phi_v^{(t)} \) must be at least \( f(e : S) \). Hence, in this case

\[
\mathbb{E} \left[ \sum_{v \in e} \phi_v^{(t)} \right| R \right] \geq 2q \cdot f(e : S).
\]

The proof then proceeds as that of Lemma 5.1.

To relate the value of the solution \( M \) to the cost of the dual, we can define weights as in Appendix A.1 and reuse lemmas A.3, A.4, and A.5, which hold for every realization of the random choices of the algorithm. From here, following our template, we can use these along with LP duality, Lemma A.7 and Lemma 2.2, to analyze this algorithm.

**Theorem A.8.** Algorithm 2 run with \( q = 1/(2C + 1) \) and \( C \) on a non-monotone MSM instance outputs a matching \( M \) of value

\[
\left( \frac{2C^2 + C}{C - 1} \right) \cdot f(M) \geq f(OPT).
\]

This is optimized by taking \( C = 1 + \sqrt{3} \), resulting in an approximation ratio of \( 5 + 2\sqrt{6} \approx 9.899 \). Moreover, the same algorithm is \( 2C + 2C/(C - 1) \) approximate for monotone MSM, yielding an approximation ratio of 8 for \( C = 2 \).

### B Tight instance for Algorithm 1

In this section we show that there exists a family of instances of MSM instances parametrized by \( C \) for which Algorithm 1 with parameter \( C > 1 \) yields an approximation factor of \( 2C + C/(C - 1) \).

**Lemma B.1.** The approximation ratio of Algorithm 1 with \( C > 1 \) and \( q = 1 \) for monotone MSM is at least \( 2C + \frac{C}{C - 1} \).

**Proof.** Define the graph \( G \) as follows. The vertex set \( V(G) \) consists of \( \{x_i, y_i\}_{i \in [0, n]} \). For convenience, for every \( i \in [1, n] \) we define the edges \( d_i = (x_0, x_i) \) and \( e_i = (x_i, y_i) \). Then the edge set \( E(G) \) consists of the edges \( \{d_i\}_{i=1}^{n} \cup \{e_i\}_{i=2}^{n} \).

To define the (monotone) submodular function, we first define an auxiliary weight function \( w : E(G) \to \mathbb{R}_{\geq 0} \). The weights are:

\[
\begin{align*}
w(d_i) &= C^{i-1} \\
w(e_1) &= 1 + C - \epsilon \\
w(e_i) &= C^i - \epsilon \\
w(e_0) &= C^n - \epsilon
\end{align*}
\]

\( (n \geq i \geq 1) \)

\( (n \geq i \geq 2) \)
Now the submodular function is:

$$f(T) := w(T \cap \{e_0\}) + \sum_{i=0}^{n} \min(w(T \cap \{d_i, e_i\}), w(e_i))$$

Since weights are non-negative, this function is monotone. Submodularity follows from preservation of submodularity under linear combinations (and in particular sums), and $$\min\{w(S), X\}$$ being submodular for any linear function $w$.

The stream reveals the edges $d_1, \ldots, d_n$ in order, and subsequently reveals $e_0, e_1, \ldots, e_n$ in order. For a run of Algorithm 1 with this choice of $C$ and $q = 1$, several claims hold inductively:

(a) On the arrival of edge $d_i$, we have $\phi_{x_0} = C^{i-2}$ (except for the arrival of $d_1$, at which point $\phi_0 = 0$) and $\phi_{x_i} = 0$.

(b) The algorithm takes every edge $d_i$ into the stack.

(c) After $d_i$ is taken into the stack, we have $\phi_{x_0} = C^{i-1}$ and $\phi_{x_i} = C^{i-1} + C^{i-2}$ (except for $\phi_{x_1}$ which is set to 1).

(d) The algorithm does not take $e_i$ into the stack.

Let $\Lambda_t$ be the statement that these claims holds for time $t$. By inspection $\Lambda_1$ holds, now consider some time $i > 1$. Claim (a) follows directly from claim (c) of $\Lambda_{i-1}$. Claim (b) follows from (a) since $f_S(d_i) = C^{i-1} = C \cdot \phi_0$ when $d_i$ arrives. Claim (c) is a consequence of how the algorithm increases the potentials $\phi$ when taking edges into the stack. Claim (d) holds since $f_S(e_i) = w(e_i) - w(d_i) = C^i - C^{i-1} - \epsilon < C \cdot \phi_{x_i}$.

From the above, we find that Algorithm 1 with parameter $C$ as above and $q = 1$ will have all edges $d_1, \ldots, d_n$ in its stack by the end, resulting in it outputting the matching consisting of the single edge $d_n$. The value of this edge (and hence this matching) is $C^{n-1}$, while on the other hand $OPT$ can take the edges $\{e_i\}_{i=0}^{n}$, which have value

$$\sum_{i=0}^{n} w(e_i) = C^n + \sum_{i=0}^{n} C^i - \epsilon(n + 1) \rightarrow C^{n-1} \left(2C + \frac{C}{C-1}\right) \quad \text{(as } n \rightarrow \infty \text{ and } \epsilon \rightarrow 0)$$

so long as $C > 1$. Hence $c(OPT)/c(ALG) \rightarrow 2C + C/(C-1)$. The lemma follows.
C  Space Bound of Algorithm 1

In this section we bound the space usage of Algorithm 1, as restated in the following lemma.

Lemma 3.1. For any constant $\epsilon > 0$, Algorithm 1 run with $C = 1 + \epsilon$ uses $\tilde{O}(\sum_v b_v)$ space.

Proof. Fix a vertex $v \in V$. If an edge $e \ni v$ is added to $S$ at time $t$, then by the test in Line 6, $f(e : S) \geq (1 + \epsilon) \cdot \sum_{u \in e} \phi_u^{(t-1)}$. Consequently, and since $\phi$ values are easily seen to always be positive, we have

$$\phi_v^{(t)} - \phi_v^{(t-1)} = w_{ev}' = \frac{f(e : S) - \sum_{u \in e} \phi_u^{(t-1)}}{b_v} \geq \frac{\epsilon \cdot \sum_{u \in e} \phi_u^{(t-1)}}{b_v} \geq \frac{\epsilon \cdot \phi_v^{(t-1)}}{b_v}.$$  

Thus, adding this edge $e \ni v$ to $S$ results in $\phi_v^{(t)} \geq \phi_v^{(t-1)} \cdot (1 + \epsilon / b_v)$. Moreover, if $e$ is the first edge of $v$ added to $S$, then, letting $f_{min} := \min \{f(e : S) \neq 0 \mid e \in E, S \subseteq E\}$ be the minimum non-zero marginal gain, we have

$$\phi_v^{(t)} = \frac{f(e : S) - \sum_{u \in e} \phi_u^{(t-1)}}{b_v} \geq \frac{(\epsilon / (1 + \epsilon)) \cdot f(e : S)}{b_v} \geq \frac{(\epsilon / (1 + \epsilon)) \cdot f_{min}}{b_v}.$$  

Therefore, if $v$ had $k$ edges added to the stack by time $t$, then

$$\phi_v^{(t)} \geq (\epsilon / (1 + \epsilon)) \cdot (f_{\text{min}} / b_v) \cdot (1 + \epsilon / b_v)^{k-1}. \tag{8}$$  

On the other hand, since $f$ is polynomially bounded, we have that for some constant $d$

$$\phi_v^{(t)} \leq \sum_{e \ni v} f_{S_v}(e) / b_v \leq n^d \cdot (f_{\text{min}} / b_v). \tag{9}$$  

Combining equations (8) and (9) and simplifying, we find that $(1 + \epsilon / b_v)^{k-1} \leq n^d \cdot (1 + \epsilon) / \epsilon$. Taking out logarithms and simplifying further, we find that

$$k \leq 1 + \frac{d \log n + \log(1 + \epsilon) + \log(1 / \epsilon)}{\log(1 + \epsilon / b_v)} = O((b_v / \epsilon) \cdot (\log n + \log(1 / \epsilon))) = \tilde{O}(b_v).$$  

That is, the number of edges of $v$ in the stack is at most $\tilde{O}(b_v)$. Since each edge requires only $O(\log n)$ bits of space (and the $\phi_v$ variables can be specified using $O(\log n)$ bits each), the algorithm’s space usage is indeed at most $\tilde{O}(\sum_v b_v)$.

D  Deferred Proofs of Section 7

Lemma 7.2 (Extension of Corollary 1.6 of [17]). Assuming ETH, every algorithm achieving an approximation ratio $(1 - \alpha) \ln |U|$ for Set Cover runs in time strictly greater than $2^{N^{\gamma\alpha}}$ for some $\gamma > 0$. Furthermore, this holds even under the assumptions that $|S| \leq K^{1/(\gamma\alpha)}$ and $|U| \leq |S|^{1/(\gamma\alpha)}$.

Proof. The first statement is precisely Corollary 1.6 of [17].

For the extra assumptions, if $K < |S|^{\gamma\alpha}$ then the brute force algorithm that checks all subsets of size $K$ runs in time $|S|^K < 2^{|S|^{\gamma\alpha}) \log |S| \leq 2^{N^{\gamma\alpha}}$. If $|S| < |U|^{\gamma\alpha}$, then one can brute force over all subcollections of $S$ in time $2^{|S| \alpha} \leq 2^{|U|^{\gamma\alpha}} \leq 2^{N^{\gamma\alpha}}$. Both running times contradict Lemma 7.2.  \(\Box\)
Lemma 7.5 (Appendix H.1 of [30]). For any constants $\gamma, \delta \in (0, 1/4)$, let $A$ be an algorithm that at the end of phase 1, with constant probability, outputs at least $\gamma n$ of the the edges of $M'_r$. Then $A$ uses $\Omega(E_1) \geq n^{1+\Omega(1/\log\log n)}$ bits of space.

Proof. Let $A$ be an algorithm that outputs $\gamma n$ of the edges of $M'_r$ at the end of phase 1 that uses fewer than $s = n \text{poly log } n$ bits. We will show that $\gamma = o(1)$.

Let $G$ be the set of possible first phase graphs. Then $|G| = (n/2^\delta)^t = 2^{\gamma m}$ for some $\gamma > 0$. Let $\phi : G \to \{0, 1\}^s$ be the function that takes an input graph $G$ to the state of the algorithm $A$ after running $A$ on $G$. Let $\Gamma(G) = \{H | \phi(G) = \phi(H)\}$, that is the set of graphs inducing the same internal state for $A$ at the end of phase 1.

Define $\Psi(G) = \bigcap_{H \in \Gamma(G)} E(H)$. Note that for any input graph $G$, the algorithm $A$ can output an edge $e$ if and only if $e \in \Psi(G)$. Also, for any $G$ let $t'$ be the number of matchings in the RS graph $G_0$ for which $\Psi(G)$ contains at least $\gamma n$ edges. Since algorithm $A$ outputs $\gamma n$ edges of $M'_r$, the number of graphs in $\Gamma(G)$ is bounded by

$$\left((1/2 - \gamma)n \delta \right)^t \left(\frac{n/2}{\delta n}\right)^{t-t'} \left(2^{-\Omega(\gamma m)}\left(\frac{n/2}{\delta n}\right)^t \left(\frac{n/2}{\delta n}\right)^{t-t'} = 2^{-\Omega(t'\gamma n)}2^{\gamma m} \quad (\ast)\right.$$

On the other hand, since the first phase graph $G$ is chosen uniformly at random, by a counting argument, with probability at least $1 - o(1)$ we have that $|\Gamma(G)| \geq 2^{(\gamma - o(1))m}$. Conditioning on this happening, we also know that $t' \geq \Omega(t)$ since the input graph is uniformly chosen within $\Gamma(G)$, and the algorithm succeeds with constant probability. These two facts together with $(\ast)$ imply that $\gamma = o(1)$. \hfill \Box
