Abstract

Fragment embedding is one way to circumvent the high computational scaling of accurate electron correlation methods. The challenge of applying fragment embedding to molecular systems primarily lies in the strong entanglement and correlation that prevent accurate fragmentation across chemical bonds. Recently, Schmidt decomposition has been shown effective for embedding fragments that are strongly coupled to a bath in several model systems. In this work, we extend a recently developed quantum embedding scheme, bootstrap embedding (BE), to molecular systems. The resulting method utilizes the matching conditions naturally arising from using overlapping fragments to optimize the embedding. Numerical simulation suggests that the accuracy of the embedding improves rapidly with fragment size for small molecules, whereas larger fragments that include orbitals from different atoms may be needed for larger molecules. BE scales linearly with system size (apart from an integral transform) and hence can potentially be useful for large-scale calculations.

1 Introduction

When applying standard electronic structure methods to study realistic systems, one usually needs to compromise between cost and accuracy. On the one hand, lower-level, mean-field approximations such as Hartree-Fock\(^1,2\) (HF) have modest computational scaling but are insufficiently accurate due to lack of electron correlation. On the other hand, higher-level, correlated wave function methods such as coupled cluster\(^3,4\) (CC), density matrix renormalization group\(^5–8\) (DMRG), and full configuration interaction\(^2\) (FCI) are capable of making reasonable predictions related to experiments\(^9–16\) but are limited to small systems owing to their high computational cost.

One way to circumvent the steep computational scaling of accurate electron correlation methods is fragment embedding. The main motivation of fragment embedding is that electron correlation is local; hence, it is possible to treat the full system in a divide-and-conquer approach. Specifically, the full system is partitioned into smaller fragments, each made to interact with an effective bath constructed to approximate the rest of the system (i.e., the environment). The computationally involved, high-level theories are required only for each individual fragment but never for the full system, which leads to reduced computational scaling. Different research groups have successfully developed and applied fragmentation methods in various contexts, each focusing on a different embedding variable, including localized orbitals,\(^17–20\) electron density,\(^21–26\) density matrix,\(^27–29\) and Green’s function,\(^30–35\) to name a few.

Applying fragment embedding to a general molecular system is not a trivial problem. The main difficulty lies in the proper description of the strong entanglement and correlation between fragments and baths arising from cutting chemical bonds. Schmidt decomposition\(^36–39\) has recently been used for embedding fragments that are strongly coupled to a bath. The central idea of Schmidt decomposition is to project the
environment associated with a fragment to a small set of local states that have non-vanishing entanglement with that fragment. This projection naturally preserves the entanglement between fragments and baths and reduces the dimension of the problem simultaneously.

Although the general formulation has been known for a long time (especially in the quantum information community\textsuperscript{40–42}), it was not until recently that Knizia and Chan have recognized Schmidt decomposition as a key ingredient in fragment embedding in their method called density matrix embedding theory\textsuperscript{43,44} (DMET). In DMET, the fragment is embedded in a mean-field bath constructed by Schmidt decomposing the HF wave function of the full system. The embedded fragment and bath, which are a small subspace of the full system, is then solved using the aforementioned high-level theories. In order to optimize the mean-field bath, the fragment-fragment block of the one-particle density matrix (1PDM) of the mean-field bath is made to match that of the high-level calculation by a self-consistently determined one-electron effective potential. Good performance has been reported for model Hamiltonians\textsuperscript{43,45,46} and atomic rings/chains.\textsuperscript{44} DMET was originally proposed as a simplification to the more complicated dynamical mean-field theory\textsuperscript{30–32} (DMFT) but was soon recognized by the community as a new wave function-in-wave function embedding theory. Extensions of the original DMET include modified matching conditions,\textsuperscript{47–51} use of more accurate baths\textsuperscript{45,52,53} and other impurity solvers,\textsuperscript{54} time-dependent formulation\textsuperscript{55,56} and low-lying excited states,\textsuperscript{57} as well as application to simple solids.\textsuperscript{48}

One of the main problems with DMET – as with many other fragment embedding methods – is the need to divide the system into fixed non-overlapping fragments.\textsuperscript{58} This prescription leads to the inaccurate description of the edges (surface) of the fragment and their interaction with the bath. To that end, Welborn et al. propose an alternative to DMET called bootstrap embedding\textsuperscript{59} (BE) that explores the matching conditions arising from using overlapping fragments to reduce the surface error. When fragments overlap, the overlapping region will be more accurately described in some fragment than in others if it is the center (i.e., most embedded region) as opposed to the edge (i.e., least embedded region) of that fragment. BE improves the description of the edge sites of a fragment by requiring their density matrix elements to match the fragments where those sites are center. These matching conditions provide an internally consistent formulation of fragment embedding, and hence lead to faster convergence compared to DMET on Hubbard model.\textsuperscript{59}

The application of BE to molecules is still challenging. In simple model systems such as the 1D Hubbard model,\textsuperscript{60} the inter-site connectivity is clear, along with the distinction between edge and center sites for a given fragment. This is not the case, however, for the \textit{ab initio} Hamiltonian of a general chemical system. As demonstrated by Ricke and co-workers in the context of 2D Hubbard model with long-range interaction, the optimal choice of the center and edge sites is not always intuitive.\textsuperscript{61} Other attempts have also been made recently by Ye et al. in incremental embedding (IE), where the calculations of all fragments of certain size are combined carefully through an incremental scheme;\textsuperscript{62} fast convergence with fragment size is observed for small molecules, but at the price of a higher computational scaling.\textsuperscript{62}

In this paper, we present an extension of BE to arbitrary molecular systems. Here, the key idea is to properly define the connectivity between orbitals and generalize the BE matching conditions to arbitrary connectivity. We present proof-of-concept calculations for several molecules using atom-centered Gaussian orbitals. Numerical results suggest that BE shows good convergence with fragment size for the correlation energy of small molecules at equilibrium geometry, and also delivers smooth energy curves for dissociating single and double covalent bonds. For large molecules, we observe that BE converges slowly with fragment size and over-estimates the all-electron correlation energy for the largest fragment size we are able to test. This is attributed to the lack of inter-atomic fragment overlapping based on
an active-space calculation on the same set of molecules. Nevertheless, the computation time of BE scales linearly with system size (apart from an integral transform) and hence is a promising method for large systems.

This paper is organized as follows. In Sec. 2, we briefly review the theory of BE, and then present how it can be generalized to treat arbitrary Hamiltonians. In Sec. 3, we present the computational details. In Sec. 4, we present numerical results and discussion on several molecules as a proof of concept. In Sec. 5, we conclude this work by pointing out several future directions.

2 Theory

In this section, we first give a brief review of Schmidt decomposition as well as BE in the context of lattice models, with an emphasis on the matching conditions that naturally arise from using overlapping fragments. Then, we present how BE can be generalized to an arbitrary Hamiltonian assuming we know the connectivity between sites. Finally, we end this section by introducing a heuristic scheme of determining the inter-site connectivity for molecules.

Throughout this work, we assume our system is described by the following second-quantized Hamiltonian,

$$
\hat{H} = \sum_{\mu\nu} \hbar_{\mu\nu} c_\mu^\dagger c_\nu + \sum_{\mu\nu\lambda\sigma} V_{\mu\nu\lambda\sigma} c_\mu^\dagger c_\lambda^\dagger c_\sigma c_\nu,
$$

in some discrete basis of size $N_{\text{basis}}$.

2.1 Schmidt decomposition

The general theory of Schmidt decomposition can be found in literature.\(^{38,39}\) Here, we review its application in DMET-related fragment embedding methods.

Suppose we partition our system into two parts, the fragment (which we assume to be of smaller size) and the environment, such that the Hilbert space observes the same decomposition, $\mathcal{H} = \mathcal{H}_f \otimes \mathcal{H}_e$. Then any state $|\Psi\rangle \in \mathcal{H}$ has the following tensor factorization,

$$
|\Psi\rangle = \sum_p \lambda_p |f_p\rangle \otimes |b_p\rangle, \tag{2}
$$

where $|f_p\rangle \in \mathcal{H}_f$ are the fragment states and $|b_p\rangle \in \mathcal{H}_b$ are the entangled bath states. Note that there are only $N_f \leq \dim \mathcal{H}_f$ states in the environment that have non-zero entanglement with the fragments. If we further restrict $|\Psi\rangle$ to be the ground state of the full-system Hamiltonian $\hat{H}$, then the embedding Hamiltonian obtained by projecting $\hat{H}$ onto the Schmidt space,

$$
\hat{H}_{\text{emb}} = \hat{P} \hat{H} \hat{P}, \quad \hat{P} = \sum_{pq} |f_p\rangle \langle f_q| \otimes |b_p\rangle \langle b_q|, \tag{3}
$$

shares the same ground state as $\hat{H}$.

For a general state $|\Psi\rangle$, the computational cost of performing the tensor factorization in eqn (2) grows exponentially with system size. In addition, $\hat{H}_{\text{emb}}$ contains many-body interactions that are not suitable for standard quantum chemistry methods even if $\hat{H}$ has only one- and two-body terms. The key approximation made by Knizia and Chan in DMET is to replace $|\Psi\rangle$ with a single-determinant (i.e., HF) state $|\Phi\rangle$, which allows the otherwise complicated many-body decomposition to be performed at mean-field cost.\(^{43,44}\) The resulting fragment and bath states are single-particle states (i.e., sites), rendering $\hat{H}_{\text{emb}}$ a simple two-body Hamiltonian,

$$
\hat{H}_{\text{emb}} = \sum_{pq} \tilde{h}_{pq} a_p^\dagger a_q + \sum_{pqrst} \tilde{V}_{pqrst} a_p^\dagger a_q^\dagger a_r a_s, \tag{4}
$$

where $\tilde{h}$ and $\tilde{V}$ are obtained by projecting $\hat{h}$ and $\hat{V}$ in eqn (1) using the $2N_f$ fragment and entangled bath sites ($\tilde{h}$ also includes the contribution from partially tracing $\hat{V}$ with the unentangled bath). Due to this simplicity, almost all Schmidt decomposition-based fragment embedding methods use a HF bath, with only a few exceptions.\(^{52,53}\) The differences among DMET, its different variants, and BE lie in the use of (1) different high-level theories to solve the embedding Hamiltonian and (2) different match-
matching conditions to optimize the embedding. BE, among others, provides an internally consistent approach to optimizing the embedding.

### 2.2 Bootstrap Embedding

![Diagram of BE](image)

**Figure 1:** Schematic illustration of the BE matching conditions on 1D lattice model. Site 3 is the center of fragment $B$ and the edge of fragments $A$ and $C$, which gives rise to the matching conditions in eqn (5) (blue arrows). Similar matching conditions exist for sites 2 (red arrow) and 4 (green arrow).

In this section, we use 1D lattice chain to illustrate the idea of BE. As shown in Figure 1, there are three different ways to partition the system into fragments of three adjacent sites. The key assumption of BE is that the wave function on the central sites is more accurate than the wave function on the edge sites; hence, one can improve the description of the edge sites by constraining the edge site wave function on one fragment to match the central site wave function on another fragment.\(^5^9\) For example, in Figure 1, site 3 is the central site in $B$ but the edge site in $A$ and $C$. Hence, we require the following two constraints,

\[
\begin{align*}
\langle \Psi_A | a_3^\dagger a_3 | \Psi_A \rangle &= P_{33}^B, \\
\langle \Psi_C | a_3^\dagger a_3 | \Psi_C \rangle &= P_{33}^B,
\end{align*}
\]

(5)

to be satisfied when solving $\hat{H}_{\text{emb}}^A$ and $\hat{H}_{\text{emb}}^C$ (blue arrows in Figure 1). Similar constraints can be imposed for sites 2 and 4, respectively.

The specific example shown above can be made general as follows. Let fragments $A$ and $B$ be two overlapping fragments, and assume the set of the central sites of $B$ (which we label $C_B$) has non-zero intersection with the set of the edge sites of $A$ (which we label $E_A$), i.e., $C_B \cap E_A \neq \emptyset$. Then according to our assumption, we require the 1PDM of fragment $A$ to match that of fragment $B$ in the overlapping region, $C_B \cap E_A$. Mathematically, this can be formulated as a constrained optimization for fragment $A$,

\[
\Psi_A = \arg \min_{\psi_A} \langle \hat{H}_{\text{emb}}^A | \psi_A \rangle, \\
\text{s.t. } \langle \psi_A | \psi_A \rangle = 1, \\
\langle a_p^\dagger a_q | \psi_A \rangle = P_{pq}^B, \quad \forall p, q \in C_B \cap E_A,
\]

(6)

where $\langle \cdots | \cdots \rangle_A$ is short for $\langle \psi_A | \cdots | \psi_A \rangle$, and we include the normalization condition of $\psi_A$ for completeness. Eqn (6) can be turned into an unconstrained optimization by introducing the following Lagrangian,

\[
\mathcal{L}_A(\psi_A; \mathcal{E}_A, \lambda_A) = \langle \hat{H}_{\text{emb}}^A | \psi_A \rangle - \mathcal{E}_A(\langle \psi_A | \psi_A \rangle - 1) + \sum_{p, q \in C_B \cap E_A} \lambda_p^A (\langle a_p^\dagger a_q | \psi_A \rangle - P_{pq}^B),
\]

(7)

whose stationary points are given by an eigenvalue equation,

\[
(\hat{H}_{\text{emb}}^A + \hat{\lambda}_A) | \psi_A \rangle = \mathcal{E}_A | \psi_A \rangle,
\]

(8)

where the Lagrange multipliers for the matching conditions appear as an effective potential,

\[
\hat{\lambda}_A = \sum_{p, q \in C_B \cap E_A} \lambda_p^A a_p^\dagger a_q.
\]

(9)

Given $\{P_{pq}^B\}$ for all $p, q \in C_B \cap E_A$, the effective potential $\hat{\lambda}_A$ is determined by repeatedly solving eqn (8) until the matching conditions in eqn (6) are satisfied. As shown by Ricke et al.,\(^6^1\) the BE optimization problem is numerically stable since the Hessian of $\mathcal{L}$ is negative semi-definite, similar to the direct optimization method used in density functional theory.\(^6^3\) This feature makes BE’s matching conditions different from those in DMET, since the exact satisfiability of the latter is not guaranteed: there are known cases where DMET’s matching conditions cannot be satisfied exactly.\(^5^2\)

The equation presented above for matching the edges of fragment $A$ to the centers of frag-
ment $B$ can be generalized to an arbitrary number of overlapping fragments – as long as a clear definition of edges and centers exists for all fragments (which is the case for simple lattice models). If the centers of all fragments are further constructed to be non-overlapping but fully partition the system, i.e.,

$$C_A \cap C_B = \emptyset, \quad \forall A, B,$$

and

$$\bigcup_A C_A = U,$$

where $U$ is the set of all sites, any physical quantity of the full system can be computed unambiguously as a sum of local contributions from the center of each fragment. Specifically, we require the number of electrons on each fragment center sums up to the correct total number of electrons, $N$. This can be done by introducing a global chemical potential, $\mu$, and optimize the full-system Lagrangian,

$$\mathcal{L}(\{\Psi_A, \mathcal{E}_A, \lambda_A\}, \mu) = \sum_A \mathcal{L}_A(\Psi_A; \mathcal{E}_A, \lambda_A) + \mu \left[ \sum_A \sum_{p \in C_A} \langle a_p^\dagger a_p \rangle_A - N \right].$$

As a result, the effective potential for each fragment $A$ defined in eqn (9) needs to be modified to include (i) the matching between $A$ and all other fragments and (ii) the global chemical potential,

$$\lambda_A = \sum_{B \neq A} \sum_{p, q \in C_B \cap E_A} \lambda_{pq}^B a_p^\dagger a_q + \mu \sum_{p \in C_A} a_p^\dagger a_p,$$

Note that now all fragment calculations are coupled through both the matching conditions and $\mu$.

In practice, we turn the problem of simultaneously determining $\{\lambda_A\}$ and $\mu$ into two uncoupled problems that are solved alternatively until the BE matching error

$$\varepsilon_{\text{BE}} = \left[ \frac{1}{N_{\text{cons}}} \sum_A \sum_{B \neq A} \sum_{p, q \in C_A \cap E_B} (P_{pq}^A - P_{pq}^B)^2 \right]^{1/2}$$

is below some pre-set threshold value, $\tau$, where $N_{\text{cons}}$ is the total number of constraints. An algorithm is outlined in Algorithm 1.

### Algorithm 1 BE iteration

0. Input: $\{\hat{H}_{\text{emb}}^A\}, \tau$
1. Initialization:
   $$\mu \leftarrow 0, \lambda_A \leftarrow 0, P_A \leftarrow \hat{H}_{\text{emb}}^A, \forall A$$
2. Determining $\{\lambda_A\}$:
   $$\lambda_A \leftarrow \text{eqns (8) and (13)}, \forall A$$
3. Determining $\mu$:
   $$\mu \leftarrow N(\mu) = N$$
4. Updating 1PDMs:
   $$P_A \leftarrow \hat{H}_{\text{emb}}^A + \lambda_A, \forall A$$
5. Checking convergence:
   If $\varepsilon_{\text{BE}} > \tau$ then
     Go back to step 2
   else
     Return $\{\lambda_A\}, \mu, \{P_A\}$

We note that while the convergence of density matching in each BE iteration is guaranteed as mentioned above, the convergence of Algorithm 1 (which uses a simple fixed-point method) is not. In principle, the BE iterations could oscillate or even diverge – just like the self-consistent field (SCF) algorithm of HF. In practice, however, we have never encountered such situations. An example demonstrating the convergence of the BE iteration algorithm is displayed in Figure S1 in Supporting Information.

In the subsequent sections, we will see that the general framework of BE described above remains unchanged when applied to molecular systems. The major task is to generalize the algorithmic choice of fragments, central, and edge sites.

### 2.3 BE for molecules

For molecules, localized atomic orbitals (LAOs) such as those obtained by the Forster-Boys
Figure 2: Schematic illustration of distance-based fragmentation for arbitrary orbital connectivity. Each fragment has one unique center (red) and $N_f - 1$ edge (green) orbitals (here $N_f = 4$). The total number of fragments is equal to the total number of orbitals.

scheme \cite{67} are usually used as the site basis. \cite{53,54,58,62} Hence, the formalism presented above in the context of lattice models is in principle applicable to molecules, too. The challenge here is two-fold: (i) how to measure the inter-orbital connectivity and (ii) how to partition the molecules into overlapping fragments that have well-defined centers and edges based on a well-defined connectivity. In the subsequent section, we will present an interaction-based metric for determining inter-orbital connectivity. Here, we tackle the second problem, assuming we have such a metric.

Suppose we have a measure for the strength of connectivity (referred hereafter as “distance”) between any pair of orbitals. Then for each orbital $p$, we can construct an $N_f$-orbital fragment by including $p$ and the $N_f - 1$ orbitals that are closest to $p$ (see Figure 2 for a schematic illustration). By construction, $p$ can be deemed the unique center of that fragment, while all other $N_f - 1$ orbitals are edges. Thus, for a molecule described by $N_{\text{basis}}$ LAOs [eqn (1)], we can construct $N_{\text{basis}}$ overlapping fragments, each of size $N_f$ and centering on one LAO. Since the $N_f - 1$ edge orbitals of each fragment are centers in other fragments, we require the population of each edge orbital to match that of the corresponding center orbital, giving rise to $N_f - 1$ matching conditions for each fragment. Moreover, the $N_{\text{basis}}$ fragment centers satisfy eqns (10) and (11), and hence we can compute full-system observables by summing all orbital contributions.

Formally, this one-center-per-fragment partition scheme is similar to orbital-specific-virtual local correlation methods. \cite{68,69} In OSVMP2, for example, each (localized) occupied orbital is correlated to only a small set of (localized) virtual orbitals that are selected by either direct optimization or tensor factorization. \cite{68} In BE, each LAO is also correlated to only a small set of orbitals consisting of two parts: (i) the edge orbitals, which are selected by the distance measure, and (ii) the entangled bath orbitals, which are generated by Schmidt decomposition. However, we note that the difference in the orbital bases used by the two methods is in fact a significant one. For instance, concepts like frontier orbitals are less obvious in LAOs than in (localized) molecular orbitals (MOs). We will see the effect of this difference in Sec. 4.2.

Despite the simplicity of the above partition scheme, we note here two potential problems. First, ties may arise when selecting edge orbitals from groups of nearly degenerate orbitals. In this work, we use fragments of fixed size and hence break the ties arbitrarily, which may break the molecule’s point-group symmetry and lead to unphysical behaviors in some cases. Alternatively, one can include all degenerate orbitals at a time whenever one of them is selected as edge orbital by a fragment. We will not, however, explore this scheme here since it usually leads to fragments whose size is beyond the ability of our high-level solver (i.e., FCI). Second, the one-center-per-fragment feature only allows one to match on-site properties (e.g., population) for overlapping fragments, even if the overlapping region may consist of more than one orbital. Multi-center fragments are needed for matching inter-orbital properties (e.g., coherences), which we will explore in future works.

### 2.4 Normalized Coulomb metric

The most straightforward candidate for measuring the distance between orbitals is a real-space metric, e.g., the Euclidean distance be-
between the average positions of two orbitals,

\[ d_{pq} = \| \langle \phi_p | \vec{r} | \phi_p \rangle - \langle \phi_q | \vec{r} | \phi_q \rangle \|_2. \] (15)

Though simple, this metric is not ideal. First, it does not reflect the symmetry and spatial extension of orbitals, especially those with high angular momentum and/or long diffuse tail. Second, it correlates to the interaction between orbitals only indirectly, which is not aligned with our purpose of recovering electron correlation.

To that end, we propose an interaction-based metric, the normalized Coulomb metric,

\[ d_{pq} = \left[ \frac{J_{pq}}{(J_{pp}J_{qq})^{1/2}} \right]^{-1} - 1, \] (16)

where \( J_{pq} = \langle pq | pq \rangle \) is the bare Coulomb interaction between orbitals \( p \) and \( q \). We choose the Coulomb interaction for several reasons. First, it is non-negative for all orbital pairs and decays as \( r^{-1} \) for remotely separated orbitals. Second, it does not vanish even for two orbitals of different symmetries (which could have vanishing one-electron interactions). The normalization in eqn (16) is important because it not only renders \( d_{pq} \) non-negative but also removes the bias arising from the orbital shape (e.g., \( J_{pq} \) tends to have a higher value for orbitals that are more s-like).

### 2.5 Computational scaling

We end this section by briefly discussing the computational scaling of BE. Three of the algorithmic steps are most time-consuming. First, electron repulsion integrals (ERIs) generated in the AO basis (of size \( N_{\text{basis}} \)) need to be transformed into the Schmidt basis (of size \( 2N_f \)) for each of the \( N_{\text{basis}} \) fragments. The transformation for each fragment formally takes \( O(N_{\text{basis}}^4N_f) \) time, hence scaling as \( O(N_{\text{basis}}^5) \) in total. Second, according to Algorithm 1, each BE iteration requires determining both the effective potentials, \( \{ \lambda_A \} \), and the global chemical potential, \( \mu \). Both steps scale linearly with the number of fragments and hence the system size, while determining \( \{ \lambda_A \} \) also scales linearly with \( N_f \) due to the \( O(N_f) \) matching conditions per fragment (Sec. 2.3). The prefactor of these linear-scaling steps comes primarily from solving \( \hat{H}_{\text{emb}} \) using the high-level method and hence also has some polynomial or even exponential dependence on \( N_f \) depending on the method. Overall, for a fixed fragment size, ERI transform is currently the computational bottleneck for large systems. The fifth-power formal scaling could potentially be reduced in the future by various techniques established for electron correlation methods.\(^{70-75}\)

We also note that the ERI transform needs to be performed only once and the transformed integrals can then be stored on disk for later use. We will present timing data from numerical calculations in Sec. 4.3.

### 3 Computational Details

In the following computational works, we examine the performance of BE using several molecular systems with atom-centered Gaussian bases. The structures of all molecules as optimized at B3LYP\(^{76} / \)cc-pVDZ\(^{77} \) level (available in Supporting Information) as well as the needed atomic integrals are obtained in Q-Chem.\(^{78}\) Forster-Boys\(^{67}\) LAOs generated by Q-Chem are used for all molecules except for the active-space calculations on polyacene chains, in which case we adopt the symmetrically orthogonalized orbitals. The BE calculations are performed in \textit{frankenstein}\(^{79}\) using spin-restricted Hartree-Fock (RHF) as bath and FCI as high-level solver. The mean-field bath is kept fixed in this work. The entangled bath orbitals for a given fragment are obtained by following the prescription described in Ref. 47. The interacting bath formulation\(^{58}\) is adopted for constructing the embedding Hamiltonian in eqn (4). We note that currently the code is not integral-direct, which limits the size of the molecules to \( \sim 200 \) basis functions.

BE calculations using fragments composed of \( N_f \) orbitals are denoted by \( \text{BE}(N_f) \). We restrict \( N_f \leq 5 \) in this work due to the use of FCI as high-level solver. In the BE iteration algorithm (Algorithm 1), the density matching (step 2)
and the determination of $\mu$ (step 3) are performed using Newton-Raphson and secant algorithms,\textsuperscript{80} respectively, which typically converge in several iterations. As discussed in Sec. 2.2, the convergence of Algorithm 1 (which uses a simple fixed-point method) is not guaranteed in principle. But for all molecules studied in this work, it often requires less than ten iterations to convergence ($\tau = 10^{-6}$ is used in this work). As an illustration, we show the convergence for hexacene in Supporting Information (Figure S1). Unless otherwise specified, we match the population (i.e., diagonal elements of 1PDM) for overlapping fragments. For all molecules tested below except polyacenes, exact numerical solutions via DMRG (as obtained in Block\textsuperscript{7,8,81–83}) are available and will be used as benchmark; for polyacenes, we benchmark our results against the CCSD(T) solution from Q-Chem. For the study of covalent bonds dissociation, we also compare BE with complete active space configuration interaction\textsuperscript{84} (CASCI) performed using frankenstein. Results for DMET are only presented with one orbital per fragment and zero correlation potential [which is equivalent to BE(1) and will be denoted by BE(1) below], due to the difficulty in both obtaining unambiguous fragments and optimizing the correlation potential\textsuperscript{47,50,51,54} for molecules.

4 Results and Discussion

4.1 Correlation energy at equilibrium geometry

We first examine the performance of BE in terms of the correlation energy recovered for a set of small molecules at their equilibrium geometries. The results with the STO-3G basis\textsuperscript{85} are shown in Figure 3, both with and without the matching conditions. Overall, BE converges relatively fast and recovers most of the correlation energy with fragments of four or five orbitals. The rate of convergence is fastest for $C_2H_6$ and becomes slower when introducing either unsaturated bonds or heteroatoms. This pattern is similar to what has been reported in previous works,\textsuperscript{62} and can be attributed to the half-filling nature of the embedding space generated from Schmidt decomposition (i.e., $2N_f$ electrons in $2N_f$ orbitals). Due to the RHF density being very good for these small molecules in the minimal basis, not much is improved by imposing the BE matching conditions.

4.2 Homolytic cleavage of covalent bonds

The second example we study is covalent bonds dissociation. Since our metric for determining orbital connectivity is structure-dependent, the partitioning of the molecules determined at different geometries may differ. Due to its discrete nature, the change in fragmentation is abrupt when geometry changes, which usually leads to discontinuous potential energy curves even the molecular structure itself varies smoothly. To that end, we use the fragments determined at equilibrium geometries for all subsequent calculations. The results of dissociating the carbon-carbon bonds of $C_2H_6$ and $C_2H_4$ in the STO-3G basis are shown in Figure 4. CASCI with a minimum active space is also included for comparison. With fixed fragments, BE delivers smooth energy curves for both molecules and different size of fragments. Overall, the accuracy of embedding increases for larger fragments. Near equilibrium geometries, BE recovers most of the correlation energy even at BE(2) level and improves drastically over CASCI. However, as both molecules dissociate, a gap emerges between BE(3) and BE(4), and the energy of BE(3) is even higher than CASCI at large bond lengths. The poor performance of BE(3) in these regimes suggests that the frontier orbitals (i.e., HOMO and LUMO for $C_2H_6$ and HOMO$-1 \sim$ LUMO+1 for $C_2H_4$), which are crucial to the description of bonds dissociation, are not accurately spanned by the fragment and entangled bath orbitals. As mentioned in Sec. 2.3, this is not surprising since the embedding calculation is performed in a localized orbital basis instead of the canonical MO basis. Nevertheless, the problem is mitigated by adopting
Figure 3: Correlation energies of several small molecules at equilibrium geometry computed by BE with increasing fragment size, (a) with or (b) without matching conditions. All calculations are performed using the STO-3G basis.

Figure 4: Energy curves of homolytic cleavage of (a) the C–C single bond in C₂H₆ and (b) the C=C double bond in C₂H₄ computed by BE. For both molecules, fragments determined at their respective equilibrium geometries are used for all bond lengths. CASCI results obtained using a minimum active space are also included for comparison (small kinks arise from frontier orbitals changing order when varying geometry). All calculations are performed using the STO-3G basis. Note that BE(3) does not improve over BE(2) for both molecules and most geometries (see main text for discussion).

a larger fragment size, as can be seen from the curves of BE(4) and BE(5).

To examine the effect of density matching, we repeat the calculations in Figure 4 without the matching conditions. The results are displayed in Figure S2. As in previous examples, the effect of density matching is not significant for both equilibrium geometry and intermediate bond length. However, at large separation, imposing the matching conditions consistently worsens the results for small fragments, while bringing only little improvement to the largest fragment size. These results might be attributed to the small size of the fragments,
an effect we will discuss in details in the next example.

### 4.3 Polyacene chains

![Figure 5](image1)

**Figure 5:** Fraction of CCSD(T) correlation energy recovered by BE with increasing fragment size for polyacene chains (from benzene to hexacene) at equilibrium geometry. All calculations are performed using the STO-3G basis.

The last example we study is polyacene chains. This example represents an important application of fragment embedding methods since the full-system calculations are beyond the capability of FCI/DMRG. The large conjugate \( \pi \)-systems in polyacenes lead to strong electron correlation and hence can be challenging for fragment embedding methods. The performance of BE for the first six polyacene chains in the STO-3G basis is shown in Figure 5.

For all six molecules, \( \sim 95\% \) of correlation energy is recovered by using three-orbital fragments. Unlike previous examples, however, the convergence with fragment size is not monotonic: BE(4) and BE(5) seriously overestimate the correlation energy by \( \sim 20\% \). An inspection of the calculations suggests that even for fragments of five orbitals, most of the fragments generated by our metric are localized on one carbon atom. This is because the interaction of orbitals on the same atom is usually greater than the interaction of those on different atoms. As a consequence, fragments overlapping and matching conditions are only explored at intra-atomic level, and the pertinent inter-atomic information (e.g., coherences between adjacent atoms) is thus missing in these calculations.

![Figure 6](image2)

**Figure 6:** Error of active-space correlation energy (normalized to six carbons) computed by BE with increasing fragment size compared to CCSD(T) for polyacene chains (from naphthalene to hexacene) at equilibrium geometry. The active space consists of symmetrically orthogonalized \( p_z \) orbitals from all carbon atoms. All calculations are performed using the STO-3G basis. Note that benzene (C\(_6\)H\(_6\)) is not included as it has only six orbitals and BE becomes exact for three-atom fragments.

To illustrate this point, we repeat the calculations in Figure 5 using an active space consisting of the \( \pi \) orbitals from each molecule. By doing so, each carbon atom is described by only one \( p_z \) orbital and we are able to perform embedding calculations using up to five atoms per fragment. The results are displayed in Figure 6. As one can see, using one atom per fragment [i.e., BE(1)] overestimates the correlation energy in a way that is similar to what BE(4) and BE(5) do in Figure 5. Including the nearest neighbors of each atom [i.e., BE(4)], however, drastically reduces the error. Despite a slow growth of the error with molecular size for small fragments, the largest fragment size tested here [i.e., BE(5)] consistently delivers accurate correlation energy (normalized error < 1 kcal/mol) for all molecules. In addition,
some improvements are observed by imposing
the density matching (see Figure S3 in Supporting
Information for the results without matching conditions), although the effect is still very
small since even BE(1) is very accurate for these
molecules. These observations emphasize the
importance of using fragments composed of or-
bitals from neighboring atoms, which we will
explore in a more systematic manner in future
works.

Despite the potential problem of over-
correlation, BE shows a favorable computa-
tional scaling and hence is promising for large-
scale calculations. In Figure 7, the CPU time
as a function of basis size for three primary steps in BE(5) calculations of
the six polyacene chains in Figure 5. Times for
the determination of both \( \{ \lambda_{A} \} \) and \( \mu \) are re-
ported per BE iteration (ERI transform needs
to be performed only once). Dashed lines are
exponential fit, with the scalings indicated be-
sides.

5 Conclusion

To summarize, we extended bootstrap embed-
ding to molecular systems by generalizing the
definition of overlapping fragments from lattice models to generic \textit{ab initio} Hamiltonians.
A heuristic interaction-based metric for deter-
mining inter-orbital connectivity is proposed and
tested in several molecules. Numerical results
suggest that BE converges fast with fragment
size for small molecules at both equilibrium
geometry and bond dissociation. For large
molecules, the lack of inter-atomic fragment
overlapping plagues the convergence with frag-
ment size and results in over-correlation for
fragments of four and five orbitals. Calculations
on polyacene chains using an active space com-
posed of only \( \pi \) orbitals, however, show fast con-
vergence with fragment size, highlighting the
important role of inter-atomic fragment over-
lapping. Nevertheless, BE exhibits linear com-
putational scaling (apart from an integral trans-
form) and hence is promising for large-scale cal-
culations.

In the future, BE could be improved in several
directions. First, in this work, the use of FCI as
high-level solver restricts us to small fragments.
Larger fragments that include orbitals from dif-
ferent atoms will be available if we adopt a less
expensive high-level solver. In addition, the
use of large fragments also enables alternative
approaches to generating fragments such as in-
cluding edge orbitals by their symmetry group
and atom-based fragmentation. \cite{48,53,54,58,89} Last
but not least, currently we only explore the
matching of on-site population (i.e., diagonal
elements of 1PDM). Future works will also in-
clude the matching of inter-orbital coherences
(i.e., off-diagonal of 1PDM), which have been
reported to be important for correlation en-
ergy. \cite{59}
