ABSTRACT

H i features near young star clusters in M81 are identified as the photodissociated surfaces of giant molecular clouds (GMCs) from which the young stars have recently formed. The H i column densities of these features show a weak trend, from undetectable values inside R = 3.7 kpc and increasing rapidly to values around 3 × 10^{23} cm^{-2} near R ≈ 7.5 kpc. This trend is similar to that of the radially averaged H i distribution in this galaxy, and implies a constant area covering factor of ≈0.21 for GMCs throughout M81. The incident UV fluxes G_0 of our sample of candidate PDRs decrease radially. A simple equilibrium model of the photodissociation-reformation process connects the observed values of the incident UV flux, the H i column density, and the relative dust content, permitting an independent estimate to be made of the total gas density in the GMC. Within the GMC this gas will be predominantly molecular hydrogen. Volume densities of 1 < n < 200 cm^{-3} are derived, with a geometric mean of 17 cm^{-3}. These values are similar to the densities of GMCs in the Galaxy, but somewhat lower than those found earlier for M101 with similar methods. Low values of molecular density in the GMCs of M81 will result in low levels of collisional excitation of the CO(1–0) transition, and are consistent with the very low surface brightness of CO(1–0) emission observed in the disk of M81.

1. INTRODUCTION

Giant molecular clouds (GMCs) in the interstellar medium (ISM) are generally accepted as the birthplaces of new stars. The most massive of these new stars produce copious amounts of far ultraviolet (FUV) radiation, which will in turn photodissociate the molecular gas of the parent GMCs, producing “blankets” of H i (and other atomic species) on their surfaces. Allen et al. (1986) were the first to present evidence that major features in the H i distribution of the nearby spiral galaxy M83 (NGC 5236), namely, the inner H i spiral arms observed with the Very Large Array (VLA), were the result of photodissociation of H_2 on galactic scales. Allen et al. (1997) confirmed that H i features existed in M81 (NGC 3031) on scales of ≈150 pc that were qualitatively consistent with the expected morphology of large, low-density photodissociation regions (PDRs), and explicitly related those H i features to nearby bright sources of far-ultraviolet (FUV) radiation found on images of the galaxy from the Ultraviolet Imaging Telescope (UIT).

Smith et al. (2000) used a simple, but quantitative, model for the equilibrium physics of photodissociation regions and applied it to VLA H i and UIT FUV observations of M101 (NGC 5457). Their work showed that this approach provides an entirely new method for determining the volume density of molecular gas in star-forming GMCs of galaxies, a method that is no longer dependent on the (often poorly known) excitation conditions for line emission by specific molecular tracers.

In this paper we return to another spiral galaxy, M81, and carry out a quantitative analysis of the GMCs in this galaxy using the methods described by Smith et al. (2000). This new analysis has been made possible by new data on M81 which was not available to Allen et al. (1997); new, higher resolution, high-sensitivity VLA H i observations, and sensitive new FUV imagery from the GALEX satellite. We have also sought an independent verification that the very basis of our approach is valid, namely, that the H i in the immediate vicinity of FUV concentrations is indeed produced in PDRs. To this end, we have examined the Spitzer/IRAC data on M81 for evidence of mid-IR emission by polycyclic aromatic hydrocarbons (PAHs), which are also thought to be tracers of PDRs.

M81 has been probed extensively for the molecular tracer CO. No global CO map of M81 has been published to date, and the detected CO emission is found to be very weak and spotty (see, e.g., Knapen et al. 2006 and references therein). Since PDRs also produce CO emission (e.g., Allen et al. 2004), comparing the CO results to the results in this paper is therefore of considerable interest.

The outline of this paper is as follows: §2 contains a description of the data we used, followed by a brief theoretical description of PDRs in §3, and the application of the method in §4. The results are presented in §5. The results are discussed and the conclusions are briefly summarized in §6.

2. DATA

The distance to M81 is taken to be 3.6 Mpc, after Freedman et al. (1994), with an inclination of i = 58° and position angle P.A. = 157° (de Vaucouleurs et al. 1991). At this distance, 1″ = 17.5 pc in the plane of the sky. The galactocentric radii in all the plots have been normalized to R_{25}, which is 12.66 kpc for M81 (Vila-Costas & Edmunds 1992). For the model we used (§3), we need H i data, FUV data, and the dust-to-gas ratio scaled to the local solar neighborhood value (β/β_0).

A new, high-quality integrated H i column density map of M81 made with the VLA has been made available by the THINGS team (Walter et al. 2005). It has an angular resolution of 7.58″ × 7.45″, equivalent to about a 130 pc linear resolution. The pixel spacing is 1.5″. An azimuthally averaged radial profile of these
data has been made available by Frank Bigiel (THINGS; 2007, private communication).

The ultraviolet data for M81 have been obtained from the publicly accessible GALEX data archive. The angular resolution is 4″ at a pixel spacing of 1.5″. The astrometry has been checked against a number of stars in the Guide Star Catalogue v2.3. The near-UV image was used for this purpose, since not all of these stars are detected in the far-UV image. The NUV and FUV images were verified to have the same astrometry. We use the FUV image at λ ≈ 150 nm as a “proxy” measure of the photons with λ ≲ 100 nm that can directly dissociate molecular hydrogen, as was done in, e.g., Smith et al. (2000).

The dust-to-gas ratio (δ/δ0) is derived from the metallicity measure 12 + log (O/H). In the case of M81, the slope of log δ/δ0 is taken as equal to the slope of 12 + log (O/H) (Issa et al. 1990). In the solar neighborhood, 12 + log (O/H) = 8.8, according to Mihalas & Binney (1981). At this value, δ/δ0 = 1 by definition. This is sufficient to derive the expression we need for δ/δ0.

The 12 + log (O/H) data for M81 has been adopted from Stauffer & Bothun (1984), but we also considered the results of Garnett & Shields (1987). The gradient they found is likely to be on the high side (D. R. Garnett 2006, private communication). Figure 1 shows both δ/δ0 fits and illustrates the possible spread in the gradient of δ/δ0, similar to the spread in 12 + log (O/H) that is implied from Figure 4 of Garnett & Shields (1987). The fit to the Stauffer & Bothun (1984) data we used yields

\[ \log (\delta/\delta_0) = -0.045R + 0.198, \]

where R is the relevant galactocentric radius in kpc for each region under consideration.

In order to identify PDRs from their PAH emission, we used M81 Spitzer data from the SINGS public release (Kennicut et al. 2003). In particular, we used their 3.6 μm and 8.0 μm data from the IRAC camera. To verify that these data lined up correctly with our other data, we checked the astrometry against the same GSC stars as we used for the UV data, and found the astrometry to be accurate to within 1″.

3. THEORY

We use the data described in the previous section to derive the desired physical quantity n, the total density of gas in the GMC:

\[ n = n_{H_1} + 2n_{H_2} \text{(cm}^{-3} \text{)} \].

The atomic hydrogen column density, FUV flux, and dust-to-gas ratio are the required parameters to calculate the total hydrogen volume density.

Atomic hydrogen is slowly but continuously converted to molecular hydrogen in the interstellar medium, a process that is catalyzed by dust grains. Molecular hydrogen is rapidly photodissociated back into atomic hydrogen by UV photons. Simple models for equilibrium concentrations of these components have been discussed by several authors, e.g., Sternberg (1988), Wolfire et al. (1990), and Hollenbach et al. (1991).

Allen (2004) has reviewed the physics and compared the timescale for equilibrium with other timescales in galactic disks. His equation (6), as derived from Sternberg (1988), explicitly includes the dependence on the dust-to-gas ratio, as well as improved values of the coefficients as determined by Allen et al. (2004) in their equation (A2). The equation we shall use from Allen (2004) is

\[ N_{H_1} = 7.8 \times 10^{20} \frac{\delta}{\delta_0} \ln \left[ 1 + \frac{106G_0}{n} (\delta/\delta_0)^{-1/2} \right] \text{cm}^{-2}, \]

where δ/δ0 is the dust-to-gas ratio scaled to the solar neighborhood value, N_{H_1} (in cm^{-2}) is the H \textsc{i} column produced by photodissociation, n = n_{H_1} + 2n_{H_2} (cm^{-3}) is the total hydrogen volume density (this gas is mostly atomic on the surface of the GMC and mostly molecular deep inside the cloud), and G_0 is a dimensionless parameter measuring the strength of the incident UV field. It is scaled to twice the equivalent Habing flux (at 1500 Å), which is appropriate for an FUV-opaque PDR illuminated over 2π sr (Hollenbach & Tielens 1999; Allen et al. 2004). The latter authors also discuss how the flux and its scaling at 1500 Å relate to the 1000 Å flux, which is in the primary range of energies of dissociation photons. The value of G_0 is equivalent to 0.85 times the field strength defined in Draine (1978) and used by Sternberg (1988). It does not include the ambient UV background radiation, so it is calculated from a background-subtracted UV flux. We evaluate G_0 as follows:

\[ G_0 = F_{\text{FUV}} (D_{\text{gal}}/\rho_{\text{HI}})^2 / F_0, \]

where D_{\text{gal}} is the distance of M81 and ρ_{\text{HI}} is the distance between the UV source and the location of the atomic hydrogen column. At 1500 Å F_0 = 2F_{\text{HI}} = 3.11 \times 10^{-6} \text{ ergs cm}^{-2} \text{ s}^{-1} \text{ Å}^{-1} (Allen et al. 2004; Van Dishoeck & Black 1988).

Equation (2) can be inverted in order to obtain the total hydrogen volume density n, using N_{H_1}, G_0, and δ/δ0. The resulting equation is

\[ n = \frac{106G_0}{(\delta/\delta_0)^{1/2}} \exp \left[ \frac{N_{H_1}(\delta/\delta_0)}{7.8 \times 10^{20}} - 1 \right]^{-1}. \]

Equation (4) is valid for PDRs with n < 10^4 cm^{-3}.

The morphology of the regions identified by Allen et al. (1997) is that of H \textsc{i} patches in the form of shells (or parts of shells) partially surrounding young star clusters. Although this morphology appears to be ubiquitous in M81 and other galaxies, independent confirmation of these H \textsc{i} features as PDRs would be very desirable. Such a confirmation could be provided by the presence of PAH emission. Although no quantitative relation between PAH, UV, and H \textsc{i} emission at this scale is currently available, the detection of PAHs is thought to be predominantly linked to UV emission (Uchida et al. 1998; Li & Draine 2002).
4. METHOD

In this section, we explain how the total hydrogen volume density in every candidate PDR is determined by investigating the H\textsc{i} structures surrounding the central FUV source. We hypothesize that this source (a cluster of young stars) creates a photon-dominated region, in which molecular hydrogen is converted into atomic hydrogen. While the exact morphology of these regions remains unclear, the distribution of H\textsc{i} suggests that large-scale photodissociation is taking place. The presence of PAH emission in these regions reinforces this picture.

We selected 27 sources based on their well-defined compact FUV emission, from faint to bright. The sources were chosen to have a range of galactocentric radii, although we suspect that all candidate PDRs should have similar total hydrogen densities regardless of their location (Smith et al. 2000). It is significant that we found no sources of this type within $R/\text{R}_{25} \approx 0.3$ and brighter than our faintest source at $0.15 \times 10^{-15}$ ergs cm$^{-2}$ s$^{-1}$ Å$^{-1}$.

There is one source at a smaller radius that has an FUV flux similar to our faintest source, but it is extended and has a lower contrast than our faintest source. The locations of these sources are shown in Figure 2 and given in Table 1.

Detailed plots of the sources are given in Figure Set 3 (four examples are shown in the print edition; the entire set is available online). These sources vary in FUV flux and galactocentric distance. Each source shows the general structure of a UV source surrounded or bordered by H\textsc{i} with PAH emission nearby. At larger scales this is clearly visible; see Allen et al. (1997) or Smith et al. (2000) for similar plots of M101.

The FUV source flux is determined first. We correct for galactic foreground extinction, but not for internal extinction. We decided against applying an internal extinction correction, despite the availability of internal extinction data (Hill et al. 1995).

It is assumed that the height of M81’s gas disk is of the same or-
der order as the size of the PDRs to which our method is most sensitive. Visser (1980) use a gas disk half height of up to 450 pc, which is comparable to the size of our candidate PDRs. In that case, the extinction from the H\(_i\) patch to the UV source is the same as the extinction of the UV source in M81’s disk toward the line of sight of the observer. Under these circumstances, the corresponding extinction corrections to the UV flux cancel each other out. Using the internal extinction correction is therefore unnecessary.

The radius at which the UV emission blends into the back-
ground radiation level determines the size of the UV source on the image and the place to measure the background. The total FUV flux within this radius is calculated, and the background flux is subtracted. Typically, the net flux is 50% of the total FUV flux. For comparison, we calculate the contrast of the source above the background level, which we define as the incident UV flux on the H\(_i\) patches, \(G\) (the unscaled \(G_0\)), divided by the incident back-
ground UV flux, \(G_{bg}\). The latter is defined as the UV background surface brightness at the edge of the aperture of the UV source, integrated over half the sky (a flux on a semi-infinite slab). Only the net flux of the source is used to calculate \(G_0\), since the model does not include calculating H\(_i\) produced by the ambient UV background. The measured flux is in ergs cm\(^{-2}\) s\(^{-1}\) Å\(^{-1}\).

The distance \(d_{H\alpha}\) from the UV source position to any surround-
ing patches (concentrations) of H\(_i\) is measured next, along with the column density of each such patch. A patch of H\(_i\) is iden-
tified as a local maximum in column density (see Fig. Set 3, middle panel). This procedure differs slightly from that of Smith et al. (2000), who took the first local maximum of the ring averaged H\(_i\) column densities around UV sources as a probe of the true H\(_i\) column density. In fact, any local bright spot in atomic hydrogen is an equally valid probe of a potential PDR. They are all likely to be direct views onto the surfaces of molecular clouds surrounding the UV source. In that case, the H\(_i\) local maxima are...
a measure of the true local column density, and each measurement represents (part of) an H\textsc{i} cloud. For this reason, we decided to use more than one measurement of the H\textsc{i} surrounding the UV source. We subtract a general background level of H\textsc{i} emission that we assume either has not been created by photodissociation, or has been created by the general UV background radiation field acting on all GMCs in the area.

In addition to identifying individual H\textsc{i} concentrations, the maximum measured column densities per 1 kpc galactocentric bin are recorded and compared to the ring-averaged values from M81's radial profile. Dividing the maximum column densities per bin of individual H\textsc{i} clouds, converted to $M_\odot$ pc$^{-2}$, by the average surface density per 1 kpc bin from M81's radial profile yields a filling factor. In the framework of the derived PDR model, this filling factor is an estimate of the extent to which GMCs fill M81's disk.

In order to determine $\rho_{\text{HI}}$, we corrected for M81's inclination and position angle assuming M81's disk to be intrinsically circular (see Fig. 4a). From this, the incident flux $G_0$ on each surrounding H\textsc{i} patch is computed using equation (3). The relevant dust-to-gas ratio at the galactocentric radius of each UV source is taken from Figure 1. The extinction between M81 and the observer is taken to be 1.37 mag at 1500 Å, after Allen et al. (1997) and Seaton (1979). The measured FUV flux is increased accordingly when calculating $G_0$. The incident flux $G_0$, the H\textsc{i} column density, and the dust-to-gas ratio $\delta/\delta_0$ finally yield a total hydrogen volume density for each patch according to equation (4). Note that this probe for molecular gas does not yield any information about the geometry of the gas clouds, but deep inside the GMC all available hydrogen is likely to be in the form of molecular hydrogen, so $n = 2n_{\text{H}_2}$.

A PAH map was obtained by subtracting a scaled and smoothed version of the 3.6 $\mu$m M81 image from the 8 $\mu$m M81 image, as described by Willner et al. (2004). This procedure assumes that the 3.6 $\mu$m image contains purely stellar emission, while the 8 $\mu$m image contains a mix of stellar and PAH emission. We determined the required scale factor empirically, by comparing four regions of M81 encompassing most of our candidate PDRs. Correlation maps of individual pixels were used to determine the slope of the appropriate correlated component. Our four scale factors are consistent with the single one used by Willner et al. (2004) being within the range of 0.7–1. Seven sources were not included in these four regions; these sources have comparatively large galactocentric radii, and any 3.6 $\mu$m contribution is negligible. In these cases we therefore used the raw 8 $\mu$m image. The relevance of the detected PAH emission around the candidate PDR was tested by checking for the presence of PAH emission near the location of the UV source and determining the separation between PAH emission peaks and H\textsc{i} patches.
To summarize, determining \( N_{\text{H}i} \), \( \rho_{\text{H}i} \), \( F_{\text{FUV}} \), and \( \delta / \delta_0 \) yields \( n \), derived using the picture of photodissociation. In addition, the presence of PAH emission reinforces the photodissociation assumption.

5. RESULTS

In this section, we present total hydrogen volume densities of the 27 candidate PDRs. Table 1 lists the FUV fluxes of the central (cluster of) sources. Table 2 lists the corresponding \( \text{H} \) \( \text{i} \) column density measurements, the resulting incident fluxes, and finally the total hydrogen volume densities. First, we will discuss the \( \text{H} \) \( \text{i} \) measurements, followed by the FUV results. These results, combined with the appropriate dust-to-gas ratios of equation (1), are then used to calculate \( n \). At the end of this section, we discuss the spatial correlation between \( \text{H} \) \( \text{i} \) and PAHs in M81.

5.1. Atomic Hydrogen

Each region can have one or more \( \text{H} \) \( \text{i} \) measurements, as explained in the previous section. The resulting \( \text{H} \) \( \text{i} \) column densities and their distance to the central FUV source are listed in Table 2.

Figure 5 shows the \( \text{H} \) \( \text{i} \) column densities of all \( \text{H} \) \( \text{i} \) patches from Table 2 as a function of (normalized) galactocentric radius. The general background column density level is of the order of \( 1 \times 10^{20} \) cm\(^{-2}\) and has been subtracted from all measured values, for the reasons mentioned above (§4). Very little \( \text{H} \) \( \text{i} \) radio emission is observed within a radius of 3 kpc of the center of M81. The \( \text{H} \) \( \text{i} \) column densities rise with increasing galactocentric radius from 0.3 to 0.6 \( R_25 \) (3.8–7.5 kpc), although there is significant scatter.

While the general morphology of our candidate PDRs is the same (FUV emission surrounded by atomic hydrogen), the actual geometry of the GMCs cannot be discerned at the available resolution. The \( \text{H} \) \( \text{i} \) structures are barely resolved, which makes it practically impossible to deal with projection effects properly. This introduces inaccuracies in the determination of \( \rho_{\text{H}i} \), (see Fig. 9 below) and \( N_{\text{H}i} \).

We cannot exclude \( \text{H} \) \( \text{i} \) patches closer than about 20 pc (roughly the size of 1 pixel), or right on top of a UV source, even though they could have a significant separation in the vertical direction. The model cannot take a \( \rho_{\text{H}i} \) of 0. We had to reject only one \( \text{H} \) \( \text{i} \) patch because it was too close to the UV source. The upper limit of \( \rho_{\text{H}i} \) (about 600 pc) is somewhat arbitrary and depends on the maximum separation that could still conceivably have \( \text{H} \) \( \text{i} \) connected to a certain UV source. In combination with the lowest measured FUV flux, the resulting \( G_0 \) would be 0.01.

We corrected for M81’s inclination and position angle (Fig. 4a), assuming M81’s disk to be perfectly circular in shape. This means we used ellipses to measure the deprojected separation between the FUV source and the associated \( \text{H} \) \( \text{i} \) patches. However, \( \rho_{\text{H}i} \), is still sensitive to projection effects, as illustrated in Figure 4b. This figure shows how the measured separation could be further deprojected if we knew the position of all \( \text{H} \) \( \text{i} \) patches in the z-direction of the disk. Therefore, the measured separation \( \rho_{\text{H}i} \) is close, but not exactly to, the real separation. This will lead to underestimating the separation between the UV source and its associated \( \text{H} \) \( \text{i} \) patches. This in turn will mean overestimating \( G_0 \) and therefore overestimating \( n \) as well. At the same time, due to our finite resolution, there is a lower limit to the separation we can observe. The lowest value of \( \rho_{\text{H}i} \) we measured was 35 pc.

In addition, the \( \text{H} \) \( \text{i} \) column that is needed for equation (4) is defined as seen along the line of sight from the UV source to the \( \text{H} \) \( \text{i} \) layer (Fig. 4c). The observer sees the \( \text{H} \) \( \text{i} \) column from a different angle. Since the geometry of the \( \text{H} \) \( \text{i} \) layer is unknown, we
assume that the observed column is nevertheless a reasonable measure of the proper H\textsc{i} column.

The range of observable H\textsc{i} columns is indicated in Figure 5. With a signal-to-noise ratio of S/N = 4-5, only regions with column density above $1 \times 10^{21}$ cm\(^{-2}\) can be reliably distinguished as H\textsc{i} clouds. ($N_{\text{HI}}$ reaches this level in the region surrounding source 11.) This limits the maximum observable total hydrogen volume density.

At a column density of about $5 \times 10^{21}$ cm\(^{-2}\), the H\textsc{i} columns may become optically thick (Allen et al. 2004). In our sample,

### Table 2

| Source No. | $\rho_{\text{H} \textsc{i}}$ (pc) | $N_{\text{HI}}$ ($10^{21}$ cm\(^{-2}\)) | G\text{0} | G/G\text{bg} | $n$ (cm\(^{-3}\)) | Error (%) | PAH-H\textsc{i} < 6'' Apart? |

two sources have H\textsc{i} columns approaching this value. One of these sources has a relatively high UV flux. Neither source has an unusual total hydrogen volume density.

Our method is biased toward low-density, large-scale H\textsc{i} regions. The H\textsc{i} from compact high-density PDRs like the Orion Nebula in our Galaxy can currently be detected at the distance of M81 because of the limited resolution of the H\textsc{i} map. The high-density regions will be of small scale size generally, and thus will be difficult to discern from the generally lumpy H\textsc{i} background. Beam smoothing will also reduce the measured value of \(N_{\text{HI}}\), in this case. Detectable quantities of H\textsc{i} can be produced through a combination of a high \(G_0\) and high \(n\) or a low \(G_0\) and low \(n\) (recall eq. [2]). The highest \(G_0\) we can detect is limited by the maximum observed FUV flux and the minimum measured \(\rho_{\text{HI}}\) (eq. [3]). Taking the respective maximum and minimum values from our results yields a maximum \(G_0\) of 140. The actual maximum \(G_0\) in our data set is 62. Obtaining a combination of a high \(G_0\) and a low \(n\) is limited by the maximum H\textsc{i} column density that is observed.

Next, we used the H\textsc{i} column densities to calculate the area filling factor of M81. It is worth mentioning here that Figure 5 weakly reflects the same highs and lows that feature in Braun’s results. The H\textsc{i} columns of individual GMCs show too much scatter to reproduce the two peaks in Braun’s results. The filling factor in Figure 6 was derived from the individual H\textsc{i} column measurements and the global radial distribution of H\textsc{i} in M81. Table 3 lists the maximum measured H\textsc{i} columns per 1 kpc interval, the equivalent surface densities, the corresponding surface densities of M81’s radial profile, and the resulting area filling factor. The radial profile has a tilted ring correction, appropriate for an inclined disk. At a local scale this correction is not appropriate, since the morphology of the individual H\textsc{i} columns is unknown. Note that we have no sources between 0.95 and 1.11 \(R_{25}\) (12 and 14 kpc, respectively). The average filling factor within \(R_{25}\) is 0.21.

### 5.2. Far-Ultraviolet Flux

Table 1 lists the locations and FUV fluxes of the central sources of our 27 selected regions. The candidate PDRs were selected to have a range of FUV fluxes and galactocentric radii. We did not find candidate PDRs in the inner region of M81 (\(R_{25} < 0.3\)) with an FUV flux above \(1.5 \times 10^{-15}\) ergs cm\(^{-2}\) s\(^{-1}\) Å\(^{-1}\). Qualitatively, neither detectable FUV emission nor detectable H\textsc{i} columns are present there.

\(F_{\text{FUV}}\) as shown in Figure 7 shows a weak correlation with galactocentric radius. No values of the FUV flux of individual sources larger than \(1.56 \times 10^{-15}\) ergs cm\(^{-2}\) s\(^{-1}\) Å\(^{-1}\) were found. At larger galactocentric radius, the UV sources become less bright. This could be caused by fewer dissociating stars per cluster or a change in the stellar population (an increasing number of B stars and a decreasing number of O stars). At the lower end of the FUV flux values, the minimum measured FUV flux values (and \(G_0\); Fig. 8) seem to decrease with increasing galactocentric radius. This is potentially a confusion effect, if the brighter sources raise the ambient UV flux, outshining the weaker sources. However, it could also be the effect that is responsible for the decreasing maximum UV fluxes. At this point we are unable to make that distinction.

Table 2 shows the ratio of the FUV flux to the FUV background level (\(G/G_{0}\)). A value of 1 means that the FUV source appears to be equally as bright as the FUV background as “seen” by the H\textsc{i} patch. Values range from a source flux of 1% of the background level to over 23 times the background level.

Figure 8 shows the incident flux on all of our candidate PDRs. The values of \(G_0\) show a tendency to decrease with increasing

### Table 3

| Radius (kpc) | Maximum H\textsc{i} Column (10\(^{21}\) cm\(^{-2}\)) | Equivalent \(\Sigma_{\text{HI}}\) (\(M_\odot\) pc\(^{-2}\)) | Radial \(\Sigma_{\text{HI}}\) (\(M_\odot\) pc\(^{-2}\)) | Filling Factor |
|-------------|-----------------------------------------------|-----------------------------------------------|-----------------------------------------------|---------------|
| 4–5         | 2.91                                         | 22.17                                         | 3.88                                          | 0.17          |
| 5–6         | 4.83                                         | 36.79                                         | 4.80                                          | 0.13          |

| 7–8         | 3.45                                         | 26.28                                         | 6.41                                          | 0.24          |
| 8–9         | 4.58                                         | 34.89                                         | 5.56                                          | 0.16          |
| 9–10        | 2.74                                         | 20.87                                         | 5.31                                          | 0.25          |
| 10–11       | 3.20                                         | 24.37                                         | 5.42                                          | 0.22          |
| 11–12       | 2.44                                         | 18.59                                         | 4.97                                          | 0.27          |
| 14–15       | 2.83                                         | 21.56                                         | 2.67                                          | 0.12          |
galactocentric radius. $G_0$ varies over a range of 4 dex, while the FUV flux only varies over 1 dex and shows only a very weak trend (Fig. 7). The same holds for the values of $\rho_{\text{H}I}$, as plotted in Figure 9, ranging from 35 pc to almost 600 pc. Taken together, they are responsible for the trend in the values of $G_0$.

5.3. Total Hydrogen Volume Density

Figure 10 shows the resulting total hydrogen volume density using the Stauffer & Bothun (1984) dust-to-gas ratios (see eq. [1]). Values range between 1 and 200 per cm$^3$, without a clear gradient. Using the Garnett & Shields (1987) dust-to-gas model (not plotted), the resulting volume densities are in the same range, but with larger values in the outer regions of M81 and smaller values in the inner parts. Even then, a clear gradient is absent. On average, the relative error of the resulting $n$ in our method is 88%; see Appendix A for a more complete error analysis.

Figure 11 illustrates the various observational selection effects by showing the range of $G_0$ and $n$ that are observable with our method. The different limits are indicated by the Roman numerals I through V. These limits arise as follows:

I. $\text{H}I$ upper limit of $5 \times 10^{21}$ cm$^{-2}$ at a characteristic $\delta/\delta_0$ of 0.9, due to the $\text{H}I$ column becoming optically thick.

II. $\text{H}I$ column density (sensitivity) lower limit of $1 \times 10^{20}$ cm$^{-2}$ at a characteristic $\delta/\delta_0$ of 1.

III. The lowest total hydrogen volume density that we can observe. It is determined by the lowest observable column density divided by the diameter of the radio beam and is roughly 0.5 cm$^{-3}$. This limit is therefore a combination of a sensitivity limit and a resolution limit.

IV. The minimum $G_0$ (0.01) we can reasonably use, as discussed above.

V. The maximum $G_0$ of 140 that we can obtain, as discussed above.

At the top end we have a theoretical limit of roughly $1 \times 10^5$ cm$^{-3}$, a combination of the highest $G_0$ and the lowest $\text{H}I$ column density (not shown). These values will not be observed due to points I and V above. Moreover, recall that equation (4) is valid only for values of $n < 10^4$ cm$^{-3}$. More common values of $G_0$ combined with low $\text{H}I$ columns yield values of up to 1000 cm$^{-3}$. In short, the range of values in our results is bounded by observational selection, and the apparent trend in Figure 11 must be considered a result of that selection.

5.4. Polycyclic Aromatic Hydrocarbons

We now turn to the additional evidence supporting the idea that the regions we selected are indeed PDRs. Morphologically,
all sources are similar in that H\textsc{i} and PAHs can be found in the neighborhood of the UV emission. This is apparent from the detailed plots of the candidate PDRs in Figure Set 3. This apparent spatial connection at high resolution between the atomic hydrogen and UV emission in M81 was previously reported in Allen et al. (1997). Almost all of our sources show PAH emission nearby. At the largest galactocentric radii, the PAH emission becomes too faint to detect. Table 2 (last column) shows whether the measured H\textsc{i} patches have PAH emission peaks within 6\textdegree, or 100 pc. 31 out of 56 H\textsc{i} patches have PAH emission peaks within that range.

Our subtracted PAH map is contaminated by nonstellar non-PAH emission (hot dust). In regions of high radiation intensity, one will observe nonstellar emission from H\textsc{i} regions in the 3.6 \textmu m image, but at a separation of a few arcseconds the general view is that the nonstellar emission is coming from PAHs (S. P. Willner 2005, private communication). Despite the contaminations in the resulting image, we are only interested in a qualitative comparison, where the presence of emission is more important than the actual amounts that occur. PAHs are thought to be a tracer of recent star formation (Peeters et al. 2004). In that case, the presence of PAH emission is a further confirmation that the physical conditions typical of PDRs are indeed present.

With the exception of four sources at higher galactocentric radius that did not show detectable PAH emission (in general, PAH emission levels drop with increasing galactocentric radius), all UV sources have accompanying PAH emission. Owing to differences in excitation conditions, we did not expect PAH emission to appear at the exact location of H\textsc{i} emission. The majority of H\textsc{i} patches, however, have associated PAH emission, suggesting a close relation between the two. A closer investigation of this correlation appears desirable, but is beyond the scope of this paper.

6. DISCUSSION AND CONCLUSIONS

The candidate PDRs in M81, which were selected on the basis of their FUV emission, seem to fit the photodissociation model well. Our results show no systematically different properties of the parent GMCs in different parts of M81. The total hydrogen volume density is roughly constant, even as the underlying H\textsc{i}, FUV, and dust-to-gas ratio vary.

The cloud densities we find are lower than the range of values (30–1000 cm\textsuperscript{-3}) found in M101 (Smith et al. 2000). The observed values of \( N_{H_1} \), of individual PDRs are similar to those seen in M101. The observed H\textsc{i} columns in both galaxies abruptly increase at the same normalized radius (0.3) and appear to decline somewhat beyond 0.7, assuming an \( R_{25} \) of 30.3 kpc for M101 (Vila-Costas & Edmunds 1992). The range of observed H\textsc{i} columns is also the same. The downward trend in \( G_0 \) also is consistent with Smith et al. (2000) when no internal extinction correction is applied to their data. Figure 10 shows that the densities of the GMCs in M81 do not appear to change with galactocentric radius, consistent with the M101 results.

Kaufman et al. (1999) modeled the expected CO intensity from a PDR for a range of incident FUV fluxes and cloud densities. The range of our results would be consistent with modeled CO intensities below \( 5 \times 10^{-8} \) ergs cm\textsuperscript{-2} s\textsuperscript{-1} sr\textsuperscript{-1}, or \( 1 \times 10^{-8} \) ergs cm\textsuperscript{-2} s\textsuperscript{-1} sr\textsuperscript{-1} for the vast majority of sources (6.4 K km s\textsuperscript{-1}). Figure 1 in Allen et al. (2004) shows that for the range of values in Figure 11, the modeled CO intensities are independent of \( n \). The low volume densities we find are consistent with a lack of CO emission in M81, as discussed by Knappen et al. (2006) and which those authors attribute to insufficient excitation. We note that the volume number densities of colliding H\textsubscript{2} molecules in the GMCs of M81 is 1/2 of the values for \( n \) calculated here. The mean value we have found for \( n \) in the GMCs of M81 translates into a mean number density for \( n_{H_2} \approx 10 \text{ cm}^{-3} \), well below the values required for collisional excitation of CO molecules. In this case, the CO emission in M81 is in general subthermal. Their reported upper limit for \( I_{CO} \) is 1.03 K km s\textsuperscript{-1} for the regions they investigated, near our source 18. The \( G_0 \) and \( n \) that we find there are consistent with that value of \( I_{CO} \) (and somewhat higher), per Figure 1 in Allen et al. (2004), when beam dilution is taken into account. The low CO emission in M81 is also explored in Casasola et al. (2007), who again point to a lack of excitation of the molecular gas. They find no molecular gas in the nucleus of M81. The absence of FUV sources to excite the gas is consistent with that finding.

After accounting for observational and projection effects (see § 5), we note that in the nearby galaxies in general to which our method is applicable, it is most sensitive to a combination of low \( G_0 \) and low \( n \).

In summary, our conclusions are:

1. We selected a number of discrete FUV sources in M81, which we consider to be potential PDRs on the surfaces of the parent GMCs.
2. The total hydrogen volume densities of GMCs close to clusters of young stars in M81 are in the range of \( 1 < n < 200 \text{ cm}^{-3} \), with a geometric mean of \( 17 \text{ cm}^{-3} \). This is approximately 10 times lower than GMCs in M101 studied with the same method.
3. The low GMC volume densities are consistent with a lack of CO emission in M81.
4. M81’s GMCs have a filling factor of \( \approx 0.21 \) within \( R_{25} \).
5. No candidate PDRs are found in M81 within \( R < 0.3 R_{25} \).
6. We have provided a thorough analysis of the observational selection effects on our results and conclude that, while such effects are (necessarily) present in our results, our main conclusions as to the range and values of the total volume densities of GMCs in M81 are not affected.
7. The presence of PAH emission in the neighborhood of our candidate PDRs lends support to our view that the H\textsc{i} patches near FUV sources are indeed produced by photodissociation. PAH emission occurs near almost all UV sources. PAH and H\textsc{i} emission coincide in more than half of our sources.
the noise levels of M81’s H i data. Thanks go to E. Brinks and F. Walter, for making available their excellent THINGS M81 data and for invaluable discussions, as well as helpful comments regarding earlier drafts of this paper. We are grateful to Frank Bigiel for providing us with the THINGS M81 radial profile. We thank G. Meurer for helping with the GALEX data. We also thank J. Morrison, K. Sahu, B. McLean, and R. Bohlin for helping out with astrometrical corrections and analysis of the UV data. We thank N. Panagia and X. Tielens for advice and useful discussions about the physics of PDRs. M. Vogelaar has been extremely helpful with resolving some specific problems peculiar to the data set we could obtain. We thank B. Holwerda for helping out with preliminary versions of the M81 Spitzer data from the archives. The anonymous referee provided many useful suggestions, for which we are grateful. Finally, we thank J. Knapen for useful general discussions about M81. J. S. H. acknowledges the support of a Graduate Research Assistantship provided by the STScI Director’s Discretionary Research Fund.

APPENDIX

ERROR ANALYSIS

To estimate the extent to which the different observables influence the result, we performed a basic error analysis. It takes into account the precision of the determination of the UV flux $F$, the H i-to-UV distance $\rho$, the dust-to gas ratio $\delta/\delta_0$ and the H i column densities $N$. Note that in this case we substitute for $G_0$ its observables $F$ and $\rho$.

Equation (4) for $n$ can be written as

$$n = C \frac{F}{\rho^2} \left( \frac{\delta}{\delta_0} \right)^{-1/2} \left[ \exp \left( N \frac{\delta}{\delta_0} \right) - 1 \right]^{-1},$$

(A1)

where $C$ is a constant that includes the extinction, the distance to M81, the scaling factor for the flux, and the other constant factors that went into the model. Also note that $N \equiv N_{\text{H}_1}/(7.8 \times 10^{20} \text{ cm}^{-2})$.

$$\sigma_n^2 = \left( \frac{\partial n}{\partial F} \right)^2 \sigma_F^2 + \left( \frac{\partial n}{\partial \rho} \right)^2 \sigma_\rho^2 + \left( \frac{\partial n}{\partial \delta} \right)^2 \sigma_\delta^2 + \left( \frac{\partial n}{\partial N} \right)^2 \sigma_N^2,$$

(A2)

the standard formula for propagation of uncertainties, where

$$\frac{\partial n}{\partial F} = n,$$

(A3)

$$\frac{\partial n}{\partial \rho} = -2 \frac{n}{\rho},$$

(A4)

$$\frac{\partial n}{\partial \delta} = -\frac{1}{2} \left( \frac{\delta}{\delta_0} \right)^{-1} n - n \left[ \exp \left( N \frac{\delta}{\delta_0} \right) - 1 \right]^{-1} N \exp \left( N \frac{\delta}{\delta_0} \right),$$

(A5)

$$\frac{\partial n}{\partial N} = -n \left[ \exp \left( N \frac{\delta}{\delta_0} \right) - 1 \right]^{-1} \frac{\delta}{\delta_0} \exp \left( N \frac{\delta}{\delta_0} \right).$$

(A6)

The square root of the result, $\sigma_n$, is the standard deviation, or the error. The dust-to-gas ratio has a disproportionate influence on the error, since it occurs twice in the equation and is also the parameter that is the least well known. The relative precision of the measurements of $F$ and $N$ is roughly 1%. The separation has an uncertainty on the order of a half a pixel, or about 9 pc. Finally, the scatter in the fit to the dust-to-gas ratio is about 0.2. Taken together, these figures introduce relative errors to the result of about 88% of the measured value of $n$ on average, or approximately a factor of 2. This means that for example $n = 1 \pm 0.8$ if $\sigma_n/n = 80\%$. Negative values of $n$ are unphysical. The spread in our resulting values of $n$ seems to reflect this, and we expect the accuracy of our results to be similar.
