ABSTRACT
The electric vehicle (EV) charging scheme can reduce the power generation costs and improve the grid resilience. However, the huge penetrations of EVs can impact the voltage stability and operating costs. In this paper, a novel EV participation charging scheme is proposed for a decentralized blockchain-enabled smart grid system. Our objectives are to minimize the power fluctuation level in the grid network and the overall charging cost for EV users. We first formulate the power fluctuation level problem of the smart grid system that takes into account of EV battery capacities, charging rates, and EV users charging behavior. And then, we propose a novel adaptive blockchain-based electric vehicle participation (AdBEV) scheme that uses the Iceberg order execution algorithm to obtain an improved EV charging and discharging schedule. The simulation results show the proposed scheme outperforms the scheme that applying genetic algorithm approach in term of lowering the power fluctuation level and overall charging costs.

INDEX TERMS Electric vehicles, smart grids, blockchain technology, adaptive charging scheme.

I. INTRODUCTION
The emergence of electric vehicle (EV) in the energy market brings the concept of vehicle-to-grid (V2G) and grid-to-vehicle (G2V) that aims to transform the overloaded grid into a beneficial resource. EV can be used as a fast-ramping power backup device for load flattening, peak shaving and frequency regulation with adequate control schemes. The bidirectional power flow of EV charging/discharging in the smart grid system is envisaged to reduce the subsidiary (reserved) power generation cost and increase the grid system robustness [1].

To be more specific, for instance, if a large number of EVs start charging at the same time interval during the power consumption peak-time interval, the large power generators have to start the subsidiary (reserved) generators (with less response time) to supplement the power consumption, where there is delay for the subsidiary generators to start providing power. They usually takes 10 to 15 minutes to start providing power. In [2], a three-party architecture including the power grid, EVs and smart communities renewable energy generations and storage capabilities is proposed to build an energy management framework, which provides an insight for applying feasible optimization methods to achieve effective and intelligent energy management in the power system.

However, the massive load caused by huge penetrations of EVs into the power grid raises concerns about the potential impacts to the operating cost and voltage stability [3].

In the conventional EV charging/discharging scheme, a centralized information center operator which is the aggregator, is used to gather the electricity consumption demand and further command the power transfer in [4]–[6]. With the aid of the aggregator, the control schemes can be applied to control the power flow in the peak hours and off-peak hours respectively. EV is characterized as a diversely distributed power load to the grid system due to the uncontrollability of user behavior. Therefore, the availability for scheduling power exchange, where a deterministic scheduling method may not account for all possible factors that could affect the power system [7]. However, the aggregator compromises the objective of the smart grid where it is designed to decentralize the conventional power grid structure and support the micro-distributed renewable generators [8]. The centralized based system lags the decision making process and undermines the autonomy of the individual grid participants, where participants are incapable of controlling their charging or discharging process. In general, almost all electricity retail consumers are currently making transactions with average price that does
To improve the efficiency and superiority of grid operations, various control strategies for EV charging and discharging scheme were proposed earlier to control the amount and duration of power transfer. In [11], an automated demand response scheduling algorithm was introduced to accommodate large number of EVs. Alonso et al. [5] introduced a smart charging schedule for a low-voltage residential level grid by considering the state-of-charge (SOC) values as the battery capacity and the battery residual that will largely affect the overall grid offload. To consider the dynamic arrival and departure times of EVs, Yao et al. [4] used an automated generation control signal to regulate the EV charging or discharging schedule to improve the performance of frequency regulation service. In [12], an aggregated-based optimization model for EV charging strategy was proposed by taking into consideration the stochastic features of the charging procedure and the Genetic Algorithm (GA) was further used to determine the parameters in the system model. However, it was noted that the aforementioned EV charging/discharging schedule algorithms in [5] and [11] presumed the static parameters for the EV available charging time. And the proposed charging scheme in [4] and [12] were based on parameter estimations and theoretical calculations where the flexibility of EVs are not fully considered. Henceforth, the implementation of algorithms in the blockchain platform will not be able to adapt the battery types and user behavior of EVs.

In order to adapt the large volumes of EV charging/discharging demand, the blockchain concept is introduced that allows peer-to-peer transaction platforms that utilizes decentralized storage to record all transaction data [13]. Henceforth, the blockchain technology enables a trustless network to eliminate the operation cost of the intermediary participation, which will realize a quicker, safer and cheaper way in the transactional energy market to reflect fluctuating wholesale prices to the end user. Moreover, blockchain technology has the capability of shifting the high-load household appliances to off-peak hours to not only reduce their electricity costs but also to help to reduce the overloaded peaks [14]. Hence, in [15], a novel mechanism for trading the energy based on the blockchain technology was proposed to adapt the decentralized and competitive environment for the locally produced energy, but the blockchain is solely used as a data storage warehouse to record transactions. Mengelkamp et al. [16] further analyzed the economic evaluation of the market mechanism for local energy trading. Furthermore, the smart contract that resides on the blockchain that allows the automation of multi-step processes to self-execute the distributed and heavy workflows is envisaged in the energy industry and the Internet of things [17].

Mnsing et al. [18] further demonstrated that the decentralized consensus techniques and blockchains can be used both to coordinate the scheduling of distributed energy resources in a microgrid, and to guarantee a fair payments without requiring a centralized aggregator.

In summary, the uncontrolled EV charging/discharging may lead to instability of the overall grid system operation. Therefore, it is critical to develop effective charging/discharging scheduling algorithms for efficient grid operations. The proposed scheme considers the uncertainty of future events, including the charging profiles of EVs arriving, future load demand in the grid, etc. Besides, the large-scale charging of EVs requires low-complexity control mechanisms to reduce the operating delay and the capital cost of equipment investments. In this regard, this paper presents an adaptive EV charging/discharging scheduling algorithm based on the blockchain platform, named Adaptive Blockchain-based Electric Vehicle Participation (AdBEV) to execute the information posting and decision making process.

To tackle the problem to be formulated, the Iceberg order management algorithm [19] which has been extensively used in the digital financial trading market is adopted to manage the EV charging and discharging demands. The analogy between the energy market and the financial sector is strongly correlated for energy balancing mechanism in the electricity market, where the impact of placing a large order in the market is similar to demanding a large volume of electricity or injecting too much electricity to the grid network. In order to adapt various types and the charging ports of EV in the market, this paper also considers the battery capacity and charging rates. The stochastic EV user behavior of charging in a city district of London are adopted as the problem constraints in the simulation. The primary contribution of the paper can be summarized as follows:

1) We develop a novel EV participation scheme that introduces the concept of decentralized EV charging and discharging on a blockchain enabled smart grid system;
2) For EV charging schedule, we formulate a charging and discharging schedule problem for EVs on blockchain enabled smart grid system;
3) To minimize the power fluctuation level, we propose the AdBEV scheme based on the iceberg order algorithm that execute the best order strategy to match the smart grid electricity charging and discharging demand;
4) We demonstrate that the proposed AdBEV scheme has better power fluctuation level as compared to the benchmark scheme that uses GA. Additionally, we also show the proposed algorithm can achieve lower computation cost as compared to the benchmark scheme in the Ethereum platform.

The rest of the paper is organized as follows. Section II builds the system model based on the matching imbalances of the EV user profile for charging/discharging. Section III presents the problem formulation and the algorithm description. Section IV demonstrates the simulation results and the
II. SYSTEM MODEL

To extend the previously developed system model from [20], we consider a residential area where the maximum power capacity of a substation transformer is \( P_{\text{max}} \). The participants in the grid system include the conventional large power plants, distributed micro renewable generators and storages which compose the electricity provider side. Besides, the consumer power loads, for example the residential area and hospital, are all connected to the public blockchain power exchanging platform, where the electricity supply and demand information are transmitted, encrypted and saved in the blockchain platform. The electrical grid structure incorporating the public blockchain platform for trading electricity is illustrated in Figure 1.

In this model, it is assumed that the EV is capable of publishing and transmitting the charging or discharging order to the smart grid public blockchain trading platform. The charging/discharging process of EV can be realized by a programmable charging installation. This is to enable the instant on/off switching of the power transmission to the EV as instructed by the grid operator (assuming the sophisticated design of switches). The work flow for the transaction to be processed in the blockchain platform is demonstrated in Figure 2. The electricity orders which include buy and sell are initiated by the driver owners, and orders are entered to the blockchain enabled trading platform as soon as the initiator’s identity is identified. The orders are then processed using the AdBEV scheme and further to be published to the open order book. The matched orders are transacted and verified by the peers in the network. Orders that are finally confirmed by both parties are saved in a distributed manner.

We first define the EV status matrix \( X \) as:

\[
X_{i,t} = \begin{cases} 
1, & \text{if } EV_i \text{ is connected at time } t \\
0, & \text{otherwise}.
\end{cases} \tag{1}
\]

The power demand of EV depends on the battery residual (\( SOC_{\text{ini}} \)) in each EV and the expected SOC (\( SOC_{\text{exp}} \)) after charging. Hence, it can be formulated as follows:

\[
P_{EV}(t) = \sum_{i=1}^{I} \left( X_{i,t} \left( SOC_{\text{exp}}(i) \pm SOC_{\text{ini}}(i) \right) \right). \tag{2}
\]

In the process of scheduling EV charging/discharging, it is important to consider the quantity of the EVs that stay connected to the grid network so that we can infer the maximum time for order waiting. In order to achieve the low power fluctuation level and user satisfaction, this paper combines the charging duration and energy transfer amount to infer the hourly charging demand pattern during a day.

We model the vehicle activity profiles for a typical residential EV charging demand in a day frame referring to [21]. By combining with the charging duration and the amount of energy transfer, we can infer the charging demand pattern during a day. Through examining the characteristic of the EV charging distribution, the amount of power transfer for
EV charging can be modeled as the sum of sines as Equation (3) considering the balance between model accuracy and complexity, and it can be represented by a time segment vector $\eta(t)$ composed the percentage of stay-on-line EV in Equation (4).

$$\kappa_j(t) = \sum_{j=1}^{J} \sum_{t=1}^{T_f} \left(a_j \sin(b_j t + c_j)\right) + \epsilon. \quad (3)$$

$$\eta(t) = [\kappa_1(t), \kappa_2(t), \ldots, \kappa_j(t)] \%. \quad (4)$$

The $T_f$ is the first time step and $T_s$ is second time step elapsed, which enables the formation of a particular fitting in jth order of sine series. The $j$ indexes the order for the sum of sine series which is referred from the Matlab curve fitting toolbox, where $J$ determines the model complexity of the sum of sines. The $a_j$, $b_j$ and $c_j$ are the parameters in the sum of sine series. As the charging load profile indicates that certain numbers of EVs must stay on-line in the process, the number of EV connecting at the charging point in each time frame Equation (4) can be reformulated as:

$$N_{car}(t) = \Omega \cdot [\kappa_1(t), \kappa_2(t), \ldots, \kappa_j(t)], \quad (5)$$

where $\Omega$ is the total number of EVs in an area.

After each iteration of order execution, the power demand after one time segment will change accordingly. Hence, we can reformulate the Equation (2) with the amount of power exchange $Q_t$ as follows corresponding to the order category:

$$P_{EV}(t') = \sum_{i=1}^{I} (X_{i,t'} Q_i) \quad (6)$$

Then, we can define the total residential load as the sum of EV charging/discharging demand and load profile without EV in order to formulate the EV charging problem.

$$P_{total}(t) = P_{home}(t) + P_{EV}(t), \quad t \in T, \quad (7a)$$

$$P_{total}(t) + \xi(t) \leq P_{sub}, \quad \forall t, \quad (7b)$$

$$V_{min} \leq V(t) \leq V_{max}, \quad \forall t, \quad (7c)$$

where $P_{home}$ is the power load without EV. The EV charging/discharging scheduling problem can be solved by aggregating the above random process (7a) with the proposed algorithm. To improve the power system operation, the peak transformer substation load demand must not be exceeded after implementing EV charging/discharging energy to the residential electricity demand. In constraint (7b), the error item $\xi(t)$ denotes power losses or branch overloaded plus the total power load shall not exceed the substation power capacity $P_{sub}$. Hence, there is a maximal number of EV max($N_{car}(t)$) that can be adopted in the grid network to avoid exceeding the substation capacity. Furthermore, we constrain the voltage levels in buses are not allowed to fall outside the maximum and minimum limits in constraint (7c).

### III. PROBLEM FORMULATION AND ALGORITHM DESCRIPTION

The scheduling of EV charging/discharging demand is adopted to minimize the impact of injecting or consuming excess amount of power to the grid. In this case, the study focuses on an adaptive charging/discharging strategy for various types of EV to flatten the load profile of the transformer substation in the distribution network.

#### A. PROBLEM FORMULATION

A half-hourly daily power exchange order book profile of a residential network is applied as the input data in the EV scheduling problem, where the decision parameters are the EV charging/discharging demand for each 24 hours. To levelize the fluctuation level of the whole system, it is necessary to develop an adaptive schedule to fill the gaps of the residential load profile. To describe the measurement of fluctuation level in two consecutive time segments of the grid, the overall utility function is as follows:

$$P_{PFL} = \sum_{t=1}^{T} \|P_{total}(t) - P_{total}(t - 1)\|, \quad (8)$$

where $P_{PFL}$ is the overall power fluctuation level for a day with half-hourly temporal resolution, $P_{total}(t)$ and $P_{total}(t - 1)$ is total power in the transformer at hour $t$ and $t - 1$.

The objective of the system is to minimize the power fluctuation level index $P_{PFL}$ of the overall power grid system with the collections of variables to be optimized for corresponding $i$ and its corresponding $SOC_{exp}$, which can be formulated as follows:

$$\min_{\forall SOC_{exp}(i) \in I} P_{PFL}. \quad (9a)$$

S.T. $\sum_{t=1}^{T} \sum_{i=1}^{I} \left(SOC_{exp}(i) \pm SOC_{ini}(i)\right) = \sum_{t=1}^{T} P_{EV}(t), \quad (9b)$

$$SOC_{ini} \in (0, 1), \quad \forall i, \quad (9c)$$

$$SOC_{exp} \leq P_{max}, \quad \forall i, \quad (9d)$$

$$X_{i,t} \in \{0, 1\}, \quad \forall i, \quad (9e)$$

Equation (9b) limits the total charging and discharging power equal to the order demand from EVs with respect to the available EV number $i$ and the achieved $SOC_{exp}$. Equation (9c) sets the initial SOC to be within the interval $(0,1)$. Though in practice, this constraint may result in a less flattened power load profile, this is to ensure the user demands are satisfied in the process. Constraint (9d) are imposed to guarantee that the maximal SOC after charging does not exceed the EV battery capacity $P_{max}$ for each $EV i$. The constraint in (9e) indicates that one EV can only have two statuses, which are connecting and disconnecting to the grid system.

The formulated problem is a mixed combinatorial non-convex problem due to the binary constraint for EV connection status $X_{i,t}$ in Eq.(8e). In general, there is no systematic
and computational efficient approach to solve this problem optimally. As can be observed, the optimization problem is to designate the optimal number of EVs to execute power transfer, (charging/discharging) thus to minimize the overall power fluctuation level.

B. ADBEV SCHEME

In this section, we propose the AdBEV scheme to solve the above problem by using the electricity exchange book for power trading system. Moreover, the power demand in the next time slot is affected by the previous scheduling results. Hence, it is needed to ensure that the total power charging demand from EV is satisfied while the minimum power fluctuation for the grid system is obtained.

When considering the charging/discharging schedule for EVs, a distributed power exchange system should rely on a price competitive market in order to provide participants the incentive for maximizing their benefits. If participants wish to meet their instant power demand, they have to initiate a high bid price order or a low ask price order. In the mean time, a large order that exceeds the grid network capacity (threshold) should be split into smaller orders according to the order specifications, which in this case the offloading balance can be achieved by tranching the large power demands in a fast responsive manner. In this algorithm, for simplicity we assume the order initiator can only send out one order until it is being executed.

1) NORMAL ELECTRICITY EXCHANGE ORDER

For a electricity exchange order with a small quantity, the demand is formatted as an input to send to the electricity exchange stand book $StdIn$ in the form of a vector which can be denoted as follows:

$$\overrightarrow{O}_i = (\gamma, Id_i, \sigma_i, Q_i),$$

where the $Id_i$ is the unique identifier for the charging/discharging initiators where they can be EVs or other components, the $\sigma_i$ is the agreed unit price for the electricity order, the $Q_i$ is the electricity demand quantity of this order, and $\gamma$ is a matrix indicating whether it is a electricity charging or discharging order:

$$\gamma = \begin{cases} 1, & \text{charging order} \\ 0, & \text{discharging order}. \end{cases}$$

Then for each inserted order message, the solution should be applied to the current book $StdIn$ to generate any matched trades in the order of matching precedence. And all non-error output (each matched trade order) should be directed to the $StdOut$. The trade information format is expressed as follows:

$$\overrightarrow{T}_i = (Id_{sell}, Id_{buy}, \sigma_m, Q_m),$$

where the $Id_{sell}$ and $Id_{buy}$ are the matched electricity buy and sell order identifier respectively, the $\sigma_m$ is the matched price in pence and the $Q_m$ is the matched quantity for the order. Following the receipt of an order message, and after receiving any matches in the book and outputting any generated trade messages, the solutions should display the current full order book in the above format.

2) ICEBERG ELECTRICITY EXCHANGE FORMAT

Assuming that a large participant holds total power demand ($\phi_0$) for exchange and it should be liquidated before time $T_{max}$, then we assign a peak size $\phi_0$ and a limit $\bar{S}$ to this iceberg exchange demand. For the charging demand side, latter is strictly higher than the initial best bid price $S_0$ which is denoted as:

$$S_0 < \bar{S},$$

such that the first proportion of the order is not immediately executable, and vice versa. In order to process the iceberg power exchange smoothly and ensure the benefit gained from participants, it is crucial to choose the price for this demand. According to [19], the best charging price $S_t$ can be modeled by a jump-diffusion process. Since we aim to build a power exchange market for EV users, in order to obtain the guide price for each time interval, for $S_t < \bar{S}$, we adopt the widely used geometric Brownian motion for stock price to model the real-time electricity price in one day:

$$dS_t = \mu S_t dt + \sigma S_t dW_t,$$

where $S_0 < \bar{S}$.

Then, the iceberg format can be formulated as the vector in Equation (16) which integrates the order best price $\sigma_S$, and the total demand $\phi_t$. And the $Q_{pl}$ is the peak size for one trading period which is never greater than $\phi_t$ theoretically.

$$\overrightarrow{O}_i = (\gamma, Id_i, \sigma_S, \phi_t, Q_{pl}),$$

Both the normal and iceberg electricity exchange should be displayed in the order book according to the priority function as follows:

$$f(P_{1p}(n), P_{2l}(n)) = \alpha Rank(Pr) + \beta Rank(T),$$

where $Rank(Pr)$ and $Rank(T)$ are defined as the ranking for price and generation time respectively, and $\alpha = 10\beta$ in order to build a price-competitive market.

Table 1 builds the trading system where the proposed algorithm first initialize the electricity charging and discharging demand and identify the normal and iceberg orders. Then we sort all orders with respect to the ranking function $f(P_{1p}(n), P_{2l}(n))$ in order to match those orders for exchange. After executing all orders within each trade frame interval, it gives the respective response for those orders.
TABLE 1. Electric Trading System with Order Book Initialization.

| Step | Description |
|------|-------------|
| 1.   | Initialization: Initialize the EV electricity exchange order in the Stdin and identify the iceberg order whose place order exceeds the market capacity. Set the order peak size $P_{\text{max}}(t) = Q_{\text{max}}$. |
| 2.   | Sort the orders: Sort all orders according to $f(P_{\text{max}}(n), P_{\text{th}}(n))$. |
| 3.   | For orders $n = 1, ..., N$ at $t \in T$: Match the charging and discharging electricity order according to the adaptive EV charging/discharging algorithm. Send the output orders to the Stdout and calculate the $P_{\text{BEV}}(t)$. |

**TABLE 2. Adaptive Blockchain-Based Electric Vehicle Participation (AdBEV) Scheme.**

| Step | Description |
|------|-------------|
| 1.   | Initialize the priority setting: For order $n = 1, ..., N$: Assign the priority $P(n) = f(P_{\text{th}}(n), P_{\text{th}}(n))$. |
| 2.   | Best order strategy: If the $P_{\text{BEV}}(t)$ in the time frame $t$ in $T$ is satisfied: Execute all matching orders; else if $\left( \sum_{i=1}^{t} O_1(S = 0) \right) < \left( \sum_{i=1}^{t} O_1(S = 1) \right)$: Execute the order according to the priority value $P(n)$, and go to step 3; else: Execute the order according to the priority value $P(n)$, and go to step 4. |
| 3.   | Aggressive iceberg execution: If the order is a normal buy order: Fill the order from the main grid electricity input; else: if $N_{Q_1} = 1$: Wait for the next cycle until reaching the time limit $W_{T_{\text{max}}}$; else: In single price level, old iceberg retains a higher priority; In multiple price level, a higher price retains a higher priority. |
| 4.   | Passive iceberg execution: If the order is normal sell order: Push the order into the next order period and remain the priority until being killed; else: Go back to step 1. |
| 5.   | Repeat: Update the order book in Table 1 and execute. |

In Table 2, we propose a best order strategy to match the electricity charging and discharging demand where three cases are considered. If the power demand is satisfied while maintaining a minimized power fluctuation level, then the algorithm executes all matching orders in the order of price ranking. If the total quantity of electricity sell orders is smaller than the buy orders, it first executes the orders with the highest priority values. Then for the unmatched power demand orders, an aggressive iceberg execution strategy is adopted to match the orders in one time frame ($t \in T$). If the number of iceberg orders equals to 1 ($N_{Q_1} = 1$), it waits until the next cycle with the same priority value, otherwise, they will be assigned with new priorities. In the case of more sell orders occurring, the passive iceberg execution is used where orders are passively waiting for the next cycle execution. For each time frame ($t \in T$), the order book is built and updated.

Since the AdBEV scheme optimizes charging pattern in day-ahead market, if a single day for the whole duration of all the time slots is taken, the proposed scheduling scheme executes only once a day based on the previous EV arrival pattern and residential load profile.

IV. SIMULATION RESULTS

A. EXPERIMENT SETUP

To evaluate the performance of the AdBEV scheme, a residential area substation transformer with $P_{\text{max}} = 250\text{kVA}$ power capacity is used which serves the size of 100 households. We assume that on average each household would have owned one EV. In order to adapt the various types of EV in the market, we choose two types of most popular EV battery capacity of 8.8kWh (Toyota Prius) and 60kWh (Tesla model S) respectively. As for the charging rate, there are different charger connector types for different models from manufacturers, where 3kW (16A) and 43kW (63A) charger compatibility are the typical ones for slow charging and fast charging inlets according to the London local regulations [22]. In the simulation process, the number of EVs for slow and fast charging is set with the ratio of 4:1 according to the availability of the charging ports. Moreover, the EV charge connection status is modeled as two parts, where the first time segment is from 06:00 to 18:00 and the second time segment is from 18:30 to 05:30 (+1). In this model, the initial battery residual ($SOC_{\text{ini}}$) for EVs is randomly generated and the battery level ($SOC_{\text{exp}}$) after charging is set to be 80% for protecting batteries, where the SOC after discharging is set to be 50% for the convenience of EV use.

Considering the distributed trading platform for electricity exchange market, we adopt the Ethereum platform to implement the designed algorithm. The Ethereum platform is a decentralized platform which gives users to run distributed applications in the public blockchain [23]. We use the Solidity language with version 0.4.0 to deploy our smart contract to execute the AdBEV scheme. Henceforth, the gas consumption mechanism from the Ethereum platform provides a direct inspection into the operation complexity in the designed algorithm. In the public blockchain platform, the users have to pay the gas cost in Ethereum platform in order to execute the commands in the smart contract [24]. With the increase in the number of peers in the network, the cost for executing a complex algorithm will largely increase the trade price for the electricity [25].

There are two types of orders we set in the simulation: normal orders and iceberg orders according to Equations (5) and (10). The aim of using iceberg orders is to reduce the power load fluctuation triggered by the orders with large trading quantity. In our simulation, the ratio of the conventional orders and the iceberg orders is around 1:1. In addition, the peak size of the trading quantity ($Q$) in each order is fixed at 4 kW in the simulation. In Table 3, we demonstrate the
Table 3: Power exchange order book.

| S(Buy/Sell) | Id | Price (pence) | Q (kW) |
|-------------|----|---------------|--------|
| Buy         | 12 | 11            | 1.07   |
| Buy         | 70 | 12            | 4      |
| Buy         | 0  | 13            | 2.14   |
| Sell        | 48 | 14            | 1.80   |
| Sell        | 18 | 15            | 0.44   |
| Sell        | 0  | 17            | 4      |

**Figure 3.** Average generated trading price in a day.

The partial order book in our simulation. The data structure is determined by the system model (see Section II). The Buy side orders are ranked in ascending order according to the price where it is in descending order in the sell side, which resembles the stock exchange market with price competitive features. Note that for the iceberg orders, we highlight them with bold figures in the quantity (Q) column. Then the system simulates the exchange process with the order input to calculate the overall price fluctuation with respect to the real-time price.

The price of electricity exchange market is varied according to the iceberg order execution algorithm where the drift of the best bid price has been assumed to be a constant. To keep the setup tractable for exposition, we assume a simplified scenario: the best bid price exhibits a zero drift $\mu = 0$ prior to the submission of the iceberg order. The original price fluctuation interval is set to be $\sigma_t \in (10, 30)$ subject to the local area, henceforth, the order price $\sigma_t$ is modified for certain hours during the day to simulate the retail electricity prices in distribution networks, which are displayed in Figure 3. The price in each hour is calculated from the average price of all the deal orders in each time frame from the order book. As we can see from the figure, the electricity price is higher during 6:00 to 8:00, 11:00 to 13:00 and 17:00 to 19:00, which conforms to the higher power demand $P_{EV}$ for EV charging period as depicted in Figure 3.

**B. POWER FLUCTUATION LEVEL MINIMIZATION**

The simulation result shows the effect of the algorithm to the power load fluctuation is depicted in Figure 4. It compares the daily half-hourly resolution of load profile in a residential area without any EV charging scheduling optimization (top panel) and with the scheduling strategy using GA (bottom panel). In the simulation, we use the domestic residential daily profile from the Elexon report [26]. The red dashed line represents the sum of EV charging demand and residential load in each time frame. The total electricity consumption exceeds the power capacity at 20:30 due to large volume charging needs during this period in this case, with $P_{PFL} = 1.15$ through Equation (7). As in line with [20], after utilizing the scheduling algorithm using GA, the EV charging load is shifted to the off-peak time and the discharging features are considered. It can been seen the GA scheduling algorithm mitigates the peak time electricity consumption with a lower power fluctuation level at $P_{PFL} = 0.85$. Compare with the $P_{PFL}$ index without any scheduling algorithm, the index decreases by 26.1% and the load at substation transformer during the peak period is mitigated.

With the proposed AdBEV scheduling scheme, EV can generate charging or discharging orders to the market with respect to their connection statuses, battery capacity and charging/discharging constraints. This enables the reduction
of the overall power demand fluctuation level where the
optimized result $P^{*}_{PFL}$ with the proposed algorithm is 0.63,
calculated by the Equation (7) which is reduced by 25.9 com-
paring to the $P_{PFL}$ using the GA scheduling algorithm. Using
the optimized EV charging scheme in [20] as the bench mark,
the index $P^{*}_{PFL}$ is proved to be capable of better flattening
the consumption loads which is depicted in Figure 5. Fur-
thermore, when we try to increase the number of EVs in the
network the $P_{EV}(t)$ will increase linearly as we assume the
SOC to be normally distributed [12]. Refer to the overall
utility function Eq. (8), we can see the power fluctuation
level $P_{PFL}$ is aggregated with the absolute value of the power
consumption difference in two consecutive hours, where with
the increase of $P_{EV}(t)$ the ability of minimizing the power
fluctuation level is linearly increased.

C. COMPUTATION COST ANALYSIS

The computation complexity should be noted as the compu-
tation cost is related to the exchange efficiency and cost. The
calculation of the gas corresponds to the low level operation
in the Ethereum Virtual Machine, where each opcode has a
gas related to it. For example, according to [27], the oper-
ators add uses 3 gas as while multiplication two integers
uses 5 gas. Also, it is important to note that all transactions
cost 21000 gas as a base even not interacting with a contract,
where the total gas is the 21000 gas plus any gas associated
with running the contract if you are interacting with a con-
tract.

In Ethereum, we model the theoretical computation cost
with respect to the number of peers in each network as
in Figure 6. Note that the actual cost for gas of a transaction
cannot be determined before the transaction is completed
as the transaction in the same block may alter the result.
However, in most scenarios, providing the estimate is suffi-
cient to refer the algorithm complexity. We can infer that
the benchmark scheduling scheme using GA costs more gas
than the proposed AdBEV scheme. With the increase in the peer
quantity in the network, the total cost for the transaction will
undermine the overall power exchange performance.

V. CONCLUSIONS

In this paper, we proposed an AdBEV scheduling scheme
to minimize the power fluctuation level which enables an
autonomous and secure trading platform for the energy
industry. We modeled the EV stay-on-line model to control
the availability of charging/discharging amount. The iceberg
order execution algorithm is adopted to process the large
demand for scheduling. Simulation results are satisfied and
such results further implies the capability of the proposed
algorithm in substantially decreasing the power fluctuation
level, as well as maximizes the EV driver benefits.

We adapt the most trendy EV battery types and charging
rate to control the charging and discharging process dynam-
ically. The AdBEV scheme provides insight into the struc-
ture for buildings in the transactional energy market into the
blockchain technology to further decentralize the smart grid
system. The proposed algorithm has a lower gas consumption
in the execution process and thus maximizes the order trading
efficiency. Hence, in the future, it is required to find the
balance between the on and off chain complexity, while still
leveraging the decentralized capabilities of the blockchain.

[22] YUE CHEN (S’02–M’03–SM’15) received the B.S. degree (Hons.) from the Beijing University of Posts and Telecommunications, China, in 2000. He is currently pursuing the Ph.D. degree with the School of Electronic Engineering and Computer Science, Queen Mary University of London, U.K. His current research interests include the Internet of Things applications, smart grid, resource allocation optimization, blockchain technology, and cryptocurrency trading.

[23] KOK KEONG CHAI (MICHAEL) received the B.Eng. degree (Hons.) and the M.Sc. and Ph.D. degrees in 1998, 1999, and 2007, respectively. He is currently a Senior Lecturer (Associate Professor) with the School of Electronic Engineering and Computer Science, Queen Mary University of London (QMUL). He is the Internet of Things Program Lead for the Joint Program between QMUL and the Beijing University of Posts and Telecommunications, and a member of the Communication Systems Research Group, QMUL. He has authored over 65 technical journal and conference papers in the areas of machine-to-machine communications, wireless communications, Internet of Things, and smart grid. His research interests include radio resource allocation in device-to-device communication, mobile and wireless communications, energy efficiency of machine-to-machine communications, smart cities applications, smart energy charging schemes, and smart grids.

[24] ENG TSENG LAU received the Ph.D. degree in 2016. His Ph.D. project is based on the joint collaboration research with the U.K. National Physical Laboratory and Brunel University London. His Ph.D. project is related to the quantification of carbon emissions and savings under smart grids. He was a Post-Doctoral Research Assistant for the Project IRENE with the Queen Mary University of London. He is currently a Research Fellow in software development for smart systems with Brunel University London. His research interests include power system integrations, mathematical modeling, and system forecast and optimization.

[25] YUE CHEN received the bachelor’s and master’s degrees from the Beijing University of Posts and Telecommunications, Beijing, China, in 1997 and 2000, respectively, and the Ph.D. degree from the Queen Mary University of London (QMUL), London, U.K., in 2003. She is currently a Professor of telecommunications engineering with the School of Electronic Engineering and Computer Science, QMUL, U.K. Her current research interests include intelligent radio resource management for wireless networks, MAC and network-layer protocoll design, cognitive and cooperative wireless networking, HetNets, smart energy systems, and Internet of Things.
