ABSTRACT

Background. Middle-aged women are at risk of musculoskeletal disorders because of the decreased muscle mass and bone density caused by a decreased endocrine function. Objectives. This study investigated the effectiveness of a stabilization exercise using respiratory resistance on female patients in their 40s with low back pain. Methods. Forty-four female patients in their 40s with low back pain were assigned randomly to an experimental (n=22) or control group (n=22). The experimental group performed lumbar stabilization exercises along with respiratory resistance, and the control group only performed lumbar stabilization exercises, both groups for 60 min per session, three sessions a week, for four weeks. The numeric rating scale (NRS), Korean-Oswestry disability index (K-ODI), Fear-Avoidance Beliefs Questionnaire (FABQ), static balance ability maximum inspiratory pressure (MIP), and maximum expiratory pressure (MEP) were measured before and after the intervention program. Results. Both groups showed significant differences in the NRS, K-ODI, FABQ, balance ability, MIP, and MEP before and after the intervention (p < 0.05). In the length and area of CoP, only the experimental group showed a significant difference (p < 0.05). In the experimental group, the K-ODI, FABQ, balance ability, MIP, and MEP showed significantly better improvement than the control group (p < 0.05). Conclusion. A lumbar stabilization exercise program using the respiratory resistance is an effective method with increased motor function, psychosocial stability, significant improvement in balance, and respiratory pressure in women in their 40s with low back pain.

KEYWORDS: Low back Pain, Respiration, Respiratory resistance, Static balance ability, Maximum Inspiratory Pressure, Maximum Expiratory Pressure

INTRODUCTION

Low back pain (LBP) is a musculoskeletal disorder that frequently occurs in modern society. The disorder is experienced at least once in approximately 90% of adults, and such back pain increases the psychological, economic, and social burdens (1). Unlike the past, current jobs are causing physical activity shortages and lifestyle changes due to automation and office work. These changes have led to a weakening of the abdominal muscles and an imbalance of the body, further leading to serious health problems, such as lumbar deformity (2, 3).

LBP is caused by poor lifestyle and lack of exercise, and the incidence increases with...
Increasing age in women than in men (4). Middle-aged women are in a period of physical aging. Changes in social structure and participation in economic activities have increased, leading to increased stress and physical and psychological burdens both at home and work (5). In particular, females in their late forties at the beginning of menopause show degenerative changes in the lumbar spine due to a decrease in muscle mass and bone density caused by a decrease in female hormones induced by a decrease in endocrine function (6).

An unstable lumbar spine causes abnormal alignment or imbalance and delivers excess gravity and weight to the lumbar spine (7). In addition, the lumbar muscle strength and endurance, and exercise control ability are reduced (8), which causes constant stimulation and stress on the lumbar area. These stimuli and stresses cause the patient to feel physically and mentally uncomfortable, while at the same time appear to decrease the functional motor control skills, such as walking, sitting and daily activities (9, 10). This causes emotional problems, such as anxiety, depression, helplessness, and poor quality of life, as back pain progresses (11).

A dysfunction of the abdominal muscles is associated with LBP (12). The abdominal muscles provide mechanical support to the spine and pelvis, so an instability between the muscles increases if the muscles are not contracted properly (13). Research on lumbar stabilization exercises to improve the stability and function of the abdominal muscles has been actively conducted (14-16). Through this, an exercise program that can improve both the correct posture and balance ability should be performed in parallel (17).

An abdominal drawing-in maneuver (ADIM) has been implemented as a selective training method for the diaphragm and abdominal muscles for LBP. This maneuver is often used in clinical practice to improve symptoms through neuromuscular retraining in patients with LBP and lumbar instability (18). To improve the respiratory function, a contraction of the diaphragm is effective in training respiratory resistance (19). This improves the diaphragm muscle strength and endurance by applying a load to the diaphragm by regulating the flow of air entering during inhalation. In addition, when applied together with a lumbar stabilization exercise program, it solves the instability of the lumbar region (20) and helps improve the lumbar stability (16, 21).

Studies on the effectiveness of respiratory resistance training and stabilization exercises in relation to LBP have been actively conducted, but the reported studies on middle-aged women in their 40s with LBP have been insufficient. This study examined the effects of a stabilization program with respiratory resistance on women in their 40s with LBP on the patient’s pain level, dysfunction, psychosocial factors, balance ability, maximum inspiratory pressure (MIP), and maximum expiratory pressure (MEP).

**MATERIALS AND METHODS**

**Participants.** This study was conducted on 65 female patients in their 40s who were hospitalized for LBP at P Hospital in D City. The inclusion criteria were (1) patients who had experienced LBP at least within the past six weeks, (2) a score of 3 or higher in the numeric rating scale (NRS), (3) three or more positives among the five lumbar instability tests, (4) and people who could stand on one leg for 30 s. The exclusion criteria were patients who had difficulties in motor performance due to pain, participated in less than 80% of the sessions, and had systemic and respiratory diseases, such as cancer, and patients who had compression fractures. The purpose and process of the study were explained to all participants, and they all signed a written consent form that their participation was voluntary. This study was approved by the Ethics Committee and is registered in the WHO International Clinical Trials Registry Platform: KCT0005233.

**Procedures.** This research was a single-blinded, randomized, control trial study. The sample size was calculated using G-power 3.19 software. The alpha level and power were set to 0.05 and 0.8, respectively. According to a previous pilot test, the effective size was set to 0.91; at least 20 participants were required in each group. On the other hand, the minimum number of participants to be selected was 22 after considering a potential dropout rate of 10% (22). This was a randomized control trial, in which the recruited participants underwent lumbar instability testing for selection screening. Lumbar instability testing consisted of the following: 1. lumbar instability test in the prone position, 2. lumbar posterior-anterior mobility test, 3. straight leg raising test, 4. passive lumbar extension test, and 5. under 40 years of age (23). After the
lumbar instability screening tests, this study excluded 21 patients who had positive results in two or fewer tests (n = 15) and a score of 3 or lower in the NRS (n = 6). To compare the effects of the interventions, 44 participants were assigned randomly to the experimental group (n = 22) or the control group (n = 22) using a randomization program (24). The participants were not given information about the group to which they had been assigned. The experimental group performed a lumbar stabilization exercise program using respiratory resistance training, and the control group performed only a lumbar stabilization exercise program. All interventions were provided 60 min a session, three sessions a week, for four weeks. Both groups were measured for the NRS, Korean version of Oswestry disability index (K-ODI), Fear-Avoidance Beliefs Questionnaire (FABQ), static balance ability, MIP, and MEP before and after the intervention. Data after the post-test assessments were recorded for analysis.

**Lumbar Stabilization Exercise Program.** Both groups were given the lumbar stabilization exercise program, which was a modification of the intervention method of Boucher (2016) (25). The stabilization exercise program is an exercise that induces stabilization by controlling the pressure applied from the outside through a contraction of the abdominal muscles and cocontraction of the lumbar muscles. The program consisted of six exercises: curl up, dead bug, superman, bird dog, bridge, and side plank with knee flexion. Stretching for 10 min was performed to warm up and cool down before and after the sessions. Each movement was made for five sets consisting of five repetitions and 10 s each repetition, with a 20 s break between each set. The intervention was implemented for four weeks, three times a week, and 60 min per session.

Curl up - the participants bent both knees in supine. After that, they placed both hands to their chest, and then slowly lifted their chest, shoulders, and head.

Side flank with knee flexion – The participants laid on their side with their knees bent. After that, one shoulder was maintained at 90° to support the trunk, and the pelvis and upper body were lifted to place the opposite arm on the side with the pelvis and knee support. After holding for 5 s, the other side was also executed.

Bridge - The participant immediately bent both knees in the prone position, and then lifted the pelvis in alignment with the thigh.

Dead bug – The participants bent both knees in the supine position. After that, one arm was raised vertically, and the other leg was bent at the knee to keep the shin bone parallel to the floor. After holding for 5 s, the other side was also executed.

Superman - The participant lifted both arms and legs in the prone position.

Bird dog - The participants were in a four-legged pose. After that, one arm was lifted, and the other leg was parallel to the floor. After holding for 5 s, the other side was also executed.

**Lumbar Stabilization Exercise Program Using Respiratory Resistance.** The experimental group performed breathing resistance training simultaneously with the lumbar stabilization exercise program. The exercise program was performed using a respiration-resisting device (Expand-a-Lung®, Miami, USA) that was composed of a silicone mouthpiece and a valve that controls ventilation. The respiration-resisting device controls the amount of ventilation during inhalation and exhalation and results in a resistance of airflow for respiratory muscle strengthening. Using a respiration-resisting device, the resistance level was set to a stage where the participants could stay below 14 in the Borg’s rating of perceived exertion (26).

The lumbar stabilization exercise program using respiratory resistance was as follows (Figure 1).

**Outcome Measures**

**Pain Level.** To identify the pain levels of the participants following the intervention program, the NRS was used. This test was a self-assessment questionnaire, 0 means no pain, 5 means moderate pain, and 10 means unbearable pain. The reliability was high (r = 0.61) (1).

**Dysfunction Level.** K-ODI was used to assess the level of dysfunction in patients with LBP. The K-ODI suggested by Kim (2005) was used to assess the level of dysfunction due to LBP (27). This assessment consisted of nine items: pain level, personal hygiene, lifting objects, walking, sitting, standing, sleeping, social participation, travel, and mobility. The scores range from zero to five, and the highest possible score was 45. The reliability of K-ODI was high (r = 0.92) (28).
Psychosocial Factor. FABQ was used to determine the level of the psychosocial factors in patients with LBP. The FABQ is a self-reported questionnaire that assesses the relationships of the fear-avoidance response, LBP, and dysfunction (29). Five items related to physical activities in FABQ-PA and 11 items related to work in FABQ-W were given on a seven-point scale (0 = Totally disagree, 6 = Perfectly agree) for self-assessment. The score range of FABQ was 0–66; a higher score means a stronger degree. The FABQ Joo (2009) was used, and the reliability of this test was 0.95.

Figure 1. Lumbar Stabilization Exercise using Respiratory Resistance

Balance Ability. A Wii balance board (WBB) (Nintendo, Kyoto, Japan) was used to measure the static balance ability according to the intervention method. The participants stepped on top of the platform WBB to track the sway from the center of pressure (CoP) to derive the path length, velocity, and area 95%. Participants who partook in the study climbed over the WBB and performed one-leg standing motion with the dominant leg, as directed by the physical therapist. The postural disturbances coming from vision was controlled by asking the participants to focus on a dot 15 cm in diameter and 3 m away. The average value measured in three trials was collected using the Balancia program (Mintosys, Seoul, Republic of Korea). The inter-rater reliability of the Wii Balance Board was ICC = 0.92-0.98 (30), and the Balancia program was a helpful assessment tool that standardized the inter-rater reliability (r = 0.79-0.96) and validity (r = 0.85-0.96) (31).

Respiratory Pressure. The subjective Respiratory Pressure of the participants was assessed using a Micro RPM (Carefusion, San Diego, USA). The participants stretched their shoulders in a standing position and spread their legs shoulder width. A mouthpiece equipped with the micro RPM was placed in the mouth, and MIP and MEP were measured. Sufficient rest was provided between MIP and MEP. The maximum value of three measurements was used for data analysis.

Statistical Analysis. Data analysis was performed using SPSS version 21.0 (IBM, Chicago, IL, USA). The general characteristics of the participants were provided using the mean and standard deviation values through descriptive statistics, and the Shapiro-Wilk test was used for normality testing. The normal distribution of all variables from the results was identified. The general characteristics between groups and the homogeneity test of the pre-intervention values were analyzed using a chi-squared test and t-test. An independent-samples t-test and chi-squared test were used to compare the intervention results between the groups, and the paired t-test was used to compare the dependent variables within the groups. Statistical significance was set at P < 0.05.

RESULT

Four patients were excluded as a result of early discharge from the experimental group and the control group, and the data from the total experiment (n = 20) and control group (n = 20) were collected. The general characteristics were similar in the two groups (Table 1).
Table 1. General Characteristics. (Mean ± SE)

|                | Experimental Group (n = 20) | Control Group (n = 20) | t/t2 | P       |

In both groups, the previous values of the dependent variables were homogenous.

Both groups showed significant differences (P < 0.05) in these parameters after the intervention. In addition, the differences in the ODI and FABQ between the groups showed a significant increase in the experimental group compared to the control group (P < 0.05) (Table 2).

Both groups showed significant differences (P < 0.05) in the CoP velocity, MIP, and MEP after the intervention. In addition, the differences in the balance ability, MIP, and MEP between the groups showed a significant increase in the experimental group compared to the control group (P < 0.05) (Table 3).

**DISCUSSION**

This study compared the effects of a lumbar stabilization exercise program with and without respiration resistance on female patients with LBP in their 40’s. Significant improvement of the motor function, psychosocial stability, balance ability, and respiratory muscle strength during inspiration and expiration were noted in the experimental group that performed stabilization exercise using respiratory resistance (P < 0.05).

Middle-aged women have a risk of LBP due to decreased hormones, pregnancy, and childbirth because of their physiological characteristics (32). In addition, as aging progresses, physical changes occur along with decreases muscle strength, muscle volume, and muscle endurance (27). Han (2010) (33) reported that in the case of female LBP, the joints were more stressed due to the increased shear force applied to the lumbar spine because of an increase in the inclination angle of the lumbar lordosis and lumbosacral. Lumbar instability occurs due to physical changes, and chronic LBP results if it continues (34). The stabilization exercises for chronic LBP strengthens the core muscles through isometric contractions of the abdominal muscles, which improves the lumbar stability (35).

Han (2010) reported that in women with LBP, the pain increased due to the increased pressure of the lumbar spine caused by an abnormal increase in shear force due to lumbar hyperlordosis. Park and An (2017) reported that stabilization exercise was effective on the pain levels in women in their 30s and 40s with chronic back pain (P < 0.05, d = 0.50) (36). This study also revealed significant differences in the experimental group (d = 5.21), who performed the lumbar stabilization exercise program using respiratory resistance, and the control group (d = 4.74), who performed only the lumbar stabilization exercise program, which is consistent with the results of a previous study (P < 0.05). Although there was no significant difference between the two groups, a larger effect size was found in the experimental group using respiratory resistance. The stabilization exercise program presented as an exercise program was to activate the muscles around the lumbar spine and abdomen to help improve the stability of the trunk (27) In particular, the strong contraction of the abdomen contributed more to the stability of the trunk during the development of respiratory resistance in the experimental group.

The quality of life decreases when a dysfunction caused by LBP increases the difficulty in daily life (37). This study evaluated the motor dysfunction and pain level of the subjects. Excluding the items related to sexual activities, a percentage was derived from the 45 points total. The level of motor dysfunction decreased from 37% to 20% and 35% to 24% in the experimental and control group, respectively (P < 0.05). In addition, statistically significant improvement was found in the experimental group using the respiratory resistance compared to the control group (P < 0.05). This is thought to have affected the level of pain and dysfunction caused by increased intra-vertebral pressure and increased intra-abdominal pressure due to the stronger contractions during inspiration and expiration.

Back pain causes psychological changes that caused the individual to avoid physical activities and work, potentially causing fibrosis and atrophy (16). Accordingly, the Korean version of FABQ was used to examine the fear-avoidance response before and after the intervention. As a result, the level of psychological anxiety was decreased significantly in both groups participating in the study (P < 0.05). In addition, compared to the control group, the experimental group using respiratory resistance showed a more significant difference (P < 0.05). In the experimental group in which stabilization exercise was performed using respiratory resistance, the decrease in the fear of physical movement and daily activities was greater as the ability of exercise function increased through stronger deep muscle contraction.

Jo (2011) reported that in the case of a patient with LBP, the trunk stability was reduced.
compared to a healthy adult without back pain when examining one leg with the dominant leg. In this study, the balance ability was evaluated by one leg standing to evaluate the movement performance of women with LBP. As a result, there was a significant difference in the velocity, path length, and area 95% of CoP between the experimental using respiratory resistance and the control group (P < 0.05). In the case of LBP, mobilization and muscle activity of the deep muscles of the trunk and the muscles of the hip joint are different from those of normal persons when one leg standing is performed (38). To prevent and reduce dysfunction, muscles of the trunk of the body should be strengthened, and unnecessary exercise should be prevented (39). Through this, the stabilization exercise using respiratory resistance contributed to the stability of the trunk by increasing the co-contraction of the deep muscles responsible for stabilizing the trunk muscles. As a result, the indicator of balance ability was improved. The respiratory pressure test is a non-invasive method that measures the muscle strength of the inspiratory and expiration muscles and used as a test to measure the ventilation and respiratory insufficiency during inspiration and expiration (40-42). In this study, a stabilization exercise using breathing resistance was conducted to examine the change in respiratory pressure. As a result, all participants in this study who conducted the exercise programs showed significant improvement in the respiratory pressure (P < 0.05). In addition, in the experimental group using the respiratory resistance showed a greater difference than in the control group (P < 0.05). This is believed to have contributed to the respiratory muscle strength because of the contractile capacity of the lung and strengthening of the diaphragm muscle during inspiration through respiratory resistance training. As a result, high-intensity respiratory resistance training of stabilization exercise using respiratory resistance increased the stability of the lumbar spine. In addition, it helped improve the motor function, psychosocial stability, and balance ability by affecting the abdominal muscle contractility due to the improvement of respiratory muscle strength. This study had some limitations. First, the participants in the study consisted only of women in their 40s, making it difficult to generalize to men of the same age or patients with LBP. Second, incorrect breathing occurs when participants breathe simultaneously through the nose and mouth using a breathing resistor. To prevent this, breathing was induced only by the mouth, and the exercise program using a breathing resistor was unfamiliar. Therefore, an adaptation period of approximately one to two days and prior practice are required. Third, although the amount of change in the respiratory pressure was confirmed through the respiratory resistor, the amount of change in lung vitality was not confirmed.

**CONCLUSION**

This study examined the effects of a lumbar stabilization exercise program using respiratory resistance on the pain, dysfunction, psychosocial factor, balance ability, and respiratory pressure of female patients in their 40s with LBP. The results showed an increased motor function, psychosocial stability, significant improvement in balance, and respiratory pressure. These results show that lumbar stabilization exercise using respiratory resistance is beneficial to patients with female patients in their 40s with LBP. Future studies will modify the difficulty levels of respiratory resistance training, and encourage interest in the stabilization exercise program to increase respiratory functions and decrease the LBP effectively.

**APPLICABLE REMARKS**

This study supports that a lumbar stabilization exercise program using respiratory resistance can improve motor function, psychosocial stability, balance and respiratory pressure in female patients in their 40s with LBP.

**CONFLICTS OF INTEREST**

No potential conflict of interest relevant to this article was reported.
