Abstract – We investigate the evolution of the electronic structure of Ce$_2$Rh$_{1-x}$Co$_x$Si$_3$ as a function of $x$ employing high resolution photoemission spectroscopy. Co substitution at the Rh sites in antiferromagnetic Ce$_2$RhSi$_3$ leads to a transition to a Kondo system, Ce$_2$CoSi$_3$ via the Quantum Critical Point (QCP) at $x = 0.6$. High resolution photoemission spectra reveal distinct signature of the Kondo resonance feature (KRF) and its spin-orbit split component (SOC) in the whole composition range indicating finite Kondo temperature scale at QCP. The intensity ratio of KRF and SOC exhibits gradual increase with the decrease in temperature in the strong hybridization limit. The scenario is reversed if the Kondo temperature becomes lower than the Néel temperature. The dominant temperature dependence of the spin-orbit coupled feature in this regime suggests the importance of spin-orbit interactions in the realization of spin-density wave quantum criticality.

Introduction. – Quantum criticality [1] in heavy fermion systems is obtained by tuning the magnetic phase transition temperature to zero by external non-thermal control parameters like pressure, chemical composition, magnetic field, etc. The study of quantum criticality has attracted a great deal of attention recently due to the finding of non-Fermi-liquid excitations in the properties of metals, for instance near the magnetic instability in correlated systems. The quantum critical point (QCP) separates two entirely different ground states: i) long range magnetically ordered state and ii) paramagnetic/non-magnetic Fermi liquid state [2]. While the physics in the ground states on either sides, far away from the QCP, are reasonably well understood, the physics in the vicinity of QCP is a long standing puzzle [3–5]. The question to be answered is how the quantum critical fluctuations affect the electronic excitations and how electronic excitations evolve as one gradually moves from one side of QCP to the other side.

In order to address the issue, in the context of Kondo lattice physics, we studied an archetypical system Ce$_2$Rh$_{1-x}$Co$_x$Si$_3$ — the compounds in the whole composition range crystallize in an AlB$_2$-derived hexagonal structure with space group $P\bar{6}/mmm$ as shown in fig. 1 [6–8]. The valence band consists of Si 3p, Co 3d and Rh 4d electronic states [9,10]. Since the binding energy of the 4d electronic states is higher than the 3d electronic states and 3d electrons are relatively more correlated due to smaller radial extension, [11,12] the substitution of Co at Rh sites influences the effective $d$-$p$ hybridization as well as the itineracy of the conduction electrons that leads to a plethora of interesting properties. For example, one of the end members, Ce$_2$RhSi$_3$ exhibits antiferromagnetic ordering at about 7 K [6]. Various studies involving lattice compression/expansion via external pressure or chemical substitutions suggested that this compound lies close to the peak of Doniach’s magnetic phase diagram [13,14]. The sample with $x = 0.6$ composition exhibits quantum critical behavior such as non-Fermi-liquid behavior in the electrical transport measurements. The compositions with

[a]E-mail: kbmai@tifr.res.in
$0 < x < 0.6$ exhibit antiferromagnetic ordering. It was shown that application of high pressure on the compounds in this composition range leads to a change in properties similar to that observed via change in composition [15]. The magnetic susceptibility measurements on the other end member, Ce$_2$CoSi$_3$, does not show magnetic ordering down to 0.5 K akin to a Kondo lattice compound with an estimated Kondo temperature, $T_K$ of about 44 K. The temperature dependence of electrical resistivity of Co-end members appears to be similar to a typical mixed valent Kondo lattice system [6,16].

In this article, we present our results of investigation on the evolution of electronic structure as a function of Rh/Co concentration employing high resolution photoemission spectroscopy. The high resolution spectra exhibit distinct signatures of Kondo resonance feature and its spin-orbit coupled component in the whole composition range. The relative intensity of the Kondo resonance feature with respect to the spin-orbit split feature exhibits distinctly different temperature evolution in the different parts of the phase diagram — a feature not recognized so far in the previous literature.

**Experimental details.** — High quality samples of Ce$_x$Rh$_{1-x}$Co$_3$Si$_3$ for various values of $x$ were prepared in the polycrystalline form by arc melting —growth of the material from congruently molten phase ensured large grain size with homogeneous stoichiometry. The samples are characterized by X-ray diffraction, transport and magnetic measurements as described elsewhere [6]. The photoemission measurements were carried out using high resolution Gammadata Scienta electron analyzer, SES2002 and monochromatic photon sources at a base pressure better than $3 \times 10^{-11}$ torr. The energy resolutions were set to 300 meV at Al $K\alpha$ (1486.6 eV) photon energy, and 5 meV at He $\Pi$ (40.8 eV) and He I (21.2 eV) photon energies. The samples were very hard and could not be cleaved or fractured. Hence, the sample surface was cleaned by in \textit{situ} scraping at each temperature using a fine grained diamond file and the surface cleanliness was ensured by the absence of O 1s and C 1s signals. The reproducibility of the spectra was ensured after each trial of surface cleaning. The Fermi level was determined at each temperature by measuring the Fermi cutoff in the spectral function of high purity silver mounted in electrical contact with the sample. The temperature variation down to 5 K was achieved using a open cycle helium cryostat, LT-3M from Advanced Research Systems, USA.

**Results and discussions.** — The photoemission measurements were carried out on four compositions, namely, $x = 0.0$ (antiferromagnetic), 0.3 (30% Co substituted and antiferromagnetic), 0.6 (corresponds to QCP), 1.0 (Kondo compound) that span the whole range of the solid solution with varied properties. In fig. 2(a), we show X-ray photoemission (XP; $h\nu = 1486.6$ eV) valence band spectra collected at 5 K for the above four compositions (energy resolution used for these spectra = 0.6 eV). The spectra primarily consist of two groups of features. The signals corresponding to Ce 5p$_{3/2}$ and 5p$_{1/2}$ photoemission appear at 17.5 eV and 20.3 eV binding energies, respectively. The features close to the Fermi energy, $\epsilon_F$ constitute the valence band. Since Ce concentration is the same in all the samples, the spectra have been normalized by the Ce 5p peak intensity. It is evident that the spectral weight around 2.8 eV gradually reduces with the decrease in Rh content.

To probe this region with greater clarity, we have obtained the high resolution (resolution = 0.3 eV) XP spectra of the valence band region close to $\epsilon_F$ as shown in fig. 2(b) after integral background subtraction — a typical background function is shown in fig. 2(a) by solid line. The spectral intensity within 1 eV of $\epsilon_F$ does not change significantly with $x$ — a small increase is observed around 0.5 eV, while there is a large decrease in intensity around 2.8 eV with the increase in Co content. Such an anomalous change can be attributed to the large photoemission cross-section of Rh 4d states ($\sim$0.012) compared that for Co 3d states ($\sim$0.0037) [17]. In order to better visualize the spectral evolution due to substitution, we renormalized the same spectra by the intensity at 1.5 eV, binding energy as shown in fig. 2(c). The increase in intensity corresponding to Co 3d photoemission is shown by gray shade and the decrease Rh 4d intensity is shown by blue shade — the gradual change in spectral intensities with the increase in $x$ is beautifully manifested in the figure. These results suggest dominant Co 3d contributions close to $\epsilon_F$, whereas Rh 4d contribute at higher binding energies.

The energy band structure calculations were performed for the end members Ce$_2$RhSi$_3$ and Ce$_2$CoSi$_3$ using full potential linearized augmented plane wave method (FLAPW) within the local density approximations using Wien2k software [18]. The lattice constants and all other structural details were obtained from the literature [6]. The calculated Ce 5p, Rh 4d/Co 3d and Si 3p partial density of states (PDOS) for Ce$_2$RhSi$_3$ and Ce$_2$CoSi$_3$ are shown in fig. 2(d) and (e), respectively. The results reveal dominance of the contributions of Rh/Co d states in the valence band. The Rh 4d PDOS appear around...
3 eV binding energies consistent with the experimental observations. The Co 3d states peak around 1 eV binding energy. Clearly, the calculated results correspond well with the experimental background function.

The d PDOS seem to have influenced the conduction electron-Ce 4f hybridization (cf hybridization) significantly – Ce 4f PDOS width is broader in Ce2RhSi3 relative to that in Ce2CoSi3 as shown in the inset of fig. 2(c). Moreover, the intensity of Co 3d PDOS in the Ce 4f region is stronger than the Rh 4d contributions in the same energy range. These observations suggest stronger Co 3d-Ce 4f hybridization than Rh 4d-Ce 4f hybridization. Evidently, the proximity of the d states has a strong influence on cf hybridization [19,20] in addition to the influence of lattice volume change often referred to in these systems [6].

In fig. 3, we compare the photoemission spectra collected using He i, He ii and Al Kα photon energies at 5 K. All the spectra are normalized by the intensities between 1 and 2.5 eV binding energy range. The features in He ii and XP spectra are quite similar except the fact that the XP spectra are broader due to higher resolution broadening. Two distinct and sharp features appear in the vicinity of \( \epsilon_F \) in the He ii spectra of both Ce2RhSi3 and Ce2CoSi3 [9,10]. The He i spectra, however, do not exhibit these intensities. Considering contributions of various electronic states near \( \epsilon_F \) depicted in figs. 2(d) and (e), and the dependence of their photoemission cross-section [17], the sharp features near the Fermi level can be attributed primarily to the photoemission from Ce 4f electronic states. The feature near \( \epsilon_F \) corresponds to \( 4f_{7/2} \) photoemission and is a manifestation of the Kondo resonance features. The corresponding spin-orbit split component \( 4f_{5/2} \) feature appears at a relatively higher binding energy (∼260 meV). In fig. 3(c), we show the He ii spectra of all the compositions at 5 K exhibiting gradual decrease of Rh 4d intensity with the increase in \( x \) as also observed in the XP spectra.

Considering significant enhancement of the Ce 4f contributions in the He ii spectra relative to the other contributions in the same energy region, one can extract
The Ce 4f spectral function by subtracting the He I spectra from the He II spectra as often done in similar Ce-based systems. The peak of the Kondo resonance feature usually appears just above the Fermi energy (unoccupied) and the photoemission spectroscopy probes the higher binding energy tail of the Kondo peak [21,22]. Thus, the extracted 4f spectral weight by the difference (He II – He I) depicting the occupied part of the Ce 4f PDOS would provide a good estimation of the Kondo resonance feature.

The (He II – He I) spectra at different temperatures are shown in fig. 4(a) for different compositions separately. The spectra of all the compositions exhibit a sharp feature near $\epsilon_F$ — the intensity of the feature reduces gradually with the increase in temperature suggesting the presence of Kondo compensation effect in every case despite the fact that the magnetism in these materials is widely varied. The intensity of the Kondo resonance feature at a particular temperature gradually increases with the increase in $x$. Since the Kondo temperature increases with the increase in $x$, the above observation suggests that the intensity of the Kondo resonance feature is directly related to the Kondo temperature, $T_K$ [5]. While such a scenario is expected in a Kondo system, a similar observation in long range ordered systems ($x < 0.6$) indicates the existence of a finite Kondo temperature scale even in these cases.

The Kondo coherence temperature for the intermediate compositions estimated [6] from the electrical transport properties is $\sim 8$ K for $x = 0.3$ and $\sim 50$ K for $x = 0.6$. When the measurement temperature is below the coherence temperature, there will be additional complications due to the expansion of the Fermi volume and presumably manifested in the evolution of the Kondo resonance feature. The Kondo temperatures for the compositions $x = 0.0$, 0.3 and 0.6 are 12 K, 30 K and 40 K, respectively [6]. The photoemission spectra collected at 120 K and 150 K are well above the coherence temperature, Kondo temperature and Néel temperature for all the compositions and still exhibit finite intensity of the Kondo resonance feature. At all the temperatures, we find a qualitatively similar trend of the evolution of the Kondo resonance feature across the solid solution indicating that the spectral weight redistributions, if any, due to the onset of the Kondo coherence are not altering the inferences drawn. This manifests applicability of the single impurity Kondo physics in the electronic structure [23] and the Kondo temperature scale remains finite at the QCP.

The intensity of the corresponding spin-orbit split feature ($4f_{7/2}$ signal) appearing around 260 meV binding energy (marked by a vertical dashed line in fig. 4(a)) in each of the samples also reduces as the temperature is increased. Interestingly, the intensity of the $4f_{7/2}$ signal seems to be similar in all the compositions although the intensity of the Kondo resonance feature at the Fermi level increases with the increase in Co concentration. At finite temperature, the spectral intensity representing the occupied part of the density of states becomes lower at $\epsilon_F$ due to the thermal effect represented by the Fermi-Dirac distribution function. The Fermi-Dirac distribution function depletes the intensity below $\epsilon_F$ and enhances the intensity above $\epsilon_F$ in a symmetric manner with the increase in temperature. We have subtracted the room temperature spectra from the spectra at different temperatures ($I(\epsilon,T) - I(\epsilon,300K)$) to investigate the spectral weight transfer with temperature. Such exercise would provide a change in spectral weight symmetric with respect to the Fermi level in a Fermi liquid system. The subtracted spectral functions, shown in fig. 4(b), however, exhibit asymmetric spectral evolutions with temperature — the gain of spectral weight below the Fermi level is larger than the loss of weight above the Fermi level. Such an effect appears in the presence of a peak such as the Kondo resonance peak in the vicinity of the Fermi level. The asymmetry seems to be weaker towards the Rh end, indicating a weaker Kondo peak. This clearly indicates that the temperature dependence of the Kondo peak and the spin-orbit peak is different.

To investigate the spectral changes with composition, $x$, at a particular temperature, we re-plot the Ce 4f spectral functions as a function of composition at a particular temperature in fig. 5(a). The experimental spectra exhibit a gradual increase in intensity of both peaks with the increase in $x$ that can be associated to the change in the Kondo temperature as discussed above and also observed earlier in other Ce-based compounds [5].

We compare the evolution of the intensities of the Kondo resonance peak and its spin-orbit split component in

![Fig. 4](Colour on-line) (a) The evolution of the extracted Ce 4f spectral functions with temperature for different compositions. (b) The spectral weight transfer obtained by subtracting the room temperature spectra from the spectra at different temperatures.
In order to deconvolve the Fermi Dirac distribution induced depletion of the spectral density of states at the Fermi level, we symmetrized the spectra with respect to the Fermi level if \( I(\epsilon) \) represents the spectral function, the symmetrized spectra can be expressed as

\[
I(\epsilon) = I(\epsilon - \epsilon_F) + I(\epsilon_F - \epsilon).
\]

It is often found that the intensity at the Fermi level can be estimated quite accurately by such symmetrization process, which is independent of the presence/absence of particle-hole symmetry. The symmetrized spectra are shown in fig. 5(b) exhibiting the intensity of the Kondo resonance feature (KRF).

The estimated intensities of the 4\( f^7/2 \) spin-orbit peak (SOC) obtained from fig. 4(a) and the Kondo peak (KRF) obtained from fig. 5(b) are shown in fig. 6(a) for \( \text{Ce}_2\text{RhSi}_3 \), fig. 6(b) for \( \text{Ce}_2\text{Rh}_{0.7}\text{Co}_{0.3}\text{Si}_3 \), fig. 6(c) for \( \text{Ce}_2\text{Rh}_{0.4}\text{Co}_{0.6}\text{Si}_3 \) and fig. 6(d) for \( \text{Ce}_2\text{CoSi}_3 \). Interestingly, the compositions exhibiting long range order show a weaker temperature dependence of the Kondo resonance feature (KRF) compared to the spin-orbit coupled (SOC) peak — the trend gets reversed on the other side of the phase diagram. This is shown by plotting the relative intensity ratio (KRF/SOC) in the insets of fig. 6(e) in the corresponding phase regime. In the weak hybridization limit, the intensity ratio, KRF/SOC, decreases with the decrease in temperature — the Kondo peak grows less rapidly than the spin-orbit peak. On the other side (strong coupling limit), the ratio KRF/SOC gradually increases with the decrease in temperature. The trend at the quantum critical point follows the strong coupling behavior.

Kondo effect essentially arises from the hybridization of the conduction electrons with the impurity moment. It is well known that in the strong coupling limit, the electrons corresponding to the local moment form a quantum mechanically entangled state with the conduction electrons, termed as Kondo singlet. In such a scenario, the Fermi surface expands due to the additional contribution from the electrons forming the local moment — here the 4\( f \) electrons. The Kondo temperature provides an energy scale deriving the expansion of the Fermi volume [24,25]. Various experiments indicated that the Kondo temperature scale vanishes at the approach to QCP [3,23,26]. Theoretical studies suggested the other limit of finite \( T_K \) at QCP termed as spin-density wave quantum criticality [4]. The results in the present study reveal a finite Kondo temperature scale at the QCP in the solid solution \( \text{Ce}_2\text{Rh}_{1-x}\text{Co}_x\text{Si}_3 \), suggesting that the magnetic Ce 4\( f \) electrons near QCP acquire itineracy at lower temperatures — the antiferromagnetism near the QCP occurs.

Fig. 5: (Colour on-line) (a) The evolution of the extracted Ce 4\( f \) spectral functions with composition, \( x \), at different temperatures. (b) The spectral functions obtained by symmetrizing the experimental spectra to estimate the spectral weight at the Fermi level.

Fig. 6: (Colour on-line) Intensity variation of the Kondo resonance feature (KRF) and its spin-orbit coupled (SOC) component as a function of temperature of (a) \( \text{Ce}_2\text{RhSi}_3 \), (b) \( \text{Ce}_2\text{Rh}_{0.7}\text{Co}_{0.3}\text{Si}_3 \), (c) \( \text{Ce}_2\text{Rh}_{0.4}\text{Co}_{0.6}\text{Si}_3 \) and (d) \( \text{Ce}_2\text{CoSi}_3 \). (e) A schematic phase diagram showing the long range ordered region (yellow) and Kondo compensated region separated by a quantum critical point (QCP). The left and right inset shows the intensity ratio of KRF/SOC as a function of temperature for the corresponding compositions in \( \text{Ce}_2\text{Rh}_{1-x}\text{Co}_x\text{Si}_3 \). \( T_N \) and \( T^* \) represent the Ne\'el temperature and Kondo coherence temperature and are obtained from ref. [6].
among the itinerant electrons and hence indicates the applicability of an SDW picture in these cases [9,15]. Interestingly, the spin-density wave states correspond to systems possessing a spin-orbit coupling strength stronger than the Kondo coupling strength—the finite Kondo temperature scale helps to impinge itineracy among Ce systems possessing a spin-orbit coupling strength stronger than its spin-orbit split counterpart if the Kondo temperature becomes lower than the magnetic ordering temperature. The spin-orbit part shows a stronger temperature dependence if the Kondo temperature becomes lower than the ordering temperature. These results show that the spin-density wave quantum criticality can be realized in systems possessing strong spin-orbit coupling, and finite hybridization between conduction electronic states via tuning their relative interaction strengths.

**Conclusions.** – In summary, we studied the evolution of the electronic structure of Ce$_2$Rh$_{1-x}$Co$_x$Si$_3$ using high resolution photoemission spectroscopy. The signature of Kondo resonance feature is revealed in the high resolution low temperature specific heat of all the compounds providing evidence of finite Kondo temperature scale at the quantum critical point. Interestingly, the temperature dependence of Kondo resonance feature is found to be stronger than its spin-orbit split counterpart if the Kondo temperature is higher than the magnetic ordering temperature. The spin-orbit part shows a stronger temperature dependence if the Kondo temperature becomes lower than the ordering temperature. These results show that the spin-density wave quantum criticality can be realized in systems possessing strong spin-orbit coupling, and finite hybridization between conduction electronic states via tuning their relative interaction strengths.
