ABSTRACT

The properties of the first generation of black hole seeds trace and distinguish different models of formation of cosmic structure in the high-redshift universe. The observational challenge lies in identifying black holes in the mass range $\sim 100$–$1000 M_\odot$ at redshift $z \sim 10$. The typical frequencies of gravitational waves produced by the coalescence of the first generation of light seed black hole binaries fall in the gap between the spectral ranges of low-frequency space-borne detectors (e.g., LISA) and high-frequency ground-based detectors (e.g., LIGO, Virgo, and GEO 600). As such, these sources are targets for proposed third-generation ground-based instruments, such as the Einstein Telescope which is currently in design study. Using galaxy merger trees and four different models of black hole accretion—which are meant to illustrate the potential of this new type of source rather than to yield precise event-rate predictions—we find that such detectors could observe a few to a few tens of seed black hole merger events in three years and provide possibly unique information on the evolution of structure in the corresponding era. We show further that a network of detectors may be able to measure the luminosity distance to sources to a precision of $\sim 40\%$, allowing us to be confident of the high-redshift nature of the sources.

Key words: black hole physics – gravitational waves

1. INTRODUCTION

An ability to probe the nature of the first massive black hole (MBH) seeds at medium-to-high redshift is fundamental to understanding the hierarchical assembly scenario, to discriminate between different models of structure formation in the high-redshift universe and to explore the link between black holes residing at the center of galaxies and their hosts (Sesana et al. 2007). If MBH seeds are massive (i.e., $\sim 10^3 M_\odot$), the future space-borne gravitational wave (GW) detector LISA (Bender et al. 1998) will probe the first epoch of mergers between these seeds at high redshift. However, if MBH seeds are light (i.e., $\sim 100 M_\odot$), the GWs from these mergers will fall between the sensitive frequency band of LISA and of currently operating and planned advanced versions of ground-based instruments—LIGO, Virgo, and GEO 600 (see Sigg et al. 2008; Acernese et al. 2008; Grote et al. 2008 for recent status reports). In this Letter, we show that third-generation laser interferometers may be able to fill this gap by directly probing the first mergers between light MBH seeds and will thus provide complementary information to other instruments.

If seed black holes (BHs) are the remnants of Pop III stars with mass $\sim 100 M_\odot$ (Madau & Rees 2001; see Sesana et al. 2007 for a short review of this and alternative scenarios) we expect dozens of MBH binary (MBBH) coalescences per year in the mass range $\sim 10^2$–$10^6 M_\odot$ (Sesana et al. 2004; NB we will use MBHB liberally to refer to any binary formed between black holes in the centers of merging dark matter halos). Most of the MBHB events occur at redshift $z \gtrsim 3$, with the consequence that LISA will be able to detect MBHBs down to $\sim 10^2 M_\odot$ with a signal-to-noise ratio $(S/N) \gtrsim 10$, but will not probe lower masses. To probe the $10^2$–$10^3 M_\odot$ range, a new GW telescope with optimal sensitivity in the frequency window 0.1–10 Hz is needed. This could be achieved either by a second-generation space-based detector, such as the Big Bang Observer (Phinney et al. 2003), ALIA (Bender et al. 2005), or DECIGO (Kawamura et al. 2006), or by the third generation of ground-based laser interferometers, for which the target is $\sim 10$-fold strain sensitivity increase over Advanced LIGO and a low-frequency cutoff at $\sim 1$ Hz (the Einstein gravitational-wave Telescope (ET) target sensitivity is compared to other instruments in Figure 1). In this Letter, we focus on third-generation ground-based instruments as these are presently undergoing conceptual design studies, and for reference we use the specific example of the ET (see, e.g., Freise et al. 2009). We demonstrate that instruments such as the ET can detect seed black hole binaries, albeit at likely rates of no more than a handful a year, and discuss whether such observations can uniquely identify these events as produced by light remnants of Pop III stars.

2. MODELS FOR POP III SEED GROWTH

The astrophysical scenario that we consider in this Letter assumes that seed black holes of mass $\sim 100 M_\odot$ are produced by the first generation of supernovae in the very high redshift universe at $z \approx 20$. These black holes are efficient at accreting mass and hierarchically merge following mergers between their host halos. We can trace the merger hierarchy by means of Monte Carlo merger-tree realizations based on the extended Press–Schechter formalism (Press & Schechter 1974), assuming a standard lambda cold dark matter ($\Lambda$CDM) cosmology with the one-year WMAP cosmological parameters (Spergel et al. 2003); technical details are given in Volonteri et al. (2003; VHM) and Volonteri et al. (2006; VSH). We consider four variants of this model, which have the same merger history for the dark matter halos, but different prescriptions for the mass distribution and accretion efficiency of the seeds: (1) VHM,ems (VHM with equal-mass seeds) is based on equal 150 $M_\odot$ seeds accreting at the Eddington limit during each merger episode; (2) VHM,smd (VHM with seed-mass distribution) differs from VHM,ems only in the seed-mass distribution, which is log-normal in the range 10–600 $M_\odot$; (3) Shank has black hole seeds with flat mass distribution in the range 150–600 $M_\odot$ and redshift-dependent accretion efficiency, following Shankar et al. (2004); (4) Hopk
The total mass of 500 $M_\odot$ for an equal-mass, optimally oriented source with a redshifted characteristic noise amplitude spectral densities $\sqrt{M}$ range 150–600 again assumes black hole seeds with flat mass distribution in the range $100-600 M_\odot$ and accretion efficiency that is luminosity-dependent according to the prescription given by Hopkins et al. (2005).

Integrated over cosmic history, all these models reproduce the X-ray and optical quasar luminosity function at $z < 3$, the observed faint X-ray counts of active galactic nuclei (AGNs; see VSH), and, integrated over all MBH masses, predict about 50–70 black hole coalescences per year in the universe. This range is statistical and does not include uncertainties in assumptions about, e.g., cosmology, that go into the merger trees, which could change the number of predicted events by a factor of a few in either direction. The accretion models considered here have been tuned to reproduce observations at low redshift, $z < 3$, rather than accretion onto seed black holes at $z > 5$. Recent work has indicated that accretion onto 100 $M_\odot$ black holes is inefficient (Alvarez et al. 2008; Milosavljevic et al. 2008) and generally sub-Eddington. This adds further uncertainties to the light seed scenario, but we emphasize that our choice of models is guided by the goal of illustrating the science potential of this new class of observations rather than an attempt to provide solid predictions for event rates.

3. WAVEFORM AND DETECTOR MODELS

To compute the sensitivity of the ET to GWs generated during the coalescence of seed MBH binaries, we model the gravitational wave emission with the phenomenological waveform family (IMR) introduced by Ajith et al. (2008). This describes radiation from a nonspinning black hole binary and includes in a self-consistent manner the inspiral, merger, and ring-down phases; these phases are marked in Figure 1, which shows a typical frequency-domain gravitational waveform $\tilde{h}(f) \equiv A(f)e^{i\psi(f)}$. Figure 1 also indicates that a significant fraction of the signal is contributed by the merger and ring-down, so an inspiral-only waveform would be inadequate.

Exact expressions for the amplitude $A(f)$ and the phase $\psi(f)$ of the IMR waveforms are provided by Equations (4.17), (4.18), and (4.19) and Table I of Ajith et al. (2008). The strain at the detector depends on the total redshifted mass $M_z \equiv (1 + z)M$, the symmetric mass ratio $\eta$, a fiducial time of arrival parameter $t_0$, and six extrinsic parameters—two sky-position angles, the orbital phase at time $t_0$, the wave polarization angle $\psi$, the source inclination angle with respect to the line of sight $i$, and the luminosity distance to the source $D_L$. The optimal $S/N$ at the instrument is $S/N^2 = 4 \int_0^\infty df |\tilde{h}(f)|^2/S_n(f)$, where $S_n(f)$ is the one-sided noise power spectral density of the interferometer, as shown in Figure 1. For a network of detectors, the total network $S/N$ is obtained by adding the $S/N$s of the individual instruments in quadrature. We report $S/N$s averaged over the sky location of the source and its orbital-plane orientation.

As a check, we also computed the $S/N$ for some events using the effective-one-body-numerical-relativity (EOBNR) waveform family introduced by Buonanno et al. (2007). The $S/N$s predicted by the EOBNR waveforms are typically somewhat higher (by up to ~25%) for equal-mass events, and are comparable for all events except those with very asymmetric mass ratios, $\eta \ll 1$, where neither waveform family has been shown to be valid.

The currently favored design for the ET calls for a 10 km triangular facility containing three 60$^\circ$ detectors (Freise et al. 2009); we refer to this design as a “single ET.” We use the noise power spectral density defined in Hild et al. (2008) for a single right-angle 10 km detector. The angle-averaged sensitivities achieved by two right-angle detectors and three 60$^\circ$ detectors (single ET) are factors of $\sqrt{2}$ and 3/2 higher, respectively, than for one right-angle 10 km instrument.

4. DETECTION-RATE ESTIMATES

For each of the four scenarios described in Section 2, we have generated 1000 independent realizations of the galaxy merger history and computed the $S/N$ of all coalescences that take place over a time span of three years, representative of a typical data-taking period for a third-generation instrument. Figure 2 shows the number of events that would be seen by the third-generation network in three years as a function of the $S/N$ in a single right-angle 10 km detector within the network, for each of the four models. Assuming that a network $S/N$ of 8 would be required for detection, the $S/N$ in one 10 km detector would be 5.3 for a single ET or 4.4 (3.9, 3.2) if one (two, four) additional 10 km detector(s) were added. Figure 2 indicates that in all models except Shank, we could expect to detect a few to a few tens of events over three years. The Shank model predicts fewer than one event in a single ET.

The ET will be sited underground, which should make it possible to suppress seismic gravity-gradient noise (Hughes & Shank...
Thorne 1998) and achieve sensitivity at frequencies as low as \sim 1 Hz (compare Advanced LIGO, Figure 1); however, it is not currently clear whether it will be possible to mitigate this noise source below \sim 3 Hz. In addition, the ET may suffer a confusion background in the 1–5 Hz range due to cosmological compact-binary systems (Regimbau & Hughes 2009). The impact of such a background on Pop III event rates needs to be properly quantified, but we have checked this crudely. The preceding results assumed a low-frequency cutoff of 1 Hz (which is also the cutoff we use for parameter estimation), but we found that only \sim 25% of the events were lost with a higher cutoff at 5 Hz. We conclude that design changes or a confusion background should not affect our qualitative conclusions.

Figure 3 indicates the distribution of masses and redshifts for the events that would be detected under each scenario. We see that most events have intrinsic masses of a few hundred \(M_\odot\) (down to a few tens in the VHM,smd model), although a few events with \(M \gtrsim 1000 M_\odot\) might also be observed. Many of the events will be at medium-to-high redshift, \(5 \lesssim z \lesssim 10\), except in the VHM,smd model which predicts a distribution peaked around \(z \sim 4\) with a long tail extending to \(z > 12\). Most of the observable events are related to the hierarchical assembly of small-to-medium size parent halos (masses in the range \(10^{11} - 10^{13} M_\odot\) at \(z = 0\)). In such halos, seeds are less likely to experience coalescences accompanied by major accretion episodes at high redshift, and they are more likely to have \(M \lesssim 1000 M_\odot\) at \(z = 10\), leaving them in the band accessible to third-generation detectors.

The number of events and their redshift distribution may provide constraints on both the mass function and accretion history of seed black holes in the early universe. Considering our example scenarios, in the Shank model seeds are born quite massive (150–600 \(M_\odot\)) and they accrete at the Eddington limit at high redshift (see Equation (2) in VSH); in this model, most of the seeds grow above 1000 \(M_\odot\) by \(z = 10\), making detection with ground-based detectors difficult. In the Hopk model, accretion is on average less efficient and many of the seeds are still in the few-hundred solar-mass range at \(z < 10\), making detection easier. The initial seed mass distribution may also leave a detectable signature on the observed events. The VHM,ems and VHM,smd models are characterized by the same Eddington-limited accretion prescription; nonetheless, their mass and redshift distributions are significantly different. In the VHM,ems model most of the 150 \(M_\odot\) seeds grow at high \(z\), radiating outside the 1–1000 Hz band; only the “tail” of \(\lesssim 10^3 M_\odot\) black holes left behind at \(z < 10\) is detectable. In the VHM,smd model, there are many \(< 100 M_\odot\) seeds which would be observable at very high redshift (\(z > 10\)). Many of them will grow inefficiently, and still have masses \(\sim 100 M_\odot\) at low redshift, making them perfect targets for ET; however, it may be impossible to discriminate between coalescences involving these low-\(z\) Pop III remnants and those involving intermediate-mass BHs (IMBHs) formed at low redshift. IMBHs might form via runaway collisions of massive stars in globular clusters (Portegies Zwart et al. 1999; but see Glebbeek et al. 2009), and scenarios have been proposed in which IMBH binaries also form (Fregeau et al. 2006). The IMBH masses considered there, \(\sim 10^3 M_\odot\), are somewhat higher than seed black hole masses, \(\sim \text{few} \times 100 M_\odot\). Therefore, if we observe an IMBH merger at \(z \gtrsim 5\) with masses \(\sim 100 M_\odot\), we can be fairly confident that the constituent black holes are Pop III seeds. Further work will be needed to identify what observational signature(s) provide the best discriminating power between these two formation channels.

This current work indicates that, while probing seeds mostly at \(z < 10\), third-generation detectors may provide useful insights into the properties and accretion history of seed black holes at higher redshift. LISA will be able to probe deeper in redshift, since ground-based detectors are limited at low frequency by a gravity-gradient “noise wall” at 1 Hz. However, LISA will not be able to observe seed black hole mergers because it is not sufficiently sensitive in the relevant frequency range (see Figure 1). LISA will only provide indirect constraints on seed black hole populations through observations of subsequent mergers of black holes in the mass range \(10^4 - 10^6 M_\odot\).

5. PARAMETER-ESTIMATION RESULTS

In order to identify an event as a seed black hole merger, we must be able to determine the redshift and mass of the system. As mentioned earlier, events at low redshift \(z \lesssim 3\) might not involve primordial black holes. A gravitational-wave observation determines the redshifted total mass \((1 + z) M\) and luminosity distance \(D_L(z)\), but not the redshift \(z\) independently. It is unlikely that electromagnetic counterparts to ET events will be observed, but if we assume a concordance cosmology inferred from other observations, we can determine the redshift from the luminosity distance. The fractional redshift error is then comparable to the fractional luminosity-distance error, plus an \(O(10\%)\) error from uncertainties in the cosmology.

We used the Fisher information matrix to evaluate the parameter-estimation errors. We carried out a Monte Carlo simulation over the extrinsic parameters for fixed choices of the intrinsic parameters, \(M_s\) and \(\eta\). We note that this approach may overstate the precision of parameter estimation at low \(S/Ns\) (Vallisneri 2008); a more rigorous study of parameter-estimation accuracy would require the computation of the full posterior probability density function and is beyond the scope of the present paper.
The intrinsic parameters, $M_\ast$ and $\eta$, are determined by the waveform phase evolution and so we expect to measure them well. The extrinsic parameters, by contrast, affect only the relative amplitudes of the signal. A single ET makes four independent measurements (two quadratures in two detectors) and so at least one additional interferometer is needed to determine the six extrinsic parameters. We computed parameter-estimation errors for several network configurations consisting of an ET at the location of Virgo and additional interferometers at Hanford and Livingston. At a fixed network S/N of 8, we found that for all networks $M_\ast$ and $\eta$ would be determined to a fractional accuracy better than 1% for all but the most massive systems ($M_\ast \sim 1000 M_\odot$). The distance, and hence redshift, will be determined less accurately. One ET plus a second 10 km interferometer will be enough to determine the distance to better than $\sim 40\%$ in 68% of cases. The addition of a third 10 km detector will improve this distance precision to $\sim 30\%$. Upgrading the 10 km detectors to ET's leads to further modest improvements, but would also increase the S/N accumulated from a source at a fixed distance. We also explored siting the second detector in Perth, Australia, instead of Hanford, but found little net difference in parameter-estimation accuracy. The error in the source-frame mass is dominated by the error in $z$ rather than that in $M_\ast$, and so is also $\sim 40\%$. Therefore, we should be able to say confidently that a source at $z \sim 5$ is at high redshift and has $M \sim 100 M_\odot$, and hence is most likely a seed black hole merger.

6. DISCUSSION

Information about seed black holes is extremely difficult to obtain using present or future electromagnetic observations. The only direct means to study seed black holes is via gravitational-wave observations of mergers. If seed black holes are remnants of Pop III stars at high redshift, then LISA may not be able to probe the early stages of their evolution. In this Letter, we have analyzed the ability of third-generation ground-based interferometers, such as the proposed Einstein Telescope, to detect the coalescences of $100–1000 M_\odot$ seed black hole binaries for a range of seed properties and accretion histories.

We have found that third-generation detectors will be able to detect $\sim 1–30$ events over a three-year observation, depending on the selected model and on the assumed telescope configuration. The distribution of detected masses, ranging from a few $\times 10 M_\odot$ to a few $\times 1000 M_\odot$, is complementary to the range probed by LISA, making the detection of low-mass seeds possible. The noise wall at 1 Hz will preclude the detection of sources at very high redshift, although in the case of a seed black hole, making the detection of low-mass seeds possible. The noise wall at 1 Hz will preclude the detection of low-mass seeds.

Previous work (Wyithe & Loeb 2004) indicated that advanced LIGO might detect Pop III seeds. That work used a seminal analytic model for structure growth and our current work contradicts their results, suggesting that their model significantly overpredicted the number of mergers occurring at low redshift. There are various sources of uncertainty in our analysis. Our waveform model ignored the effects of black hole spin and higher gravitational-wave harmonics, which tend to enhance the S/N and increase the event rate. These effects also help to break degeneracies between parameters, improving the validity of the Fisher Matrix approach to computing parameter accuracies used in this Letter. However, the S/N threshold of 8 may be optimistic when source confusion and realistic instrumental noise are taken into account. The merger-tree models have various uncertainties, such as the choice of cosmological parameters, e.g., $\sigma_8$, which could change the rates by a factor of a few in either direction. More work is also needed to understand how to distinguish IMBH binaries formed in globular clusters from seed black holes. Despite these uncertainties, this Letter is a proof of concept which clearly demonstrates that third-generation ground-based instruments have the capability to detect seed black holes, allowing us to confirm (or discard) the hypothesis that MBH seeds are light remnants of Pop III stars, and suggests that this could be one of the science drivers for these instruments.

We thank M. Volonteri for useful discussions and for providing the Monte Carlo realizations of the halo and MBH merger hierarchy. A.S. acknowledges support from NSF grant Nos.
