Learning Reduced Nonlinear State-Space Models: an Output-Error Based Canonical Approach

Steeven Janny¹, Quentin Possamai¹, Laurent Bako³, Christian Wolf⁴ and Madiha Nadri²

Abstract—The identification of a nonlinear dynamic model is an open topic in control theory, especially from sparse input-output measurements. A fundamental challenge of this problem is that very few to zero prior knowledge is available on both the state and the nonlinear system model. To cope with this challenge, we investigate the effectiveness of deep learning in modeling of dynamic systems with nonlinear behavior by advocating an approach which relies on three main ingredients: (i) we show that under some structural conditions on the to-be-identified model, the state can be expressed in function of a sequence of the past inputs and outputs; (ii) this relation which we call the state map can be modeled by resorting to the well-documented approximation power of deep neural networks; (iii) taking then advantage of existing learning schemes, a state-space model can be finally identified. After the formulation and analysis of the approach, we show its ability to identify three different nonlinear systems. The performances are evaluated in terms of open-loop prediction on test data generated in simulation as well as a real world data-set of unmanned aerial vehicle flight measurements.

Keywords: nonlinear system identification, state-space models, model reduction, deep learning, auto-encoding

I. INTRODUCTION

A large majority of deployed methods from control theory have as a prerequisite the provision of relatively precise dynamic model characterizing the temporal evolution of the state variables at stake. This model generally plays a central role, since the performance of the control method is often directly related to the accuracy of the model [2], [8], [24]. Consequently, modeling and identification of a dynamic system is an essential preliminary step, since it will serve as foundation for additional processing, such as controller or observer design. However, this is not a trivial task: in the general case, the system is complex, non-linear, and involves physical phenomena that are often difficult or even impossible to model correctly without strongly impacting the required computation time. On the other hand, the identification of the parameters of a non-linear model is a non-convex problem, which can require tremendous hours of calibrations and experiments. Moreover, identification of a dynamic system often requires the intervention of domain experts and the ability to freely interact with the system.

The development of data-driven techniques for the identification of non-linear systems has provided a promising response to these issues and has received great interest over the last decade (see for example [12], [14], [17]). Specifically, neural networks propose to remove the burden of modeling by replacing it with the collection of massive datasets from the system of interest. Modeling methods based on deep learning constitute an alternative solution to painstaking physical modeling. The main idea is based on the use of an extremely versatile model, capable of approaching most dynamics with a certain degree of precision, that can be directly identified from pairs of input-output measurements in the case of dynamic systems, provided that these measurements gather enough information necessary to approximate the true dynamic. Nevertheless, the great flexibility of neural networks comes at the cost of a lack of mathematical structure making it difficult to perform theoretical analysis in terms of robustness, precision and stability. Moreover, learning complex, high-dimensional dynamical systems is not straightforward. The general formulation leads to latent dynamic models lacking of meaningful physical structure and requires large dimensional state spaces.

In this article, we propose a new identification structure for nonlinear state-space systems from a set of observation trajectories and associated inputs. We demonstrate the existence of a regressor inspired by finite impulse response models allowing to map a series of past observations to future outputs, and provide bounds derived from the prediction error during deployment. We then deduced a high-dimensional canonical state-space model discovered using an output-error based approach and propose to learn an auto-encoder projecting the dynamics into a smaller state-space. We evaluate our proposal on different systems in simulation and in the real world.

II. RELATED WORK

Data-driven dynamic models are widely studied in the community and get a lot of attention. In particular, [6], [9], [20] propose to find governing physical equations by performing a sparse regression from the data. At the junction between physical model and learning, [13], [15], [23], [25] use neural networks to model complementary phenomena not described by the initial physical model. In particular, [2], [18], [22] extend the dynamic model of a unmanned aerial vehicle with a neural network in charge of predicting aerodynamic disturbances, which are often very demanding and intractable for real time physical simulation.
A substantial part of recent publications in system identification has therefore naturally turned to the use of deep learning. The most common approach consists in learning an auto-encoder structure that projects observations of the dynamical system into a higher-dimensional latent space in which the dynamics can be identified. The form of the latent dynamics can then take different forms: Koopman operator [5, 19], KKL observer [7, 11], [16], or, more generally, any sufficiently expressive neural network [3], [4], [14], [26].

Our proposal differs from this line of works in three main points: (1) we provide theoretical results and conditions for the existence of the dynamical system that we identify, (2) we propose to use a high-dimensional regressor structure without explicit state representation, which will be deduced from a dimensionality reduction operation and (3) we evaluate our approach on challenging and unstable systems.

**Notation.** \( \mathbb{R} \) and \( \mathbb{N} \) denote the sets of reals and natural numbers respectively. \( \| \cdot \| \) refers to a generic norm on some appropriate space.

### III. Problem Statement and Preliminary Results

#### A. Problem statement

We consider a nonlinear discrete-time system of the general form

\[
\begin{align*}
x_{t+1} &= f^o(x_t, u_t) \\
y_t &= h^o(x_t, u_t) + w_t,
\end{align*}
\]

with \( x_t \in X \subset \mathbb{R}^{n_x} \), \( u_t \in U \subset \mathbb{R}^{n_u} \), \( y_t \in Y \subset \mathbb{R}^{n_y} \) being the state, the input and the output of the system at discrete time \( t \in \mathbb{N} \) respectively. \( f^o : \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \to \mathbb{R}^{n_x} \) and \( h^o : \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \to \mathbb{R}^{n_y} \) are some nonlinear vector-valued functions. As to \( w_t \in \mathcal{W} \subset \mathbb{R}^{n_w} \), it represents measurement noise. We will make the following important assumptions:

1. The external signals \( u \) and \( w \) take values in compact sets \( U \) and \( \mathcal{W} \) respectively with \( \mathcal{W} \) being such that \( 0 \in \mathcal{W} \).

2. The state-space \( X \) is a compact set containing the initial state \( x_0 \).

3. \((X, U, \mathcal{W}, Y)\) and \((f^o, h^o)\) satisfy the following invariance conditions: 

   \[
   \forall (x, u) \in X \times U, f^o(x, u) \in X \\
   \forall (x, u, w) \in X \times U \times \mathcal{W}, h^o(x, u) + w \in Y
   \]

4. \( f^o \) (and \( h^o \)) are uniformly Lipschitz continuous on \( X \times U \subset \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \) with respect to \( U \), i.e., there exists a constant \( \gamma_f > 0 \) such that \( \| f^o(x, u) - f^o(x', u) \| \leq \gamma_f \| x - x' \| \) for all \((x, u) \in X \times U \).

The assumptions 1–4 are required essentially to theoretically ensure the well-definedness of optimization problems that will be expressed later in the paper. Of course, in the context of system identification, such types of assumptions are not intended to be checked prior to applying the method to be developed.

The problem of interest in this paper can be stated as follows: given a finite number \( N \) of input-output data pairs \( \{(u_t, y_t) : t = 1, \ldots, N\} \) generated by a nonlinear system of the form (1), find an appropriate dimension \( n_x \) of a state-space representation along with estimates of the associated functions \( f^o \) and \( h^o \). Here, the number \( n_y \) of outputs and the number \( n_u \) of inputs are known a priori. However the dimension \( n_x \) of the state is a parameter of the model which needs to be estimated along with the maps \((f^o, h^o)\).

We develop a solution in three steps: first, a nonlinear regression model is derived from the data-generating system equations in (1). The underlying nonlinear map is then modelled by a deep neural network structure and trained with the available data following an output-error framework. Given this map, one can readily form an equivalent canonical state-space representation of (1) with, however, the drawback that its dimension may be high. Hence, the third and last step of the proposed procedure consists in model reduction, an objective which is achieved through the design of an appropriate encoder-decoder.

#### B. Preliminary results

An important challenge concerning the identification of the system (1) is the fact that the state \( x_t \) is not entirely measured. We therefore need to express it first as a function of the available past input-output measurements \( \{(u_\tau, y_\tau) : \tau < t\} \).

Indeed, if the noise \( w_t \) in (1) is assumed to be identically equal to zero, then under appropriate observability conditions on the system, there exists a time horizon \( \ell \) and a map \( \phi : \mathbb{R}^\ell \to \mathbb{R}^{n_x} \), with \( \ell = (n_u + n_y) \), such that the state \( x_t \) can be written as

\[
x_t = \phi(z_t)
\]

with \( z_t = (u_{t-\ell}^\top y_{t-\ell}^\top \cdots u_{t-1}^\top y_{t-1}^\top)^\top \) being the so-called regressor vector. To show the existence of such a map \( \phi \), some observability conditions on the system to be identified (1) are needed. For this purpose let us start by introducing some notations. For a positive integer \( i \), let \( F_i : \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \to \mathbb{R}^{n_x} \) be the map defined recursively from the function \( f^o \) in (1) as follows: for \( x \in \mathbb{R}^{n_x} \) and \((u_1, \ldots, u_i) \in \mathbb{R}^{im_u} \),

\[
F_i(x, u_1, \ldots, u_i) = f^o(F_{i-1}(x, u_1, \ldots, u_{i-1}), u_i).
\]

Before proceeding further, let us mention a useful property of the maps \( F_i \).

**Lemma 1:** Under Assumption 3, if \( f^o : \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \to \mathbb{R}^{n_x} \) is uniformly \( \gamma_f \)-Lipschitz on \( \mathcal{X} \times U \) with respect to \( U \), then the map \( F_i \) defined in (3) is uniformly \( \gamma_f \)-Lipschitz on \( \mathcal{X} \times U^i \) with respect to \( U^i \subset \mathbb{R}^{im_u} \).

**Proof:** The proof of this lemma is straightforward and is therefore omitted.

For notational simplicity, let us pose \( \tilde{u}_{i+1} = (u_1, \ldots, u_i) \).

Now consider the function \( \mathcal{O}_i : \mathbb{R}^{n_x} \times \mathbb{R}^{i n_u} \to \mathbb{R}^{i n_y} \) given
by
\[ O_t(x, u_{1:j}) = \begin{pmatrix} 
\hat{h}^c(x, u_1) \\
\hat{h}^c(F_1(x, u_1), u_2) \\
\vdots \\
\hat{h}^c(F_{j-1}(x, u_{1:j-1}), u_j) 
\end{pmatrix}. \] (4)

**Definition 1:** The system (1) is said to be finite-time observable over a time horizon \( r \in \mathbb{N} \) if for each \( \bar{u} \in U^r \), the function \( O_r(\cdot, \bar{u}) \), with \( O_r \) defined as in (4), is injective.

Note that if the observability property in Definition 1 holds for some \( r \in \mathbb{N} \) then it holds as well for any \( i \geq r \).

**Proposition 1 (Existence of the map \( \hat{o} \)):** If the nonlinear system (1) (considered under the assumption that \( w \equiv 0 \)) is finite-time observable in the sense of Definition 1, then there exist \( \ell \in \mathbb{N} \) and a (nonlinear) map \( \hat{o} : \mathbb{R}^L \to \mathbb{R}^{n_x} \) such that (2) holds for all time \( t \geq \ell \), any initial state in \( \mathcal{X} \) and any input signal taking values in \( U \).

**Proof:** For discrete time indices \( (i,j) \) with \( i \leq j \), let \( \bar{y}_{i:j} = (y_i^T \cdots y_j^T)^T \) be a vector of outputs from time \( i \) to time \( j \). Likewise define \( \bar{u}_{i:j} = (u_i^T \cdots u_j^T)^T \). By iterating the system equations, it is easy to see that
\[ \bar{y}_{t-\ell|t-1} = O_t(x_{t-\ell}, \bar{u}_{t-\ell|t-1}). \] (5)

By the finite-time observability assumption on the system, \( O_t(\cdot, \bar{u}) \) admits an inverse for any given \( \bar{u} \in U^\ell \). Denote with \( O_t^*(\cdot, \bar{u}) : Y^\ell \to \mathcal{X} \) the inverse map of \( O_t(\cdot, \bar{u}) \) which is such that \( O_t^*(O_t(x, \bar{u}), \bar{u}) = x \). It hence follows from (5) that
\[ x_{t-\ell} = O_t^*(\bar{y}_{t-\ell|t-1}, \bar{u}_{t-\ell|t-1}) \] (6)

which, by recursively applying the first equation of (1), gives
\[ x_t = F_t (O_t^*(\bar{y}_{t-\ell|t-1}, \bar{u}_{t-\ell|t-1}), \bar{u}_{t-\ell|t-1}) \triangleq \hat{o}(x_t). \] (7)

Consider now the more realistic scenario where the (unknown) measurement noise sequence \( \{w_t\} \) is nonzero. Then Eq. (5) becomes
\[ \bar{y}_{t-\ell|t-1} = O_t(x_{t-\ell}, \bar{u}_{t-\ell|t-1}) + \bar{w}_{t-\ell|t-1}. \] (8)

As a consequence, the state can no longer be obtained exactly by Eq. (6) or (7) since \( \bar{y}_{t-\ell|t-1} \) does not lie in the range of \( O_t(\cdot, \bar{u}_{t-\ell|t-1}) \). Let in this case the state \( x_{t-\ell} \) and \( \hat{x}_{t-\ell} \) be estimated by
\[ \hat{x}_{t-\ell} \in \arg \min_{x \in \mathcal{X}} \| \bar{y}_{t-\ell|t-1} - O_t(x, \bar{u}_{t-\ell|t-1}) \|, \]
\[ \hat{x}_t = F_t (\hat{x}_{t-\ell}, \bar{u}_{t-\ell|t-1}), \] (9)

Given the same norm \( \| \cdot \| \) on \( \mathbb{R}^{n_x} \). The optimization problem in (9) is well-defined since, by Assumptions 1-4, the function \( x \mapsto \| \bar{y}_{t-\ell|t-1} - O_t(x, \bar{u}_{t-\ell|t-1}) \| \) is defined on a compact set \( \mathcal{X} \) and is continuous. These, by the extreme value theorem, are sufficient conditions for the existence of a minimum and for the existence of the minimizer \( \hat{x}_{t-\ell} \) as defined above.

In contrast, the estimates \( \hat{x}_{t-\ell} \) and \( \hat{x}_t \) need not be uniquely defined in a general setting. Uniqueness would require some more strict conditions on the system under consideration.

Here, we will be content with a set-valued version \( \hat{o} \) of \( o \) in the noisy estimation scenario. Hence let \( \hat{o} \) be defined by
\[ \hat{o}(z_t) = \{ F_t (\hat{x}_{t-\ell}, \bar{u}_{t-\ell|t-1}) : \hat{x}_{t-\ell} \text{ as in (9)} \}. \]

A question we ask now is how far the noisy estimate (9) lies from the true state \( x_t \). To study this, a stronger notion of observability is introduced as follows.

**Definition 2:** The system (1) is called finite-time uniformly observable over a time horizon \( \ell \in \mathbb{N} \) if there exists a constant \( \alpha_{\ell} > 0 \) such that for each \( \bar{u} \in U^\ell \),
\[ \| O_t(x, \bar{u}) - O_t(x', \bar{u}) \| \geq \alpha_{\ell} \| x - x' \| \] (10)

for all \( (x, x') \in \mathbb{R}^{n_x} \times \mathbb{R}^{n_x} \). Based on this property, it is possible to bound the error between the noisy estimate (9) and the true state.

**Proposition 2:** Under Assumptions 1-4, if the system (1) is finite-time uniformly observable over a time horizon \( \ell \in \mathbb{N} \) in the sense of Definition 2, then
\[ \| \tilde{x}_{t-\ell} - x_t \| \leq 2\gamma_{f} / \alpha_{\ell} \| \bar{w}_{t-\ell|t-1} \| \] (11)

where \( \gamma_{f} \) is the Lipschitz constant of \( f^0 \) (See Assumption 4) and \( \alpha_{\ell} \) is the constant appearing in (10).

**Proof:** It follows from the definition (9) of \( \hat{x}_{t-\ell} \) that
\[ \| \bar{y}_{t-\ell|t-1} - O_t(\hat{x}_{t-\ell}, \bar{u}_{t-\ell|t-1}) \| \leq \| \bar{y}_{t-\ell|t-1} - O_t(x_t, \bar{u}_{t-\ell|t-1}) \|, \]

for all \( x \in \mathbb{R}^{n_x} \). In particular this inequality holds for \( x = x_{t-\ell} \). By then invoking (8) we get
\[ \| O_t(x_{t-\ell}, \bar{u}_{t-\ell|t-1}) - O_t(\hat{x}_{t-\ell}, \bar{u}_{t-\ell|t-1}) + \bar{w}_{t-\ell|t-1} \| \leq \| \bar{w}_{t-\ell|t-1} \|. \]

By the triangle inequality property of norms, it follows that
\[ \| O_t(x_{t-\ell}, \bar{u}_{t-\ell|t-1}) - O_t(\hat{x}_{t-\ell}, \bar{u}_{t-\ell|t-1}) + \bar{w}_{t-\ell|t-1} \| \]
\[ \geq \| O_t(x_{t-\ell}, \bar{u}_{t-\ell|t-1}) - O_t(\hat{x}_{t-\ell}, \bar{u}_{t-\ell|t-1}) \| - \| \bar{w}_{t-\ell|t-1} \|, \]

Combining with the previous inequality yields
\[ \alpha_{\ell} \| \tilde{x}_{t-\ell} - x_{t-\ell} \| \leq \| O_t(x_{t-\ell}, \bar{u}_{t-\ell|t-1}) - O_t(\hat{x}_{t-\ell}, \bar{u}_{t-\ell|t-1}) \| \]
\[ \leq 2\| \bar{w}_{t-\ell|t-1} \|. \]

Here, the first inequality is a consequence of the assumption of uniform finite-time observability. As a consequence, \( \| \tilde{x}_{t-\ell} - x_{t-\ell} \| \leq 2\alpha_{\ell} \| \bar{w}_{t-\ell|t-1} \| \). The result follows now by applying (9), the uniform Lipschitz assumption on \( f^0 \) stated in 4 and Lemma 1.

It can be observed from the expression of the error bound (11) that the more strongly the system is observable (that is, the larger the constant \( \alpha_{\ell} \)), the more robust the estimate \( \hat{x}_t \).
the measurement function $h_t$ into the output equation of (1), which gives $w_z$ with $\xi_t$ for some nonlinear function $\mathbf{H}$ as defined in (16) (b) Training: the Fig. 1: (a) Block diagram of our canonical reduced state space representation as defined in (16) (b) Training: the a high dimensional (canonical) state-space representation this problem, note by Proposition 2 that the true state of $u$ with $z_t$ is a function of $z_t$, we end up with the expression $y_t = H^\circ(\hat{x}_t, u_t) + \xi_t$ for some nonlinear function $H^\circ$. $h(x_t) = 10^{-1} \|w_t - \hat{w}_{t-1}\|$. Consider now plugging the state estimate $\hat{x}_t$ into the output equation of (1), which gives

$$y_t = h^\circ(\hat{x}_t + \delta_t, u_t) + w_t$$

$$= h^\circ(\hat{x}_t, u_t) + \xi_t,$$

with $\xi_t$ being an error component entirely due to the noise. It is indeed equal zero whenever $w \equiv 0$. It can be shown that $\xi_t$ can be written as $\xi_t = u_t + \hat{\delta}_t$ with $||\hat{\delta}_t|| \leq \gamma h_t^\circ ||\tilde{w}_{t-\ell-1}||$, where $\gamma_h$ is the Lipschitz constant of the measurement function $h^\circ$ of system (1). Since $\hat{x}_t$ is a function of $z_t$, we end up with the expression $y_t = H^\circ(\hat{x}_t, u_t) + \xi_t$

(12)

for some nonlinear function $H^\circ$.

Remark 1: In the absence of noise, the exact expression of $H^\circ$ is $H^\circ(\hat{x}_t, u_t) = h^\circ(F_t(\mathcal{O}_t^*(z_t), \eta(z_t)), u_t)$ with $\eta(z_t) = \tilde{u}_{t-\ell-1}\). The first step of the identification method is to construct a high dimensional (canonical) state-space representation whose state is the vector $z_t$ defined in (2). More precisely, consider

$$\begin{aligned}
z_{t+1} &= \tilde{A}z_t + \tilde{B}u_t + \tilde{S}H^\circ(z_t, u_t) + \tilde{\xi}_t \\
y_t &= H^\circ(z_t, u_t) + \xi_t,
\end{aligned}$$

(13)

where $\tilde{A} = A \otimes I_{n_x+n_y}, \tilde{B} = e_{n_x-1} \otimes I_{n_x}, \tilde{S} = e_{n_x} \otimes I_{d_y}, e_i \in \mathbb{R}^{n_x}$ being the canonical basis vector which has 1 in its $i$-th entry and zero everywhere else, $\otimes$ referring to the Kronecker product and $A \in \mathbb{R}^{n_x \times n_x}$ given by:

$$A = \begin{pmatrix}
0 & 1 & 0 & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
0 & \cdots & 1 & 0 & 0 \\
0 & \cdots & 0 & 1 & 0 \\
0 & \cdots & 0 & 0 & 1
\end{pmatrix}.$$ 

From (12) it can be seen that (13) constitutes a state-space representation for system (1) since both models have the same input-output behavior for $t \geq \ell$.

Given a finite set of input-output data points $\{(u_t, y_t)\}_{t=1}^{T+\ell}$, an estimate of the function $H^\circ$ can be obtained in a certain nonlinear model class $\mathcal{H}$ as $\hat{H} = \arg \min_{H \in \mathcal{H}} J(H)$, where $J(H)$ is a regression loss given as

$$J(H) = \frac{1}{T} \sum_{t=1}^{T} \alpha_t ||y_t - H(\hat{z}_t, u_t)||^2,$$

s.t. $\hat{z}_{t+1} = \tilde{A}\hat{z}_t + \tilde{B}u_t + \tilde{S}H(\hat{z}_t, u_t), \hat{z}_{t+1} = z_{t+1},$ (15)

where $\alpha_t$ is a weighting coefficient such as $\alpha_{t+1} = 10$ and $\alpha_t = 1$ for all $t = \ell + 1, \ldots, \ell + T$. Regression starts after a burn-in phase of $\ell$ steps (i.e. the window size), which are needed to construct a full state-representation.

Our ansatz for this paper is to propose a canonical method for system identification and model reduction. This guides the choice of model class $\mathcal{H}$ to neural networks, which proved to be impressively efficient for a wide range of engineering applications. We evaluated two classical neural network structures, namely multi-layer perceptron (MLP) and gated recurrent unit (GRU). However, the equations described above are not tied to these specific models, and can be adapted to various structures, such as KKL/Koopman observer, LPV systems, backstepping, etc... yielding any relevant stability or robustness properties adapted to downstream tasks.

B. Model reduction

Despite their undeniable success, neural networks tend to model dynamical systems with high dimensional latent state space. In effect, the model described in (13), although structurally simple, may suffer from a high dimensional state vector $z_t$. This may be a concern for some applications. We therefore propose a second deep learning structure allowing nonlinear state-space model reduction by encoding the state variable $z_t$ into a low dimensional state variable $\hat{x}_t \in \mathbb{R}^n$ for some user-defined dimension $n \in \mathbb{N}$. Formally, we train an auto-encoder $\mathcal{E}, \mathcal{D}$ such that $\hat{x}_t = D(\bar{x}_t)$ and $z_t = D(\hat{x}_t)$. By applying these maps to Eq. (13) and neglecting the noise

$$\bar{x}_{t+1} = \tilde{A}\bar{x}_t + \tilde{B}u_t + \tilde{S}H(\bar{x}_t, u_t),$$

$$\bar{y}_t = H(\bar{x}_t, u_t) + \xi_t,$$
terms, we get an approximate representation of the initial system (1) as follows:
\[
\begin{align*}
    \bar{x}_{t+1} &= \mathcal{E}(\bar{A}\bar{x}_t) + \bar{B}u_t + \bar{S}\bar{H}(\bar{D}(\bar{x}_t), u_t) \\
    \bar{y}_t &= \bar{H}(D(\bar{x}_t), u_t).
\end{align*}
\] (16)

The state space equation is summarized in figure 1a. The parameters of the encoder \(\mathcal{E}\) and decoder \(\mathcal{D}\) are learned with the following reconstruction loss from data samples \(\{z_t\}\) collected from the training set (see also Fig. 1b).
\[
(\mathcal{E}, \mathcal{D}) = \arg \min_{\mathcal{E}, \mathcal{D}} \| z_t - \mathcal{D}(\mathcal{E}'(z_t)) \| \quad (17)
\]

Note that the dimension \(n_{\Theta}\) of the compressed state \(\bar{x}_t\) in the estimated model (16) is potentially different from the true state dimension \(n_x\). Another observation is that by going from (13) to (16), one reduces the dimension of the state vector but at the cost of introducing some structural complexity. Hence the computational price associated with simulating a model such as (16) may still be high depending on the complexity of the auto-encoder \((\mathcal{E}, \mathcal{D})\).

From a formal point of view, this reduced state has several advantages. The constructed state-space \(z_t\) is not part of the update equation (16) anymore. We can also experimentally show (see section V), that this method can discover state representations of smaller size with a method which is generic in nature and can be applied to a broad class of problems.

V. EXPERIMENTAL RESULTS

We illustrate and evaluate the proposed nonlinear dynamical model identification approach on the estimation and prediction of the state of a system with unknown dynamics. To demonstrate the practical feasibility of our model, we propose to study its behavior in three different scenarios. First, we demonstrate the capabilities of our regressor function \(H^o\) for output prediction on simulated systems.2 We also study the influence of key parameters, namely the length \(\ell\) of the time window and the impact of the state reduction.

A. Dynamical systems and benchmarks

We use two simulated and one real system to validate our contributions.

**Tank** — we test the proposed method on the cascade tank system introduced in [21]. This system relates the water level in two connected tanks without consideration of overflow. It has the form (1) of a discrete-time state-space model with \(f^o\) and \(h^o\) implicitly instantiated as follows
\[
\begin{align*}
    x_{1,t+1} &= x_{1,t} - k_1\sqrt{x_{1,t}} + k_2u_t \\
    x_{2,t+1} &= x_{2,t} + k_3\sqrt{x_{1,t}} - k_4\sqrt{x_{2,t}} \\
    y_t &= x_{2,t} + w_t.
\end{align*}
\] (18)

with \(x_t = (x_{1,t}, x_{2,t}) \in \mathbb{R}^2\) being the state and \(k_i, i = 1, \ldots, 4\) known parameters.

**2D Drone** — we introduce a model of a 2-dimensional drone, i.e. an unmanned aerial vehicle, which moves in a 2D plane. The drone is equipped with two propellers and its dynamics is modeled by:
\[
\begin{align*}
    \dot{\bar{p}}_x &= -\frac{k_x}{m}(\Omega_1^2 + \Omega_2^2) \sin(\theta) - \frac{n}{m}(\Omega_1 + \Omega_2)\bar{p}_x \\
    \dot{\bar{p}}_y &= \frac{k_y}{m}(\Omega_1^2 + \Omega_2^2) \cos(\theta) - \frac{n}{m}(\Omega_1 + \Omega_2)\bar{p}_y - g \\
    \dot{\theta} &= \frac{k_z}{J}(\Omega_2^2 - \Omega_1^2) \\
    y &= (p_x, p_z, \theta)^T,
\end{align*}
\] (19)

where \((p_x, p_z)\) is the position, \(k_f\) the thrust constant, \(\Omega_i\) the rotational speed of the \(i\)th propeller, \(L\) the length of the UAV, \(m\) its mass, \(J\) its inertia and \(\gamma\) its friction coefficient.

The main interest of such a system is its naturally unstable dynamics, which complicates the identification process. The system has been discretized.

**3D Drone** — we also evaluate on recordings of the Blackbird UAV flight dataset [1], which consists of 10 hours of aggressive quadrotor flights, measured with an accurate motion capture device. We use this real world data to demonstrate that our observer discovers a state representation containing the same information as in the physical state without any supervision. We processed the raw data gathered from the on-board inertial measurement unit (IMU) and propeller rotation speeds as observation and command signals. The regressor is trained to simulate the IMU measurements, i.e. acceleration and angular speed of the drone expressed in the local frame.

Noise has been added to the observations for the two simulated systems, tank and 2D Drone. More details about the dataset generation is provided in the appendix.

B. Baseline methods

To experimentally compare our model to competing approaches from the literature, we introduce a neural baseline in the form of gated recurrent units (GRU) [10], the state-of-the-art variant of recurrent neural networks. This is a pure data-driven technique from the machine learning field, where the learned state representation directly corresponds to the hidden state vector of the GRU. For a fair comparison, we limit the size of the hidden vector to fit the corresponding size of \(z_t\). We refer to this model as classic GRU. Its update equations are given by:
\[
\begin{align*}
    h_{t+1} &= \text{GRU}([y_t; u_t], h_t), \quad h_0 = 0 \\
    y_t &= \text{MLP}(h_t),
\end{align*}
\] (20)

where \(\text{GRU}(\cdot)\) is a shorthand notation corresponding to the classical update equations of GRUs [10]. For simplicity, and as usually done, gates have been omitted from the notation.

The baseline is evaluated in a setting which is comparable to the proposed model. In particular, the model has access to the same window of input/output pairs \([y_{t+k}, u_{t+k}]_{k=1, \ell}\) during the initial burn-in phase. However, these values do not explicitly make up the state, as in our model. This data-driven baseline is sufficiently general to be able to learn the same state representation in theory, but there is no guarantee that training will lead to this solution.

We also experiment with the model introduced in [14] which consists of an auto-encoder with a learned latent dynamics that operates on the reduced state representation. This model has been evaluated on the same tank system, 2D drone, and bird UAV flight dataset [1], which consists of 10 hours of aggressive quadrotor flights, measured with an accurate motion capture device.
yet, with a different data collection technique. Train and test trajectory in the Tank dataset as proposed in [14] are generated from PRBS-like signals, which is a classical approach for system identification. Our version of Tank dataset is much more challenging: observations are collected from closed-loop simulations with targets generated in a procedural manner and PID control. In our dataset, we took care to explore a wide range of possible states with sparse measurements in the train set to prevent over-fitting on a specific command design.

C. Extension: a hybrid state-space model

We also introduce an extension of our model, which combines the advantages of both methodologies. It uses our proposed state representation \( z_t \), but implements the mapping \( H^* \) by a GRU in place of the MLP proposed in section IV. Formally, the GRU updates a zero-initialized hidden vector using the previous observations and command. This vector is then decoded by a MLP to the desired observation. Equation (13) is then used for forward prediction. We refer to this model as Ours (GRU), it is given as follows:

\[
\begin{align*}
    z_{t+1} &= \tilde{A}z_t + \tilde{B}u_t + \tilde{S} \text{MLP}(h_t) \\
    h_{t+1} &= \text{GRU}([y_t; u_t], h_t), \quad h_{t-1} = 0 \\
    y_t &= \text{MLP}(h_t).
\end{align*}
\]  

D. Output prediction and parameter analysis

Output forecasting – the identified dynamic model can be evaluated by performing open-loop forward prediction from initial conditions and the set of inputs applied to the real system. The model then forecasts outputs, which may be compared to actual ground truth measurements. We assessed the first stage of our method using this task, i.e. the resolution of the regression problem. Table 1 reports the mean squared error on 100 step roll-out predictions for each baseline and different window sizes \( \ell \in \{5, 10, 15, 20, 25, 30\} \).

Our method shows excellent prediction error even for low window sizes, and consistently outperforms the closest competing method from the literature, Masti et al. [14], by a large margin. We conjecture two key arguments to justify this difference: (1) the structure proposed by [14] suffers from complex interaction between the auto-encoder and the latent dynamics that penalizes learning, and (2) the model design process over-fitted on the simpler dataset used in that paper.

Machine learning baseline – is competitive with our contribution. However, its structure forces to observe only one couple \( (y_t, u_t) \) at a time. Relevant information needs to be stored in its memory, the vectorial hidden state, and this storage process is fully learned by gradient descent, a difficult process. In principle, these models can learn a state representation which is similar or even identical to our designed state-map, but there is no guarantee that this representation emerges. Our state map model can therefore be seen as a form of useful inductive bias for recurrent neural models.

For moderate window sizes, our model benefits from the immediate availability of all the components of \( z_t \) in its state. For very large window sizes or complex dynamical systems (such as 3D Drone), the GRU extension (Ours (GRU)) outperforms the MLP regressor. In this situation, the GRU takes advantage of its incrementally updated memory, and manages to manipulate the large dimension of \( z_t \) by processing it piecewise, whereas the MLP must manipulate the entire vector. Figure 2 shows samples of predicted trajectory using the MLP regressor approach for each dataset.

Fig. 2: Visual example of the output prediction made by \( \hat{H} \) (Ours (MLP)) for different value of \( \ell \) on the three datasets.
TABLE I: Quantitative evaluation: we report MSE error over 100-step rollouts by the learned regression model and compare with baselines, for different windows sizes $\ell$. Our model consistently outperforms all baselines.

| Window size $\ell$ | Classic GRU$^\dagger$ | Masti et al. [14] | Ours (GRU) | Ours (MLP) | Classic GRU$^\dagger$ | Masti et al. [14] | Ours (GRU) | Ours (MLP) | Classic GRU$^\dagger$ | Masti et al. [14] | Ours (GRU) | Ours (MLP) |

| 25                | 0.600           | 915             | 0.481       | 0.606       | 80.3           | 53.6           | 23.0        | 5.17        | 21.3           | 12.1           | 4.83        | 13.6        |
| 30                | 1.73            | 917             | 0.193       | 0.448       | 104            | 51.3           | 25.0        | 3.13        | 19.2           | 12.6           | 4.61        | 13.1        |

$^\dagger$ The size of the hidden state of each GRU model is adapted to the window size s.t. fits the size of the equivalent regressor model.

E. Model reduction

The reduction step is performed downstream of the regression model training. Nevertheless, the difficulty of the reduction task is directly related to the initial size of the state representation $z_t$, that is, to the size of the window $\ell$. In order to accurately evaluate the compression capabilities of our approach, we trained several auto-encoders for each value of $\ell \in \{5, 10, 15, 20, 25, 30\}$ corresponding to different rates of compression increasing by steps of 15%.

Figure 4 shows the compression capabilities of our encoder-decoder structure for different window sizes $\ell$. The results are consistent on the three datasets. The compression rate is more sensitive on small input dimensions, and conversely, a larger dimension can be reduced extensively with negligible loss of accuracy. Indeed, increasing the number of inputs arguably leads to an increase in the redundancies exploitable by the encoder to reduce the dimension of the state space and reconstruct it with limited deviation with respect to the initial vector.

Yet such reduction introduces noise to the state representation that the regressor will have to cope with. We thus evaluate the impact of state-space reduction on the output forecasting capabilities of our model, and summarize the results in Figure 3. Our reduction method manages to reduce the dimension of the state in a consistent way up to 60% for the two datasets in simulation without sensible variation of the prediction error. The error bars reflect the double dependence of our approach both on the performance of the regression model $H^0$ but also on the quality of the encoding-decoding. We compare favorably to the baseline in [14].

VI. CONCLUSION

In this work, we take advantage of the power of high-capacity deep neural networks to design a new methodology to estimate nonlinear dynamical systems from a set of input/output data pairs. We show that the state can be expressed as a state map computed as a function of past inputs and outputs. We learn a mapping from this representation to model outputs from training data using deep networks and show that this approach is competitive. We tackled the problem of reducing the state space, showing that this way, a state of similar size than the original problem can be obtained through machine learning with an auto-encoding solution. The proposed approach can be used to reduce the order of a given nonlinear model, such as infinite-dimensional discrete systems. The methodology was validated using three numerical examples and using a data-set from real experiments from the literature.

APPENDIX

A. Dataset details

Tank — dataset is generated by uniform sampling of five waypoints lying in \([0, 5]\) evenly distributed on time on a 200 steps reference constructed by cubic spline interpolation between the waypoints. This reference is then tracked with a PID controller. Our dataset contains 60 trajectories for the train set, and 20 for both the validation and test set.

3D drone — dataset built on the BlackBird dataset [1]. We extracted IMU measurements and commands from raw data and apply pre-processing as follows: temporal synchronization of both signals, noise filtering have using Butterworth filters, and sampling rate reduction to 50Hz. To create train/valid/test splits, we sampled 20 flights to form the validation and 10 for test split. The remaining 146 flights were used for the training set. Each flight have been sliced in 200-steps chunks to facilitate training.

2D drone — dataset is generated by uniform sampling of 5 to 10 2D waypoints lying in \([-2, 2]\) evenly distributed on time on a 600 steps reference constructed by cubic spline interpolation between the waypoints. This reference is then tracked with an model predictive control approach. Our dataset contains 500 flights for training, and 20 flights for validation and test sets. For simulation, we choose \(k_T = 4 \times 10^{-4}, \gamma = 10^{-3}, L = 0.15, m = 1\) and \(J = 2.7 \times 10^{-3}\). The system is simulated with Euler integration scheme at 30Hz.

B. Models details

Classic GRU — is a 2 layer gated recurrent unit. The hidden vector size is chosen such that the cumulated dimension of the two hidden vectors matches the one of the corresponding state \(z_t\), formally \(n_h = \frac{1}{2}(n_u + n_y)\). The hidden vector is then decoded by a multilayer perceptron with one hidden unit of size \(n_h\).

Ours (MLP) — uses a MLP to model \(H^\circ\) with 3 hidden units of size 256 for simulated dataset and 2 layer with 2048 units for the 3D Drone. The encoder-decoder is modeled with 2 MLP with 2 layers of 512 units.

Ours (GRU) — model \(H^\circ\) with a GRU with three layers, and hidden size of 128. The encoder-decoder is identical as Ours (MLP).

Each model is implemented in Pytorch and trained with Adam optimizer, with learning rate of \(10^{-4}\). We trained the regressor (both MLP and GRU) for 10,000 epochs, and the encoder for 3,000 for the simulated datasets and respectively 300 epochs for the 3D drone dataset.
