The production of different quarkonium states provides unique insight to the hot and cold nuclear matter effects in the strongly interacting medium that is formed in high energy heavy ion collisions. While LHC explores the energy frontier, RHIC has a broad physics program to explore the nuclear modification at different energies in a wide range of systems. Some of the most interesting recent results on J/ψ and Υ production in p+p, d+Au and A+A collisions from PHENIX and STAR are summarized in this work.

Keywords: Brookhaven RHIC Coll, quarkonium: heavy, quarkonium: production, quark gluon: plasma

1. Introduction

In the first decade of its operation, the Relativistic Heavy Ion Collider (RHIC) mostly concentrated on measurements of the more abundantly produced particles such as light mesons. These investigations led to the discovery of a strongly interacting quark-gluon plasma (sQGP), and the understanding of its basic properties\(^1,2,3,4,5\). In more recent years, however, vastly improved luminosity and newly installed detector subsystems allowed for rarer probes, such as comprehensive heavy flavor measurements. These probes provide us with tools to explore the thermal and dynamical properties of the sQGP from new aspects.

It has long been suggested that, due to the screening of the heavy quark potential, the production of heavy quarkonia (charmonium and bottomonium states) is suppressed in heavy ion collisions compared to expectations.

* e-mail: vertesi.robert@wigner.mta.hu
from p+p collisions. Charmonium suppression was, in fact, anticipated as a key signature of quark-gluon plasma (QGP) formation. Moreover, different charmonium states are expected to dissociate ("melt") in the QGP at different temperatures due to their different binding energies. It has therefore been suggested that comprehensive charmonium measurements can be used as a QGP thermometer.

A nuclear modification that is chiefly governed by melting in the sQGP implies a monotonous increase in the suppression of a given charmonium state with the beam energy. Recent measurements at RHIC and LHC, however, outline a more complicated situation: the beam energy dependence of $J/\psi$ production is found to be rather weak, moreover, data at LHC energies show less suppression than at RHIC energies. Our current understanding on this observation is that several nuclear matter effects influence the resulting yields besides melting. In hot nuclear matter, uncorrelated quark-antiquark pairs can recombine in later stages, thus increasing the overall production. Cold nuclear matter effects can also be significant, such as nuclear shadowing and anti-shadowing, initial state energy loss or co-mover absorption of quarks. There is also a sizeable but largely uncertain contribution to the yields from feed-down processes such as $\chi_c$, $\phi$ and $B$ decays to $J/\psi$, and $\chi_b$, $\Upsilon(2S)$ and $\Upsilon(3S)$ to $\Upsilon(1S)$. Detailed experimental studies are required to disentangle these various effects.

2. Experimental approach

RHIC is an extremely versatile accelerator and detector complex that can be utilized to measure different charmonium states produced in several collisional systems in a wide range of energy, centrality, momentum and rapidity. Symmetric and asymmetric collisions are studied in p+p, p+Au, d+Au, Cu+Cu, Cu+Au, Au+Au and U+U systems over energies ranging from $\sqrt{s_{NN}}=7.7$ to 200 GeV for heavy ions, and up to 510 GeV in the case of (polarized or unpolarized) protons. Both the PHENIX and STAR experiments that currently take data at the RHIC ring have a rich heavy flavor program. STAR is capable of measurements in the dielectron channel in full azimuth at midrapidity ($|\eta|<0.5$) using the Time Projection Chamber for tracking, aided by the Barrel Electromagnetic Calorimeter for particle identification. From 2014 onwards, an outer Muon Telescope Detector (MTD) allows for measurements in the dimuon channel with significantly improved resolution. Tracking in PHENIX is done using the Drift and Pad Chambers, while the Electromagnetic Calorimeter serves for
mid-rapidity particle identification in the central arm (covering $|\eta|<0.35$ in pseudorapidity and $2 \times \pi/2$ in azimuth). The muons are tracked and identified in the forward arms ($1.2<|\eta|<2.2$).

The most common experimental approach is to measure the nuclear modification factor ($R_{AA}$) of a given state. It is computed by comparing the corrected number of particles measured in A+A collisions to the yield in p+p collisions scaled by the average number of binary nucleon-nucleon collisions, as

$$R_{AA} = \frac{\sigma_{AA}^{incl}}{\langle N_{coll} \rangle} \frac{1}{\sigma_{pp}^{incl}} \frac{d\sigma^{AA}}{dy} / \frac{d\sigma^{pp}}{dy}.$$ 

Here $\sigma_{AA}^{incl}$ is the total inelastic cross section of the A+A (p+p) collisions, $d\sigma^{AA}/dy$ denotes the production cross section of the observed state in A+A (p+p) collisions, and $\langle N_{coll} \rangle$ is the average number of binary nucleon-nucleon collisions from the Glauber model. In the case of quarkonia, where the reconstruction is done via the dielectron (dimuon) decay channel, usually the $B_{ee(\mu \mu)} \times d\sigma^{AA(pp)}/dy$ is specified, where $B_{ee(\mu \mu)}$ is the branching ratio corresponding to the given decay process of the state to an electron-positron ($\mu^+\mu^-$) pair. A similarly defined $R_{dAu}$ is used for describing the nuclear modification in d+Au collisions.

3. $J/\psi$ measurements

Besides providing reference for nuclear modification in heavier systems, p+p data serve as a benchmark for QCD models. Figure 1 shows the transverse momentum spectrum of inclusive $J/\psi$ production at RHIC in p+p collisions at $\sqrt{s_{NN}}=200$ GeV$^{16,17,18}$, compared to several theoretical calculations on prompt $J/\psi$ production. The prompt color evaporation model$^{19}$ may provide an acceptable description of the spectrum over the whole transverse momentum range. However, the same models that describe the spectrum face difficulties understanding the $J/\psi$ polarization$^{20}$.

Collisions of d+Au (p+A) systems are generally considered adequate for CNM effect studies because they are too cold for the plasma to form$^{3,4}$. Figure 2 shows the nuclear modification of the $J/\psi$ mesons in d+Au collisions at $\sqrt{s_{NN}}=200$ GeV, measured by PHENIX$^{21}$. While there is a suppression in the whole rapidity range, the strongest effect is in the gold-going (backward) direction, while it gradually decreases through mid-rapidity and the $R_{AA}$ is marginally consistent with unity in the deuteron-going (forward) region. This pattern is reasonably explained by the EPS09 model$^{22}$, containing nuclear shadowing and final state breakup of the $c\bar{c}$ pair.
Figure 1. $p_T$-spectrum of $J/\psi$ mesons in $p+p$ collisions at $\sqrt{s_{NN}}=200$ GeV at mid-rapidity measured by PHENIX (open symbols) and STAR (solid symbols), compared to calculations for prompt $J/\psi$ production.

Figure 2. Nuclear modification factor $R_{dAu}$ versus rapidity in d+Au collisions at $\sqrt{s_{NN}}=200$ GeV measured by PHENIX.

Figure 5 shows the $J/\psi$ nuclear modification factor at forward rapidities for $\sqrt{s_{NN}}=39$, 62.4 and 200 GeV Au+Au collisions at PHENIX, as a function of the number of participant nucleons ($N_{\text{part}}$). A significant suppression is observed at all energies in mid-peripheral to central collisions, and all three datasets are consistent with each other within uncertainties. STAR data at mid-rapidity exhibits similar trends. Model predictions that include in-medium dissociation of the $J/\psi$ as well as later regeneration from $c\bar{c}$ pairs are consistent with data. The weak dependence of $R_{AA}$ on collision energy suggests that the different contributions to the $J/\psi$ nuclear modification largely cancel each other. Figure 6 shows PHENIX forward rapidity measurements of $R_{AA}$ vs. $N_{\text{part}}$ in U+U and Au+Au systems. The two datasets mostly overlap each other, similarly to other measurements of open and hidden heavy flavor at RHIC. However, there is a significant discrepancy at higher $N_{\text{part}}$ values that may be a hint that there is more coalescence in collisions of non-spherical Uranium nuclei.

We saw that it is difficult to disentangle the sources of nuclear modification, because the $R_{AA}$ is rather insensitive to beam energy over a wide range and also to the number of nucleons in the chosen heavy ion system. At high momentum, however, the impact of CNM effects and regeneration decreases and hot nuclear modification becomes dominant. Figure 3 shows the nuclear modification factor for $J/\psi$ mesons with a transverse momentum $p_T>5$ GeV/c, measured by STAR at mid-rapidity in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV, compared to $J/\psi$ mesons from the same col-
Figure 3. STAR and PHENIX minimum bias (black circles and empty squares) $J/\psi$ vs. $N_{\text{part}}$, as well as STAR high-$p_T$ $J/\psi$ vs. $N_{\text{part}}$ (shaded circles) in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV at mid-rapidity, compared to models.

Figure 4. $\Upsilon(1S+2S+3S)$ vs. rapidity in $\sqrt{s_{NN}}=200$ GeV d+Au collisions from STAR (stars) and PHENIX (diamonds), compared to theoretical calculations.

Collisions without momentum selection\textsuperscript{16}. The suppression of high-$p_T$ $J/\psi$ at higher $N_{\text{part}}$ values is a clear sign of nuclear modification in the sQGP.

4. $\Upsilon$ production

Theoretical calculations that include shadowing and/or parton energy loss\textsuperscript{11,12} predict an $R_{dAu} \approx 1$ at mid-rapidity. While the cross sections for $\Upsilon$ production in $\sqrt{s_{NN}}=200$ GeV p+p collisions\textsuperscript{30} are consistent with NLO pQCD color evaporation model predictions\textsuperscript{11}, the nuclear modification in d+Au, shown on Figure 4, is stronger than what the above models can explain\textsuperscript{30}. This suggests that CNM effects may not be well understood or that CNM effects alone may not be enough to explain the suppression in the d+Au mid-rapidity bin ($|y|<0.5$). However, the uncertainties on the measurement are still quite high. Evaluating the high-statistics p+Au data taken at RHIC in 2015 is essential to see whether there is an effect beyond model predictions or not.

While the most heavy-ion luminosity in RHIC is collected in Au+Au collisions, central U+U data at $\sqrt{s_{NN}} = 193$ GeV are estimated to have a 20% higher average energy density than that of Au+Au\textsuperscript{29}, thus allowing for the extension of measurements towards higher $N_{\text{part}}$ numbers and further tests of the sequential suppression hypothesis. Figure 7 shows the nuclear modification factor of $\Upsilon(1S+2S+3S)$ from Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV as well as from U+U collisions at $\sqrt{s_{NN}}=193$ GeV, with respect to
Figure 5. PHENIX forward rapidity $J/\psi$ vs. $N_{\text{part}}$ in Au+Au collisions at $\sqrt{s_{NN}}=39$, 62.4 and 200 GeV compared to theoretical calculations.

Figure 6. PHENIX forward rapidity $J/\psi$ vs. $N_{\text{part}}$ in Au+Au collisions at $\sqrt{s_{NN}}=200$ GeV (squares) and U+U collisions at $\sqrt{s_{NN}}=193$ GeV (circles).

5. Summary and outlook

Recent RHIC measurements show that the presence of a hot medium affects quarkonium production. The significant suppression of high-$p_T$ $J/\psi$ yields and $\Upsilon(1S)$ states in central heavy ion collisions, and an even stronger suppression of $\Upsilon(2S+3S)$ states in 0-60% Au+Au collisions is in accordance with the sequential melting picture. The trends in U+U measurements are generally an extension of those observed in Au+Au to higher number of participant nucleons, although there is some indication in the $J/\psi$ data that there may be more coalescence in U+U than in Au+Au. There is no strong dependence of the $J/\psi$ suppression on the beam energy between $\sqrt{s_{NN}}=39$ and 200 GeV, and the suppression in LHC 2.75 TeV collisions is even weaker than at RHIC, which attests to the role of $J/\psi$ regeneration.
Measurements in d+Au systems show that cold nuclear matter effects are significant in the case of J/ψ and also may not be negligible in the case of Υ mesons.

The developments of PHENIX and STAR, paired with the increased luminosity delivered by RHIC in recent years, will highly increase precision of the measurements in the near future. The first results with STAR MTD have already been presented\cite{32}. There are ongoing measurements with the inner silicon tracking systems of both experiments, where the prompt and non-prompt J/ψ contributions will be separated, thus providing means to estimate the fraction of J/ψ mesons coming from feed-down from B mesons.

Besides heavy ion measurements, high luminosity p+Au data recorded in 2015 will help the understanding of cold nuclear matter effects.

Acknowledgments

The author would like to thank the Editors of the Exploring Quantum Field Theory Gribov 85 memorial issue, especially Júlia Nyíri for the invitation of this contribution; and the organizers of the Joint Wigner-CCNU High-Energy Heavy-Ion Balaton Workshop 2015, Tihany, Hungary for the invitation to present this material.
