Weyl points and line nodes in gyroid photonic crystals

Ling Lu*, Liang Fu, John D. Joannopoulos and Marin Soljačić

Weyl points and line nodes are three-dimensional linear point and line degeneracies between two bands. In contrast to two-dimensional Dirac points, which are their lower-dimensional analogues, Weyl points are stable in momentum space, and the associated surface states are predicted to be topologically non-trivial. However, Weyl points are yet to be discovered in nature. Here, we report photonic crystals based on double-gyroid structures, exhibiting frequency-isolated Weyl points with complete phase diagrams by breaking the parity and time-reversal symmetries. Gapless surface dispersions associated with non-zero Chern numbers are demonstrated. Line nodes are also found in similar geometries, the associated surface states forming flat dispersion bands. Our results are based on realistic ab initio calculations with true predictive power and should be readily realizable experimentally from microwave to optical frequencies.

Two-dimensional (2D) Dirac points are unique linear-dispersion point degeneracies in 2D periodic systems. For example, most of the remarkable properties of graphene are tied to the Dirac points at its Fermi level. In photonic, 2D Dirac cones significantly alter the dynamics of photons and thus enable novel applications. Topologically, opening up the 2D Dirac point degeneracies can generate topologically non-trivial frequency gaps inside which unidirectional 1D edge states are protected against disorder. Similarly, it is expected that if a material could be found that exhibits three-dimensional (3D) linear dispersion relations between frequency (energy) and wave vector (k), it would also display a wide range of interesting phenomena. Such electronic systems, is the ease of its eventual experimental realization.

Before proceeding, we first point out one intriguing distinction between the 2D Dirac points and the 3D Weyl points. 2D Dirac cones are not robust; they are only protected by the product of time-reversal symmetry (T) and parity (P) inversion. In two dimensions, the Dirac cone effective Hamiltonian takes the form of $H(k) = v_k + i s \sigma_z$, where $v_k$ are the group velocities and $\sigma_z$ are the Pauli matrices. This form is protected by PT (product of P and T), which requires $H(k)$ to be real. Thus, one can open a gap in this dispersion relation upon introducing a perturbation, proportional to that is imaginary; for example, even an infinitesimal perturbation that breaks just P or just T will open a gap. In contrast, 3D Weyl points are topologically protected gapless dispersions robust against any perturbation. In three dimensions, Weyl point dispersions are governed by the Weyl Hamiltonian $H(k) = v_k + i s \sigma_z$. The $\sigma_z$ term can exist only when PT is broken; indeed, this is a necessary condition for the existence of Weyl points. Because all three Pauli matrices are used in the Hamiltonian, there is no possibility of constructing a term that can open a gap in this two-band degeneracy of 3D periodic systems, thereby making a single Weyl point absolutely robust to perturbations. The only way to eliminate and create Weyl points is through pair-annihilations and pair-generations of Weyl points of opposite chiralities, which typically requires a strong perturbation. The chirality ($c = \pm 1$) of a Weyl point can be defined as $c = \text{sgn}(\det(v_k))$ for $H(k) = k + x$ or $k + y$ or $k + z$. It can also be defined by the Chern number of a closed surface enclosing the single Weyl point in momentum space.

The organization of this Article is as follows. Our starting point for obtaining Weyl points and line nodes is a DG photonic crystal with a band structure that exhibits a threefold degeneracy (quadratic in all three directions) at the Brillouin zone centre (0) in an otherwise complete bandgap. We first obtain the line nodes by applying a perturbation preserving P and T and show the controlled flat band surface states in the surface Brillouin zone. Second, we obtain the Weyl points by applying perturbations breaking either P or T and explore the phase diagrams when both P and T are broken. Third, we present the Chern numbers of the Weyl points and the topologically non-trivial surface states associated with them. Finally, we discuss various opportunities for experimental realizations.

Gyroid photonic crystals

The gyroid, discovered by Schoen in 1970, is an infinitely connected bi-continuous triply periodic minimal surface containing no straight lines. Consisting of triple junctions in a body-centred cubic (bcc) lattice, the gyroid surface can be approximated by isosurfaces of $g(r) = \sin(2\pi x/a) \cos(2\pi y/a) + \sin(2\pi y/a) \cos(2\pi z/a) + \sin(2\pi z/a) \cos(2\pi x/a)$ (ref. 22), where $a$ is the lattice constant. The space group of a single gyroid (SG) is $I4_32$ (no. 214), which lacks inversion; adding its inversion counterpart $g(-r)$ gives the DG structure belonging to $Ia\overline{3}d$ (no. 230), which is a

Line nodes and their flat surface bands

The threefold degeneracy of quadratic dispersions at $\Gamma$ can be lifted by breaking the $I_{4h,32}$ space group without breaking $P$ or $T$ symmetries. This is done by replacing a part of the gyroid material with two air-spheres (one on each gyroid). The first air-sphere is placed in the red gyroid as illustrated in Fig. 1a, and the other is its inversion counterpart in the blue gyroid (not shown in Fig. 1a). This perturbation lifts the fifth band out of the threefold degeneracy with the third and fourth bands at $\Gamma$, as shown in Fig. 2b. The fourth and fifth bands cross one another linearly, forming a closed line degeneracy around the $\Gamma$ point in the (101) plane through $\Gamma$, inside an otherwise complete frequency gap. The area enclosed by this nodal line can be controlled by the strength of the perturbations (the radii of the air-spheres).

Similar to the line-node semimetals, the surface states associated with this line-node bulk bandstructure contain flat dispersion bands. We constructed an interface between the DG and SG photonic crystals by removing only the perturbed gyroid (Fig. 1c). The surface states are trapped by the pseudo-gap of the DG and the full gap of the SG. We define a termination parameter $\tau$ ($0 \leq \tau < 1$) to indicate the periodically equivalent termination positions along the [101] direction. $\tau=0$ is set at the origin of the unit cell, as shown in Fig. 1c.

Figure 3a shows one surface band in the bulk pseudo-gap of the original DG photonic crystal of quadratic point degeneracy. When $\tau$ increases periodically, the surface dispersion, at every surface k point, moves from the air band (conduction band) through the pseudo-gap to the dielectric band (valence band). At $\Gamma$, the surface dispersion is pinned into the bulk states at the degeneracy point. The surface band of $\tau=0.0$, except for the $\Gamma-P$ region, is very flat. The high density of states associated with the flat surface dispersion is potentially useful for enhancing the light–matter interactions at the surface. Even more interesting surface states are shown in Fig. 3b for the line-node photonic crystal. The nodal line bulk states project onto the (101) surface Brillouin zone as a closed line that separates the surface Brillouin zone into two disconnected areas. So, the surface dispersions can be flat bands in either of the two regions in the Brillouin zone. The green dispersion in Fig. 3b has all its frequencies nearly degenerate inside the line-node area, while the red dispersion is relatively flat in the rest of the Brillouin zone. The general features of the flat surface dispersions do not change when the line-node photonic crystal is terminated by other means. For example, when the SG photonic crystal is replaced by air, one could selectively enhance, by changing the surface terminations, the light emission of source into either radiative or non-radiative surface modes (that is, inside or outside the light cone of air).

Phase diagrams of Weyl points under PT-breaking

In what follows, we break the PT symmetry to obtain Weyl points of photons for the first time. We start by individually breaking $P$ or $T$ of the DG photonic crystal, and then consider the general case where $P$ and $T$ are broken simultaneously.

First, we break $P$ while preserving $T$. Because $T$ maps a Weyl point at $k$ to $-k$ with the same chirality (as velocities and $\sigma_y$ change signs), there must exist at least two other Weyl points, both of opposite chirality, to neutralize the whole system. So, the minimal number of Weyl points in this case has to be four. As illustrated in Fig. 1a, we break $P$ by placing only one air-sphere on one of the gyroids (but not the other) at the middle point of two neighbouring triple junctions. Under this pure $P$-breaking perturbation, two pairs of Weyl points, shown in Fig. 2c, emerge along $\Gamma-N$ and $\Gamma-H$ directions. The fact that all the Weyl points appear along high-symmetry lines significantly simplifies the analysis. There are no other states in the vicinity of the Weyl points’ frequencies.
We next apply d.c. magnetic fields \( \mathbf{B} \) (along different directions) to the original DG photonic crystal structure of Fig. 2a to break \( T \) while preserving \( P \). We assume the high-index gyroid material is gyromagnetic and use a generic model\(^8\) to describe its magnetic response. When \( \mathbf{B} \) is along \( \hat{z} \), we assume the permittivity tensor takes the form of

\[
\varepsilon(\mathbf{B}) = \begin{pmatrix}
\varepsilon_{11}(\mathbf{B}) & i\varepsilon_{12}(\mathbf{B}) & 0 \\
-i\varepsilon_{12}(\mathbf{B}) & \varepsilon_{22}(\mathbf{B}) & 0 \\
0 & 0 & \varepsilon
\end{pmatrix}
\]

where \( \det(\varepsilon(\mathbf{B})) = (\varepsilon_{11}(\mathbf{B}) - \varepsilon_{22}(\mathbf{B}))/\varepsilon = \varepsilon' ; \) this constant determinant condition ensures the dispersions as a whole do not move much in frequency with the external d.c. \( \mathbf{B} \) fields. The dimensionless effective magnetic field intensity is defined as \( |\mathbf{B}| = \varepsilon_{12}/\varepsilon \) in this Article. When the \( \mathbf{B} \) field is along other directions, the corresponding \( \varepsilon \) tensor can be obtained via coordinate transformations. (Note that \( T \)-breaking can be implemented equally well via \( \mu \) for gyromagnetic materials\(^9\).) Under this pure \( T \)-breaking perturbation, only a single pair of Weyl points emerges along the direction of the magnetic field, as shown in Fig. 2d. This is the minimum number of Weyl points that can exist with inversion symmetry. These two Weyl points are frequency-degenerate: \( P \) maps a Weyl point at \( \mathbf{k} \) to \( -\mathbf{k} \) with the opposite chirality (because velocities change signs).

Third, we apply both \( P \)- and \( T \)-breaking perturbations continuously, at the same time, to observe the phase transitions between the two (II) Weyl points in the pure \( T \)-breaking phase and the four (IV) Weyl points in the pure \( P \)-breaking phase. Interestingly, different magnetic field directions produce strikingly different phase diagrams. When \( \mathbf{B} \) is applied along \( \Gamma - \mathbf{H} \), only two phases exist: the \( T \)-breaking dominated phase (II) and the \( P \)-breaking dominated phase (IV). The pure \( P \)-breaking phase, shown in the contour plot Fig. 2c, has four Weyl points: two with positive chiralities along \( \Gamma - \mathbf{H} \) and two with negative chiralities along \( \Gamma - \mathbf{N} \). Applying a magnetic field along the \( \Gamma - \mathbf{H} \) direction drives the two negative-chirality Weyl points towards the lower positive one. Increasing the magnetic field further annihilates two of the Weyl points of opposite chiralities and the system enters the \( T \)-breaking dominated phase,
which has only two Weyl points along Γ-H. A detailed description of this phase diagram is shown in Supplementary Fig. SA.

An even richer phase diagram, shown in Fig. 4, appears when we switch the magnetic field to the Γ-N direction. The system undergoes two phase transitions from the P-breaking dominated phase (IV) to the T-breaking dominated phase (II). The extra intermediate phase (VI) of six Weyl points is generated when one of the negative-chirality Weyl points in the pure P-breaking phase (red contour plot) splits (orange contour plot) into three Weyl points (blue contour plot) under the increasing B field. Of these three Weyl points, the original Weyl point flips its chirality from negative to positive, and the other two negative Weyl points move away from their creation position towards the neighbouring two positive ones. The two pairs of Weyl points eventually meet (green contour plot) and annihilate simultaneously, leaving the remaining two Weyl points (purple contour plot) along the direction of the magnetic field (Γ-N). When two Weyl points annihilate, the band dispersions are quadratic along the directions in which they meet.

In general, P-T phase diagrams depend on the form of the perturbations: the d.c. magnetic field can be oriented along arbitrary directions and, in addition, there are many different ways to break the inversion symmetry. We also note that there are new topological phases outside of the Weyl-point phases. For example, by further increasing the T-breaking strength in phase II of Fig. 4, the two Weyl points could annihilate around the Brillouin zone boundary and enter a new topologically non-trivial phase of a complete 3D bandgap that resembles the 3D quantum Hall effect in electronics.

Chern numbers and non-trivial surface states

Weyl points are topologically stable objects in the 3D Brillouin zone: they act as monopoles of Berry flux in momentum space, and are therefore intimately related to the topological invariant known as the Chern number. The Chern number can be defined for a single bulk band or a set of bands, where the Chern numbers of the individual bands are summed, on any closed 2D surface in the 3D Brillouin zone. The difference of the Chern numbers defined on two surfaces, of all bands below the Weyl point frequencies, equals the sum of the chiralities of the Weyl points enclosed between the two surfaces. In Fig. 5a we illustrate the Chern numbers of the 2D planes perpendicular to Γ-H(Γ); these are closed surfaces in the 3D periodic Brillouin zone. The first contour plot (red), of a pure P-breaking phase in Fig. 4, is used as an example. The Chern number of all lower bands on the plane is plotted in light blue on the left side. The Chern number vanishes when the plane is outside the Weyl points. It changes by 1 when the plane moves across one Weyl point and changes by 2 when the plane crosses two Weyl points of the same chirality.

As a result of the non-zero Chern numbers of all the lower bulk bands (first, second, third and fourth), there are topologically protected gapless chiral surface states inside the bandgap (between fourth and fifth bands) away from the Weyl points. This is a higher-dimensional generalization of the protection of one-way chiral edge states (1D) by the non-zero Chern numbers of the 2D bulk bands. An example of the non-trivial gapless surface dispersion, along a line cut in the 2D surface Brillouin zone in Fig. 5a, is plotted in Fig. 5b. A surface mode profile is also shown. Because T is not broken in this example, the surface dispersions are degenerate between |k and −k while the Chern number flips sign. Similar to the ‘Fermi arcs’ in Weyl semimetals, at the frequency of the Weyl points, the surface dispersions connect the Weyl points (of opposite chiralities) as line segments that do not close in the surface Brillouin zone. The above analysis on Chern numbers and surface modes applies for surfaces terminated along other directions and for other Weyl-point phases as well.

Proposals for experimental realizations

The theoretical predictions discussed above can be readily realized using many available materials and fabrication techniques, and the bulk and surface dispersions can be verified by transmission experiments. The line nodes and the Weyl-point phases of pure P-breaking perturbations, without T-breaking, can be realized in the following ways to break the inversion symmetry. We also note that there are many different ways to break the inversion symmetry. We also note that there are new topological phases outside of the Weyl-point phases. For example, by further increasing the T-breaking strength in phase II of Fig. 4, the two Weyl points could annihilate around the Brillouin zone boundary and enter a new topologically non-trivial phase of a complete 3D bandgap that resembles the 3D quantum Hall effect in electronics.
Conclusions

In summary, this article provides a detailed design of the minimum number of frequency-isolated Weyl points and line nodes along the high-symmetry lines and planes in the Brillouin zone of a DG photonic crystal system. Complete P–T phase diagrams are investigated by means of annihilations and creations of Weyl pairs. The topologically non-trivial surface states of Weyl-point photonic crystals and flat surface dispersions of line-node photonic crystals are presented. This work may open doors to new paradigms in photonics: topologically protected surface states realized at optical frequencies, radiation-controllable photonic density of states enhanced by flat surface dispersions, possible new 3D topological phases of complete frequency gaps by annihilations of the Weyl points, novel transmission properties and other unconventional phenomena associated with the density of states and dispersion relations close to the degeneracy points.
