Abstract

In the last few years metagenomic and 16S rRNA sequencing have completely changed the microbiological investigations of food products. In this preliminary study, the microbiological profile of chicken carcasses collected from animals fed with different diets were tested by using shotgun metagenomic sequencing. A total of 15 carcasses have been collected at the slaughterhouse at the end of the refrigeration tunnel from chickens reared for 35 days and fed with a control diet (n=5), a diet supplemented with 1500 FTU/kg of commercial phytase (n=5) and a diet supplemented with 1500 FTU/kg of commercial phytase and 3g/kg of inositol (n=5). Ten grams of neck and breast skin were obtained from each carcass and submitted to total DNA extraction by using the DNeasy Blood & Tissue Kit (Qiagen). Sequencing libraries have been prepared by using the Nextera XT DNA Library Preparation Kit (Illumina) and sequenced in a HiScanSQ (Illumina) at 100 bp in paired ends. A number of sequences ranging between 5 and 9 million was obtained for each sample. Sequence analysis showed that Proteobacteria and Firmicutes represented more than 98% of whole bacterial populations associated to carcass skin in all groups but their abundances were different between groups. Moraxellaceae and other degradative bacteria showed a significantly higher abundance in the control compared to the treated groups. Furthermore, Clostridium perfringens showed a relative frequency of abundance significantly higher in the group fed with phytase and Salmonella enterica in the group fed with phytase plus inositol. The results of this preliminary study showed that metagenome sequencing is suitable to investigate and monitor carcass microbiota in order to detect specific pathogenic and/or degradative populations.

Introduction

Techniques and technologies used for detection and characterization of foodborne pathogens in food products have tremendously over the past several decades (Gracias and McKillip, 2004; Nugen and Baeummer, 2008; Valderrama et al., 2015). Traditional methods for pathogen detection, including microscopy and culture-based analyses, are biased according to the specific culture requirements for most genera and species. Moreover, they do not assess the microbiome at ecological level. More modern approaches, including immunoenasays and/or nucleic acid amplification, only allow for detection of single or a few specific pathogen(s) at a time. However, it is well known that changes in the surrounding environment cause stresses on bacterial populations, leading to reorganization of microbial communities, which potentially affects the persistence of foodborne pathogens in the food production chain (Larsen et al., 2014; Pricope et al., 2013). Therefore, the real challenge is to assess the influence that the entire microbial communities have on presence of pathogens in food products. Within this framework, shotgun metagenomic, which is the study of whole-community DNA extracted directly from samples, has been increasingly used in multiple disciplines, particularly as sequencing costs decrease and output increases (Manichanh et al., 2008). When compared to target amplicon metagenomics (e.g., 16S rRNA gene sequencing), shotgun metagenomics provides the potential for both higher resolution identification of organisms (i.e., to the strain level), as well as study of microbial communities without introduction of sequencing bias due to unequal amplification of the target gene (Shah et al., 2011). Although obtaining a complete individual genome from metagenomic sequences is still challenging, it is sufficient to characterize the major functions of the microbial communities, as well as to identify their taxon by assigning to public genome reference databases (Li et al., 2014). Overall, the goals for metagenomic analysis are to understand i) community composition/structure, including the taxonomic breakdown and relative abundance of the various species; ii) genomic contribution of each member of the community, including number and functional capacity; iii) intra-species or intra-population heterogeneity of the genes (Scholz et al., 2012).

Although there are many opportunities to use metage-nomics tools to support detection of foodborne pathogens from foods and food-associated environments, most metagenomics studies on the detection of microbes in foods have focused on characterizing the microbial ecology and micro-bial successions during fermentations (van Hijum et al., 2013). The opportunities for metagenomics approaches to improve foodborne pathogen detection are illustrated by a study that used metagenomics approaches to characterize the species composition associated with the tomato phyllosphere – both on the native plant and in the pre-enrichment and enrichment media used to isolate Salmonella (Ottersen et al., 2013). This study was conducted because isolation of Salmonella from the tomato phyllosphere has previously proven challenging despite the fact that tomatoes have been implicated as the source of several human salmonellosis outbreaks. Interestingly, this metagenomic study identified considerable growth of Paenibacillus spp. during enrichment; this is important because this organism may out-compete or even kill Salmonella during enrichment. In addition, sequences matching different Salmonella serovars were identified both from the uncultured samples as well as from different enrichments, sug-

Abstract

In the last few years metagenomic and 16S rRNA sequencing have completely changed the microbiological investigations of food products. In this preliminary study, the microbiological profile of chicken carcasses collected from animals fed with different diets were tested by using shotgun metagenomic sequencing. A total of 15 carcasses have been collected at the slaughterhouse at the end of the refrigeration tunnel from chickens reared for 35 days and fed with a control diet (n=5), a diet supplemented with 1500 FTU/kg of commercial phytase (n=5) and a diet supplemented with 1500 FTU/kg of commercial phytase and 3g/kg of inositol (n=5). Ten grams of neck and breast skin were obtained from each carcass and submitted to total DNA extraction by using the DNeasy Blood & Tissue Kit (Qiagen). Sequencing libraries have been prepared by using the Nextera XT DNA Library Preparation Kit (Illumina) and sequenced in a HiScanSQ (Illumina) at 100 bp in paired ends. A number of sequences ranging between 5 and 9 million was obtained for each sample. Sequence analysis showed that Proteobacteria and Firmicutes represented more than 98% of whole bacterial populations associated to carcass skin in all groups but their abundances were different between groups. Moraxellaceae and other degradative bacteria showed a significantly higher abundance in the control compared to the treated groups. Furthermore, Clostridium perfringens showed a relative frequency of abundance significantly higher in the group fed with phytase and Salmonella enterica in the group fed with phytase plus inositol. The results of this preliminary study showed that metagenome sequencing is suitable to investigate and monitor carcass microbiota in order to detect specific pathogenic and/or degradative populations.
gesting the presence of Salmonella despite
the fact that these samples were negative by
both bacteriological methods and real-time
PCR. Although these findings do support
the possibility that Paenibacillus may have
outcompeted Salmonella during enrichment,
itis also possible that the detection of
Salmonella DNA sequences is due to pres-
ence of dead Salmonella cells (Bergholz et
al., 2014).

The administration of feed additives in
chickens has been linked to changes in the
animal gut influencing meat safety. Lactobacillus administration has been
shown to reduce colonization by foodborne
pathogens like Campylobacter (Ghareeb et
al., 2012; Neal-Mckinnet et al., 2012), Clostridium (La Ragione et al., 2004) and
Salmonella (Chen et al., 2012) improving
the microbial food safety of poultry meat.
Beside probiotics, broiler diet can be sup-
mplemented with enzymes like phytase.
Other than making the phosphorus available
for the host, the supplementation of phytase
can avoid the anti-nutritional effect of phyt-
ic acid reducing endogenous losses and
increasing protein digestibility.

Since the effect of phytase supplemen-
tation on microbiological profile of poultry
meat has been never investigated, in this
preliminary study shotgun metagenomics
has been applied to compare the microbial
compositions of 15 chicken carcasses col-
lected at the end of the rearing period (i.e.,
35 days) from animals fed with a control
diet and diets supplemented with 1500
FTU/kg of commercial phytase and 1500
FTU/kg of commercial phytase plus 3g/kg
of inositol.

Materials and Methods

A total of 15 poultry carcasses were ran-
domly collected at the slaughterhouse at the
carcases were obtained from birds belonging to the
same breeder flock and hatching session,
housed in the same poultry house at the
stocking density of about 10 chicks/m² and
fed with three different diets up to 35 days.
A total of 5 carcases were obtained from
birds fed with a basal diet (group A); 5 car-
casses from birds fed with the basal diet
supplemented with phytase at the concen-
tration of 1500 FTU/kg feed (group B); 5
carcasses from birds fed with the basal diet
supplemented with phytase at the concen-
tration of 1500 FTU/kg feed and 3g/kg
inositol (group C). According to the official
sampling procedures to verify the hygienic
quality of broiler carcasses, ten grams of
neck and breast skin were collected from
each carcass and placed in a sterile bag with
40 mL of sterile saline solution. After
homogenization for 1 minute using the
Pulsifier® (Microgen Bioproducts Ltd.,
Cambrige, UK) the whole rinse fluid was

[Italian Journal of Food Safety 2018; 7:6923]
placed in a 50-mL falcon tube and centrifuged at 6500 x g for 20 minutes at 4°C to pellet bacteria.

A total of 0.25 g of pellet were suspended in 1 mL lysis buffer (500 mM NaCl, 50 mM Tris-Cl, pH 8.0, 50 mM EDTA, 4% SDS) with MagNA Lyser Green Beads (Roche, Milan, Italy) and homogenized on the MagNA Lyser (Roche) for 25 sec at 6500 rpm. The samples were then heated at 70°C for 15 min, followed by centrifugation to separate the DNA from the bacterial cellular debris. The samples were then subjected to 10 M v/v ammonium acetate (Sigma, Milan, Italy) precipitation, followed by isopropanol (Sigma) precipitation and a 70% ethanol (Carlo Erba, Milan, Italy) wash and re-suspended in 100 µL 1X Tris-EDTA buffer and incubated overnight at 4°C, before being processed through the QiAmp® DNeasy Blood & Tissue Kit (Qiagen, Milan, Italy) according to manufacturer’s directions.

The DNA extracted from each sample was quantified on a BioSpectrometer® (Eppendorf, Milan, Italy) and submitted to library preparation procedure with the Nextera XT DNA Library Preparation Kit (Illumina, San Diego, CA). A total of 5 µL of each library (1.3-2 nM) were pooled together and sequenced in the same flow cell using the HiScanSQ sequencer (Illumina) at 100 bp in paired-end mode. Metagenomic sequencing yielded an average of 6.841 million mapped reads/sample, with a Phred quality score always higher than 30. The trimming process was performed to filter all reads shorter than 50 bp and to discharge the trimmed paired-end reads shorter than 50 bp. The suitable reads were then mapped to reference sequence databases using MG-RAST.

Results regarding relative frequency of abundances of bacterial taxa at different taxonomic level were compared through the Statistical Analysis of Metagenomic profile Software v 2.0.9 (STAMP) (Parks et al., 2014). After removing non-bacterial species, taxa abundances were normalized so that each sample total abundance resulted one. Relative frequencies of abundance showing P<0.05 were considered significantly different.

Results

The microbiota associated to the skin carcasses investigated is summarized in Table 1. Proteobacteria and Firmicutes represented more than 98% of whole bacterial populations associated to carcass skin in all groups (Table 1). Proteobacteria relative frequency of abundance was higher in the control group in comparison to the groups treated with phytase and phytase plus inositol. On the contrary, Firmicutes abundance

was higher in the treated groups in comparison to the control. However, those differences were not significantly different.

Gammaproteobacteria was the most abundant class within Proteobacteria, followed by Betaproteobacteria and Alphaproteobacteria (Table 1). Enterococcaceae was the most represented family within Proteobacteria class, followed by Moraxellaceae and Aeromonadaceae (Table 1). Enterococcaceae showed a significantly lower relative frequency of abundance in the control group (22.84%) in comparison to groups treated with phytase (42%) and phytase plus inositol (37.56%) (P<0.05). On the contrary, Moraxellaceae showed a significantly higher abundance in the control (51.36%) compared to the treated groups (23.71 and 22.05%, respectively) (i.e., P<0.05).

Firmicutes phylum was mostly represented by Bacilli and Clostridia. Within the Bacilli class, the most represented families were Streptococcaceae, Enterococcaceae and Planococcaceae (Table 1). The Enterococcaceae relative frequency of abundance was significantly higher in the group treated with phytase plus inositol in comparison to control group and group treated with phytase only (P<0.05). On the contrary, Planococcaceae relative frequency of abundance was significantly lower in the group treated with phytase and inositol in comparison to the other groups (P<0.05) (Table 1). Concerning Clostridia class, both Clostridia (P<0.05) and Clostridiaceae (P<0.05) were significantly more abundant in the groups treated with phytase compared to the control.

Within the phylum Bacteroidetes, Flavobacteriia and Flavobacteriaceae showed a significantly lower frequency of abundance in the group treated with phytase only in comparison to the control group (P<0.05) and the group fed with phytase and inositol (P<0.05). On the contrary Bacteroidia and Bacteroidaceae showed a relative frequency of abundance significantly higher in the group treated with phytase only compared to other groups (P<0.05) (Table 1). Finally, phylum Actinobacteria showed a relative frequency of abundance significantly higher (P<0.05) in the control group in comparison to treated groups (P<0.05) (Table 1). Moreover, in the group treated with phytase and inositol, Bifidobacteriaceae showed a significantly higher abundance in comparison to the control group (P<0.05) and group treated with phytase only (P<0.05) (Table 1).

Table 2 summarizes the top 30 bacterial species, in terms of abundance, identified in the investigated groups. The control group showed a dominance of Acinetobacter and Aeromonas genera, while the treated groups showed a more diversified bacterial population (Table 2). Treated groups presented higher relative frequency of abundances of *Escherichia coli* compared to the control group (Table 2). On the contrary, *Clostridium perfringens* showed a relative frequency of abundance significantly lower in the control group in comparison to the group fed with phytase only (Table 3). Moreover, *Salmonella enterica*, representing, one of the top 30 species in both treated groups, was significantly higher in the carcasses collected from birds fed with phytase and inositol in comparison to the control (Table 4). Concerning other foodborne pathogens, *Aeromonas hydrophila* and

**Table 3.** Statistically significant differences between means of relative frequency of abundance (%) of skin bacterial species in control group (A) and group fed with phytase (B).

Aeromonas veronii had a higher relative frequency of abundances in the treated groups in comparison to the control but those differences were not statistically relevant (Table 2). On the contrary Pseudomonas pseudoalcaligenes was significantly higher in the control in comparison to both treated groups (Tables 3 and 4), whereas Pseudomonas aeruginosa was significantly higher in the control in comparison to the group treated with phytase only (Table 3). Finally, species belonging to genera Shigella and Shewanella were significantly lower in the control group in comparison to the treated groups (Tables 3 and 4).

Discussion

The results of this preliminary study showed that the carcass skin microbiota is mainly composed by Proteobacteria and Firmicutes. The same phyla represent more than 95% of bacterial population in the caeca of one-day old chicks (De Cesare et al., 2017). During the chicken life, the mean relative frequency of abundance of Proteobacteria in the caeca tends to decrease, between 9.61% at day 1 to 1.74% at day 41. On the contrary, the mean relative frequency of abundance of Firmicutes tends to increase, between 85.85% at day 1 to 93.93% at day 41. In the carcasses investigated in this study at the end of slaughtering, the mean relative frequency of abundance of Proteobacteria ranged between 92.68 and 94.99%, whereas that of Firmicutes between 4.01 and 6.46%. Statistically significant differences were determined between bacterial classes and families colonizing carcasses obtained from animals fed with different diets. Enterobacteriaceae were more abundant in the treated groups than in control group and this difference corresponded to a higher abundance of Escherichia coli and Salmonella enterica in carcasses collected from chickens fed with phytase and inositol in comparison to the control. Moreover, Clostridiaceae were significantly higher in the treated groups in comparison to the control and this difference corresponded to a significant higher abundance of Clostridium perfringens in the group fed with phytase in comparison to the control. Differences in contamination of carcasses belonging to control and treated groups might come from the chicken diet but might also come from cross contamination during slaughtering. Beside the origin of the contamination, it is important to note that metagenomics sequencing was able to detect differences even related to low levels of abundance like those associated to

[Italian Journal of Food Safety 2018; 7:6923]
Salmonella enterica. Differences were also quantified in relation to degradative microflora. In fact, Moraxellaceae class resulted significantly more abundant in the control in comparison to treated groups.

Even if the results of this preliminary study support the potential for metagenomics applications in food safety, the use of metagenomics as a tool for the detection of foodborne pathogens in foods still faces several challenges. For one, metagenome sequencing will detect DNA from both dead and alive organisms. An additional challenge is that metagenomics will create massive sequence data sets linked to a given food or food-associated facility (e.g., processing facility or farm), and these are likely to contain at least some sequence data that can easily be misconstrued as indicating a food safety hazard (e.g., the presence of antimicrobial resistance genes or virulence genes). Because, at least in some countries, food safety testing data may have to be released, under specific circumstances, to lawyers or regulatory agencies, some facilities may be reluctant to use these tools out of fear that the data created could inadvertently (and incorrectly) implicate a facility as having evidence of pathogen presence in a food or environment. In addition, data from metagenomic studies of human specimens could potentially be linked to individuals because the data generated may also contain host sequence data that could potentially identify a patient. Both these potential issues may be addressed through initial filtering and removal of sequence data (e.g., human sequences). Future development of guidelines on the proper and ethical use of metagenomics data in food safety may nevertheless be necessary to encourage and facilitate the use of these potentially powerful tools (Bergholz et al., 2014).

Conclusions

The results of this preliminary study showed that metagenome sequencing is a suitable approach to investigate the microbiota composition of chicken carcasses. Statistically significant differences have been detected between the metagenomes associated to carcasses obtained from chickens fed with different diets. Further studies will clarify if such differences derive from the diets or from other factors and the relationship between abundance of sequencing reads and number of bacterial cells belonging to degradative and pathogenic bacteria.
