**Abstract**

*Bradyrhizobium japonicum* RegSR regulatory proteins belong to the family of two-component regulatory systems, and orthologs are present in many Proteobacteria where they globally control gene expression mostly in a redox-responsive manner. In this work, we have performed a transcriptional profiling of wild-type and *regR* mutant cells grown under anoxic denitrifying conditions. The comparative analyses of wild-type and *regR* strains revealed that almost 620 genes induced in the wild type under denitrifying conditions were regulated (directly or indirectly) by RegR, pointing out the important role of this protein as a global regulator of denitrification. Genes controlled by RegR included *nor* and *nos* structural genes encoding nitric oxide and nitrous oxide reductase, respectively, genes encoding electron transport proteins such as *cycA* (bll7544) or *cycB* (bll2388), and genes involved in nitric oxide detoxification (bll2806-09) and copper homeostasis (capCAB), as well as two regulatory genes (bll3466, bll4130). Purified RegR interacted with the promoters of *norC* (bll3214), *nosR* (bll3014), a *fixK*-like gene (bll3466), and bll4130, which encodes a *LysR*-type regulator. By using fluorescently labeled oligonucleotide extension (FLOE), we were able to identify two transcriptional start sites located at about 35 (P1) and 22 (P2) bp upstream of the putative translational start codon of *norC*. P1 matched with the previously mapped 5′ end of *norC* mRNA which we demonstrate in this work to be under FixK2 control. P2 is a start site modulated by RegR and specific for anoxic conditions. Moreover, qRT-PCR experiments, expression studies with a *norC*-lacZ fusion, and heme c-staining analyses revealed that anoxia and nitrate are required for *RegR*-dependent induction of *nor* genes, and that this control is independent of the sensor protein RegS.

**Introduction**

The *Rhizobiales* order of α-Proteobacteria include Gram-negative nitrogen-fixing soil bacteria collectively named rhizobia which have the unique ability to establish *N₂*-fixing symbioses with legume roots and stems of some aquatic legumes, leading to the formation of new plant organs called nodules. Expression of nitrogen fixation and other symbiosis-related genes requires low-oxygen conditions [1–2]. To cope with oxygen limitation prevailing under microoxic free-living conditions or in so-called bacteroids existing within plant cells of nodules, rhizobial species express the high-affinity *chtB* oxidase encoded by the *fixNOQP* operon [3]. Moreover, some rhizobial species are able to use nitrate as final electron acceptor to support respiration under microoxic or anoxic conditions [4–6]. The switch from oxygen to nitrate respiration leads to a reduction in the ATP yield, yet it allows bacteria to survive and multiply under oxygen-limiting conditions [7]. Denitrification has been defined as the dissimilatory reduction of nitrate (*NO₃⁻*) or nitrite (*NO₂⁻*) to *N₂* via the gaseous intermediates nitric oxide (*NO*) and nitrous oxide (*N₂O*) with concomitant ATP generation [8]. This process requires four separate enzymatic reactions catalyzed by nitrate-, nitrite-, nitric oxide-, and nitrous oxide reductasases, encoded by *nor/nap*, *nir*, *nor*, and *nos* genes, respectively [9–11].

In recent years, it has emerged that many rhizobial species have denitrification genes [4–6]. Among them, the soybean symbiont *Bradyrhizobium japonicum* is considered the model organism for studying rhizobial denitrification. In this bacterium, denitrification depends on the *nap*EDABC, *nirK*, *norCBQD*, and *nosRZD1FLX* genes that encode a periplasmic nitrate reductase (*Nap*), a copper-containing nitrite reductase (*NirK*), a *c*-type nitric oxide reductase (*cNor*), a nitrous oxide reductase (*Nos*) respectively [4]. Similar to
many other denitrifiers, expression of denitrification genes in *B. japonicum* requires both oxygen limitation and the presence of nitrate or a derived nitrogen oxide [4]. Perception and transduction of the “low-oxygen signal” are mediated by conserved regulatory proteins that are integrated into species-specific networks in different rhizobia [1–2]. Two interlinked oxygen responsive regulatory cascades are present in *B. japonicum*, the FixLJ-FixK2 and the RegSR-NifA cascades [12]. A moderate decrease in the oxygen concentration in the gas phase (≤5%) is sufficient to activate expression of FixLJ-FixK2-dependent targets [12]. This “low-oxygen” signal is sensed by the heme-based sensory kinase FixL which auto-phosphorylates and transfers the phosphoryl group to the FixJ auto regulator which then activates transcription of *fixK2*. In turn, *fixK2* induces expression of regulatory genes such as *tphN*, *fixK*, *nnrR* [13–15], genes associated with microoxic metabolism, e.g. *fixNOQP* [14–16] as well as genes involved in denitrification such as *nap*, *nnr*, *nor*, and *nos* [4,13–14,17]. Induction of genes controlled by the RegSR-NifA cascade requires very low oxygen concentration (≤0.5%) because of the pronounced oxygen sensitivity of NifA. The response regulator RegR of the RegSR-NifA two-component regulatory system induces expression of the *fixSR-nifA* operon which is preceded by two overlapping promoters, P1 and P2 [18–20]. RegR activates transcription originating from P2 under all oxygen conditions via binding to a DNA element located around position −67 upstream of the transcription start site. Upon a switch to low-oxygen or anoxic conditions, the redox-responsive NifA protein in concert with RNA polymerase containing RpoN (σ54) enhances its own synthesis via activation of the −24/−12-type promoter P1. In *B. japonicum*, RpoN is encoded by the two highly similar and functionally equivalent genes *rpoN1* and *rpoN2* [21]. Since *rpoN1* is under the control of FixK2, this gene represents the link between the two regulatory cascades. Targets of NifA include *nif* and *fix* genes, which are directly or indirectly involved in nitrogen fixation, and also genes that are not essential for this process or have an unknown function [1,22–23]. Recent results from our group showed that NifA is also required for maximal expression of *nap*, *nnr*, and *nor* genes, suggesting a new role for the RegSR-NifA regulatory cascade in the control of the denitrification genes in *B. japonicum* [24]. A large number of members of the RegR regulon have been identified by transcriptome analysis of a *B. japonicum* *regR* mutant grown under oxic and microoxic free-living conditions and also in bacteroids [25]. However, no data are available about the RegR regulon in cells grown under denitrifying conditions. Moreover, we have recently demonstrated that the level of NorC is significantly lower in membranes isolated from a *B. japonicum* *regR* mutant compared to the wild type when cells were grown under denitrifying conditions [26]. However, the involvement of RegSR in *norCBQD* genes expression has not been investigated so far.

Here, we have performed a comparative transcriptome analysis of *B. japonicum* wild type and a *regR* mutant grown under denitrifying conditions. Among the novel RegR targets, *nor* genes encoding the nitric oxide reductase were identified. By different approaches we also demonstrated that RegR control of *nor* genes induction requires anoxia and nitrate, and that this control is independent on the sensor protein RegS.

### Materials and Methods

#### Bacterial Strains and Growth Conditions

The wild-type strain *B. japonicum* 110/pc4 [27] and its derivatives 2426 (*ΔregR*), 2409 (*ΔregS*), [20], and 9043 (*ΔfixK2*) [15] were used in this study. Strain 2499 [13] is *B. japonicum* 110/pc4 containing a *norC–lacZ* fusion. In this work, plasmid pRJ2499 containing the *norC–lacZ* fusion [13], was integrated by homologous recombination into the chromosome of the *regR* and *regS* mutant strains resulting in strains 2499RR and 2499RS, respectively. *B. japonicum* strains were grown oxically at 30 °C in peptone-salts-yeast extract (PSY) medium supplemented with 0.1% L-arabinose [14,27]. Growth under oxygen-limiting conditions was performed in Bergersen minimal medium [28] with succinate as carbon source and supplemented (BSN) or not (BS) with 10 mM KNO3. For comparison with previous experiments, yeast extract-mannitol (YEM) medium [29] supplemented with 10 mM KNO3 was used for anoxic cultures of the wild type and *fixK2* mutant in some primer extension experiments. Once they were inoculated to an OD600 of about 0.2, cultures were subjected to oxygen-limiting conditions generated by two different experimental procedures. In the first set of experiments, 17 ml serum tubes or 500 ml flasks containing 5 or 200 ml medium, respectively, were sealed with rubber stoppers and the headspace atmosphere was replaced by a gas mixture (2% oxygen, 98% argon) before cultures were incubated. In the second set, cells were incubated in completely filled, sealed 200 ml bottles or 17 ml tubes without gas exchange. The latter conditions are referred to as anoxic conditions throughout the manuscript. Antibiotics were added to *B. japonicum* cultures at the following concentrations (μg ml−1): cloramphenicol 20, spectinomycin 200, streptomycin 100, tetracycline 100. *Escherichia coli* strains were cultured in Luria-Bertani (LB) medium [30] at 37°C. *E. coli* S17-1 [31] served as the donor for conjugal plasmid transfer. Tetracycline was used at 10 μg ml−1 in *E. coli* cultures.

#### RNA Isolation, cDNA Synthesis, and Microarray Analysis

Cultures of *B. japonicum* wild type and *regR* mutant strains were grown anoxically in BSN medium to an OD600 of about 0.4. Cell harvest, isolation of total RNA, cDNA synthesis, fragmentation, labeling and conditions for microarray hybridization were done as described previously [22,25,32–33]. Details of the custom designed Affymetrix *B. japonicum* gene chip BJAPETHa520090 (Santa Clara, CA) have also been described previously [22]. For each strain, a minimum of four biological replicates was analyzed. Details on data processing, normalization, and further analysis are described elsewhere [33]. GeneSpring GX 7.3.1 software (Agilent Technologies, Santa Clara, CA) was used for comparative analyses. Only the probe sets that were called “present” or “marginal” in ≥75% of the replicates of each experiment were considered for further analysis. The student *t*-test with a P value threshold of 0.025 was applied for statistical comparisons. We considered genes passing the statistical tests as differentially expressed only if the relative change in expression (n-fold) was ≥ 2 or ≤−2 when different conditions or strains were compared. Operon predictions were done as described in Hauser et al. [2007] [22] and Masa et al. [2008] [14]. An operon-like organization of genes (bicistronic or larger) was assumed if they were oriented in the same direction and separated by less than 32 bp. This distance was enlarged to 100 bp if the first three letters in the gene names were identical.

#### Quantitative Real-Time PCR

Expression of *nosZ*, *nosY*, *norC*, *blr2308*, *napE*, *napA*, *cycA*, *copC*, *bll3466*, *bll4130* and *bll2388* genes was also analyzed by quantitative reverse transcription-PCR (qRT-PCR) using an iQ<sup>™</sup>5 Optical System (Bio-Rad, CA). *B. japonicum* wild-type and *regR* cultures, RNA isolation and cDNA synthesis were performed as described for microarray experiments. Primers for the PCR reactions (Table S1 in supplemental material) were designed with

Primer3Web v.0.4.0 [http://frodo.wi.mit.edu/primer3/input.htm] to have a melting temperature of 57°C to 62°C and generate PCR products of 50 to 100 bp. Each PCR reaction contained 9.5 μl of qS^™ SYBR Green Supermix (Bio-Rad), 2 μM (final concentration) of individual primers and appropriate dilutions of different cDNAs in a total volume of 19 μl. Reactions were run in triplicates. Melting curves were generated to verify the different cDNAs in a total volume of 19 μl. Reactions were run in triplicates. Melting curves were generated to verify the specificity of the amplification. Relative changes in gene expression were calculated as described elsewhere [34]. Expression of the primary sigma factor gene sigA was used as a reference for normalization (primers SigA-1069F and SigA-1155R; [25]).

**Heme-Staining Analysis**

Cells of *B. japonicum* grown oxically in 150 ml PSY medium were harvested by centrifugation at 8,000 × g for 5 min, washed twice with BS or BSN, resuspended in 500 ml of the same medium, and cultured under anoxic conditions or with 2% initial O2 concentration for 48 hours (final resulting OD600 about 0.5). Cells were disrupted using a French pressure cell (SLM Aminco, Jessup, MD, USA) and membranes were isolated as described previously [35]. Membrane protein aliquots were diluted in sample buffer [124 mM Tris-HCl, pH 7.0, 20% glycerol, 4.6% sodium dodecyl sulfate (SDS) and 50 mM 2-mercaptoethanol], and incubated at room temperature for 10 min. Membrane proteins were separated at 4°C in 12%-SDS polyacrylamide gel electrophoresis (20 μg protein per lane), transferred to a nitrocellulose membrane and stained for heme-dependent peroxidase activity as described [31]. The reaction mixture (50 μl) was added to the reactions which were further incubated at 37°C, and washed with 50 mM Tris-HCl for 5 min, washed twice with 100 mM phosphate buffer (pH 7.4) and 900 mM 2-mercaptoethanol, and incubated at 4°C and 95°C for 5 min, respectively. Finally, 2 μl of RNase (2 mg ml⁻¹) was added to the reactions which were further incubated at 37°C for 90 minutes. The length of the reverse transcribed cDNA products was determined with permeabilized cells from at least three independently grown cultures assayed in triplicate for each strain and condition. β-Galactosidase assays were performed essentially as previously described [30]. The absorbance data for A420, A500, and A600 were determined for all samples in a plate reader (SUNRISE Absorbance Reader, TECAN, Männedorf, Switzerland) using the XFluor4 software (TECAN). Data were then transferred to Microsoft Excel to calculate the specific activities in Miller units.

**β-Galactosidase Assays**

To measure β-galactosidase activity, strains 2499, 2499RR and 2499RS were grown oxically in PSY medium, collected by centrifugation at 8,000 × g for 10 min at 4°C, washed twice with BS or BSN medium and cultured anoxically or under 2% initial O2 in the same medium for 48 h (OD600 of about 0.5). Activity was determined with permeabilized cells from at least three independently grown cultures assayed in triplicate for each strain and condition. β-Galactosidase assays were performed essentially as previously described [30]. The absorbance data for A420, A500, and A600 were determined for all samples in a plate reader (SUNRISE Absorbance Reader, TECAN, Männedorf, Switzerland) using the XFluor4 software (TECAN). Data were then transferred to Microsoft Excel to calculate the specific activities in Miller units.

**Fluorescently Labeled Oligonucleotide Extension (FLOE)**

*B. japonicum* wild type, regR and fixK2 mutant strains were cultured as indicated above for microarray and qRT-PCR experiments. Cells were harvested and total RNA was isolated using the hot phenol extraction procedure described by Babst and coworkers (1996) [38]. To determine the transcription start site of norC gene, the NorC53 reverse primer was synthesized, HPLC-purified, and labeled with 6-carboxyfluorescein (6-FAM) at the 5’-end (Eurofins MWG Operon, Ebersberg, Germany). The sequence of NorC53 was 5’-GAGCCCGGCTAGAAGACGGTTTGCT-3’ which corresponds to positions 53-31 downstream of the annotated translation start codon of norC. The primer extension assay was performed using Avian Myeloblastosis Virus Reverse Transcriptase (AMV RT; Promega, Wisconsin, USA). The reaction mixture (50 μl) contained MgC12 (5 mM), dNTPs (2 mM each), AMV RT 1X buffer, 50 pmoles FAM-labeled primer, 7-10 μg of RNA and water. Reactions were incubated at 65°C for 15 minutes, then 2 μl of the AMV/RNasin mixture (1:1; Promega) was added. Next, the mixtures were kept at 15°C for 10 minutes followed by incubation at 45°C and 95°C for 45 and 5 minutes, respectively. Finally, 2 μl of RNase (2 mg ml⁻¹) was added to the reactions which were further incubated at 37°C for 90 minutes. The length of the reverse transcribed cDNA products was analyzed in an ABI Prism 3100 Genetic Analyzer capillary electrophoresis instrument (Newbiotechnic S.A., Seville, Spain). GeneScan version 3.1.2 (Applied Biosystems, Austin TX) was used to analyze the data, *i.e.* peak identification and determination of the length and abundance of cDNA.

**Electrophoretic Mobility Shift Assays (EMSAs)**

Binding of RegR to putative target promoters was tested by EMSA using radiolabeled PCR fragments obtained with the

![Figure 1. Venn diagram based on anoxically induced genes of the B. japonicum wild type (WT; dark grey circle) and genes which, when compared with the wild type, are differentially expressed in the regR mutant both grown under anoxic dentifying conditions (light grey circle). The overlap shows the fraction of genes which are induced in the wild type and differentially transcribed in the regR mutant (the number of genes upregulated or downregulated in the regR mutant appears in brackets). Strains and conditions are indicated alongside the circles. Up-down arrows reflect increased and decreased gene expression in microarray analyses. Numbers in parentheses indicate the total number of differentially expressed genes. doi:10.1371/journal.pone.0099011.g001](http://frodo.wi.mit.edu/primer3/input.htm)
bands were visualized with a phosphorimager (Bio-Rad, Spain). Buffer pH 8.2 for 2 h at 70 V. Gels were dried, and radiolabeled gels in Tris-borate 89 mM and EDTA 2 mM electrophoresis loading dye and separated on 8% non-denaturing polyacrylamide gels. After 15-min incubation at 30°C, samples were mixed with loading dye and separated on 8% non-denaturing polyacrylamide gels in Tris-borate 89 mM and EDTA 2 mM electrophoresis buffer pH 8.2 for 2 h at 70°C. Gels were dried, and radiolabeled bands were visualized with a phosphorimager (Bio-Rad, Spain).

Microarray Data Accession Number
The microarray data are available in the NCBI Gene Expression Omnibus database (GEO; http://www.ncbi.nlm.nih.gov/geo) under GEO Series accession number GSE56668.

Results
Transcriptional Profiling of a B. japonicum regR Mutant Grown Under Free-living Denitrifying Conditions
Comparative analyses of B. japonicum wild type and the regR mutant strain grown under anoxic conditions in BSN medium revealed that approximately 1,700 genes were differentially expressed in the regR mutant (Fig. 1). The main focus of this work was the identification of genes that were upregulated in the wild type under denitrifying conditions (in comparison with oxically-grown wild type) [22,33], and at the same time regulated by RegR. The comparison of both regulons gave a total number of 620 genes involved in the denitrification process, such as nosRZDFYLX encoding nitrous oxide reductase [40], and norECBQD genes encoding nitric oxide reductase [41]. We also identified cycA which codes for cytochrome c550 that is implicated in electron delivery to NirK, the Cu-containing nitrite reductase [42-43]. Of the napEDABC genes specifying periplasmic nitrate reductase [35], only napB and napC genes were identified as RegR dependently transcribed, yet the relative fold change (FC) of expression was only −2.8 and −3.4, respectively (Table S2). Surprisingly, nirK could not be identified among the RegR-controlled genes (Table S2). We also found as RegR target the cycZ gene (bll2388) that encodes the previously identified FixK-dependent cytochrome c2 [14], which suggests that this gene might be relevant for life under denitrifying conditions. In addition to denitrification genes, numerous other genes were identified as candidates for being RegR targets under anoxic conditions (Table S2).

To validate the microarrays results, we performed qRT-PCR with several selected genes. Among them, we have selected genes encoding (i) denitrification enzymes (nosZ, nosI, nosC, napE and napD) and electron transfer proteins (cycA, bll2388), (ii) NO detoxification proteins (bll2806-09), (iii) copper homeostasis proteins (copC), and (iv) transcription factors (bll3466 encoding a FixK-like protein and bll4130 which encodes a LysR-type regulator). As shown in Fig. 2, we confirmed by qRT-PCR RegR-dependent induction of genes for nitrous oxide reductase (nosZ, nosI), nitric oxide reductase (nosC), and also cycA and bll2388. Likewise, qRT-PCR confirmed the microarray data which indicated that genes encoding the periplasmic nitrate reductase (napE and napD) are not significantly controlled by RegR. Furthermore, we could verify RegR-dependent expression of bll2808 which is part of a gene cluster (bll2806-bll2809) possibly involved in NO detoxification and nitrate assimilation [44]. Finally, qRT-PCR also confirmed RegR-dependent expression of copC, bll3466, and bll4130 (Fig. 2). Note that differences observed between FC values determined by microarray technology and...
Figure 3. Analysis of RegR binding to the promoter region of several putative target genes by EMSA. Increasing amounts of purified RegR—P were incubated with constant amounts (0.5 to 1 μg) of double-stranded 32P-labeled PCR amplified products from the promoter region of *B. japonicum* bll4130, norC, nosR, bll3466, bll2388 and blr2806 genes. In panels A to D, RegR concentrations were 1.5 μM (lanes 2), 3 μM (lanes 3), 4.5 μM (lanes 4), 6 μM (lanes 5) and 7.5 μM (lanes 6). In panels E and F, RegR concentrations were 0.8 μM (lanes 2), 1.6 μM (lanes 3) and 3.2 μM (lanes 4). No RegR protein was added to the control reactions loaded in lane 1 of all panels. Samples were run on 6% non-denaturing polyacrylamide gels and visualized with a phosphorimager. doi:10.1371/journal.pone.0099011.g003
RegR Binding to the Promoter Region of New Target Genes

Because microarray analysis cannot discriminate directly and indirectly controlled genes, we performed DNA binding analyses by EMSA to identify direct RegR target genes. We used PCR fragments corresponding to the promoter region of six candidate genes whose expression was found to be under positive control of RegR (Table 1). 32P-labeled fragments were incubated with increasing concentrations of phosphorylated RegR (0 to 7.5 μM). As positive and negative controls, we used amplification products increasing mobility were observed with the bll4130 promoter and increasing retarded band (Fig. 3B, C and D), up to 3 bands of distinct retardation were observed with the bll4130 promoter and increasing phosphorylated RegR concentrations (Fig. 3A).

Inspection of DNA sequences included in the EMSA assays by using the previously proposed RegR box as query [25] allowed us to identify two putative RegR binding sites in all promoter regions except for bll2388 (Table 1). As described previously [25], half sites of the proposed RegR boxes are differently spaced and not perfectly conserved (Table 1).

Table 1. Summary of RegR binding studies with promoter regions of anoxically induced, RegR-controlled B. japonicum genes.

| Gene no. | Gene name | Description | Genomic region | Putative RegR-box position | Sequence of putative RegR-box |
|----------|-----------|-------------|----------------|----------------------------|-------------------------------|
| bll0314  | nosR      | Nitrous oxide reductase expression regulator | −195 to +46 | −73 | TGGCTCAAGCGGCGA |
| bll2388  | cyO       | Cytochrome c2 | −143 to +31 | −39 | C6GCGCCCGGTGCGG |
| bll2806  | Nitrite extransit protein | −214 to +34 | −64 | C6GCGCTCGTGGCGG |
| bll3214  | norC      | Nitric oxide reductase subunit C | −149 to +53 | −64 | C6GCGGAGCGGCG |
| bll3466  | fixK      | Transcriptional regulator FixK-type | −160 to +58 | −123 | C6GTGCGCGGTCG |
| bll4130  | Transcriptional regulator protein LysR-family | −114 to +61 | −51 | TGGCCGTTCGTCG |

Mapping of norC Transcripts

In order to substantiate RegR control of norC genes, we mapped the transcriptional start site of norC in wild-type and regR cells grown under denitrifying conditions. Using FLOE technique we identified two signals with cDNA derived from wild-type RNA (Fig. 4, panel A, upper electropherogram) suggesting the presence of two transcriptional start sites. The cDNA signal marked as P1 corresponds to the previously proposed start site of norC [41] which maps to a guanosine 35 bp upstream of the transcriptional start codon of NorC (Fig. 5). The cDNA signal designated as P2 corresponds to a second start site which maps to an adenosine located 14 bp downstream of P1 and 21 bp upstream of the norC start codon (Fig. 5). As the peak area is directly proportional to the number of cDNA molecules [45], the FLOE technique allows quantification of intensity of each signal in arbitrary units. The average area of P2 from 6 different replicates indicated that the abundance of P2 cDNA obtained with RNA from the regR mutant relative to the wild type was reduced by 40% compared to the wild type-derived cDNA (Fig. 4A, upper electropherogram). However, the area of the P1 cDNA peak did not significantly change in the regR mutant relative to the wild type (Fig. 4A). This suggests that RegR is needed for efficient synthesis of the P2 transcript under anoxic conditions. The transcriptional start site P1 is located 45 bp downstream of a FixK2 box (Fig. 5), which supports our previous notion that norC transcription depends on the FixK2 transcription factor [41]. To confirm this hypothesis, we also have performed primer extension experiments with RNA isolated from a B. japonicum fixK2 mutant. As shown in Fig. 4B (lower electropherogram), the primer extension signal corresponding to P1 was absent in cDNA derived from the fixK2 mutant but present in cDNA obtained with wild-type RNA (Fig. 4B, upper electropherogram).
In other bacteria, RegSR orthologous two-component regulatory systems (e.g. RegBA, PrrBA, or ActSR) respond to different oxygen levels to adapt their respiration accordingly [46]. Therefore, we were interested to determine whether the P2 transcript proposed to be RegR-modulated under anoxic conditions is also synthesized under another oxygen-limiting condition. To do so, we performed primer extension experiments using RNA from cells grown in BSN medium and flushed with 2% oxygen at the beginning of the incubation. As shown in Fig. 4C, no P2 cDNA was detected when RNA was isolated from wild-type cells grown under these conditions. By contrast, P1 cDNA corresponding to the FixK2-dependent transcript was present when wild-type cells were cultured under both anoxic or 2% initial oxygen conditions (Fig. 4A, C). Similar results were obtained when we used RNA from regR mutant cells grown under the same conditions (data not shown). These results suggest that, in contrast to P1, P2 transcript is specific for anoxic conditions.

RegR Control of nor Genes Requires Anoxia and Nitrate and is RegS Independent

In order to investigate whether or not anoxic conditions are required for RegR-dependent induction of nor genes, we analyzed expression of nor genes in wild-type and regR mutant cells cultured anoxically or under 2% initial O2 in the absence or the presence of nitrate (Table 2). The presence of nitrate induced expression of a norC-lacZ transcriptional fusion in wild-type cells grown under anoxic conditions or 2% initial O2 about 14-fold and 9-fold, respectively. Interestingly, β-galactosidase activity derived from the norC-lacZ transcriptional fusion was about 38-fold lower in the regR mutant compared to wild-type levels when cells were cultured under both anoxic or 2% initial O2 conditions (Table 2). Therefore, β-galactosidase activity that is RegS Independent (Fig. 6; lanes 1, 2). No difference of NorC expression was observed in regS mutant cells compared to wild-type cells (Fig. 6; lanes 1, 3). Furthermore, when cells were incubated under 2% initial O2 concentration in BSN medium, NorC expression did not decrease in the regR mutant (Fig. 6; lanes 4, 5).

Finally, we also tested the involvement of RegR in nor expression at the level of Nor activity by measuring NO consumption of wild-type and regR mutant cells cultured anoxically in BSN medium. As expected, NO consumption by regR mutant cells was drastically decreased (54 ± 7 nmoles NO mg protein \(^{-1}\) min \(^{-1}\)) compared to wild-type cells (832 ± 7 nmoles NO mg protein \(^{-1}\) min \(^{-1}\))

Discussion

The ability of B. japonicum to denitrify is well documented [4]. However, so far no information has been available about target
genes controlled by RegR under denitrifying conditions. Our transcriptome analyses showed that expression of approximately 1,700 genes was altered in a regR mutant compared to the wild type when cells were grown anoxically in BSN medium. If only those genes are considered which showed a fold-change value of expression $\leq -5$ and $\geq 5$ (343 genes; Table S3), the large majority of them (83%) are subject to positive control by RegR. This documents that this protein predominantly acts as an activator under the applied growth conditions, which extends the results obtained previously with regR mutant cells grown under oxic or microoxic free-living conditions, or as bacteroids in root nodules [25]. Notably, among this group of 343 genes we found the previously described RegR targets such as fixK, nirA, the blr1515-blr1516 operon that encodes a predicted multidrug efflux system [25,47], and bll4130 encoding a LysR-type regulator, which validates the approach used in this work. Among the 620 genes anoxically induced whose expression differed in the regR mutant, a group of 344 genes were positively regulated (Figure 1). Based on this observation we propose a relevant role for RegR in B. japonicum denitrification. For example, we found among RegR targets structural denitrification genes (nor, nos) and genes participating in electron transport through the denitrification pathway (cyCL, cyO), and the respective microarray data was validated by qRT-PCR. In this context, the involvement of R. sphaeroides PrrBA [48] and Brucella suis RegBA [49] in norK regulation is worth to be mentioned. Likewise, insertional inactivation of the response regulatory Agrobacterium tumefaciens actR gene significantly reduced norK expression as well as expression of pac encoding the electron-transport protein pseudoazurin [50]. Recently, it has been reported that the redox-responsive NitX and PrrBA two-component systems of Brucella abortus co-ordinately regulate the expression of denitrification in response to oxygen-limited conditions [51–53]. Results from our work indicate that, in contrast to nor and nos genes, nirK and nap denitrification genes were not under the control of RegR, which documents that B. japonicum denitrification genes differ with regard to their dependence on RegR. Notably, disparate regulation of nap, nirK and nor genes by FixK2 was found previously during transcription profiling studies with a B. japonicum fixK2 mutant strain grown under microoxic conditions [14]. Specifically, nap, nirK, and mbrA, but not nor or nos genes were among the targets of FixK2.

We have also identified and validated as RegR targets, copCAB genes encoding proteins involved in the assembly of periplasmic and secreted cuproproteins [54] which might be involved in maturavation of the Cu-containing NitK or Nos enzymes. Furthermore, genes involved in NO detoxification and nitrate assimilation (bll2806-09) [44] as well as genes encoding transcriptional regulators were found to be controlled by RegR. Among the latter group was bll3466 encoding a FixK-like protein proposed to be involved in the negative feed-back of fixK2 expression [55] and bll4130 encoding a LysR-type regulator. Finally, phyB (bll7795) and the associated ECF $\sigma$-factor gene ecfG (bll7797) which contribute to stress tolerance and symbiotic proficiency of B. japonicum [56], were also identified as targets of RegR in this work.

Electrophoretic mobility shift experiments revealed RegR binding to the promoter regions of norC, nosR, bll3466, and bll4130. RegR binding to the latter, a LysR-type regulator gene, was also previously observed by Lindemann and co-workers (2007) [25]. Interestingly, we observed several bands of different mobilities in the case of the bll4130 promoter. It might be possible that at low concentration, RegR starts binding to one of the RegR-boxes found within this promoter region, and that at higher concentration it also binds to the secondary binding site of probably lower affinity. A hierarchical binding was also described for PhoB, the response regulator of the PhoR/R two-component system which activates the transcription of several genes involved in phosphate uptake and assimilation [57]. By EMSA assays, these authors demonstrated that two PhoR dimers bind to two consecutive pho boxes in a hierarchical and cooperative manner. Using the FLOE technique we identified two transcriptional start sites in the norC promoter region (P1 and P2). P1 is the previously proposed FixK2-dependent start site [41], and P2 is a start site whose abundance was modulated by RegR under our experimental denitrifying conditions. Contrary to this work, previous primer

Table 2. $\beta$-Galactosidase activity derived from a norC-lacZ fusion present in B. japonicum wild type (2499), regR (2499RR) or regS (2499RS) mutant cells.

| Strain   | Relevant genotype | Miller units          |
|---------|-------------------|-----------------------|
|         |                   | Anoxia | + nitrate | 2% $O_2$ | + nitrate |
| 2499    | wild type         | 76.2 (6.8) | 1079 (70) | 39.8 (11.3) | 347.3 (52) |
| 2499RR  | regR              | 144 (41)       | 28.6 (3.9) | 169.6 (25.7) | 499.5 (22.6) |
| 2499RS  | regS              | nd            | 1266 (90)  | nd         | nd        |

Cells were cultured under anoxic conditions or under 2% initial $O_2$ in Bergersen minimal medium without (BS) or with nitrate (BSN). Data are means with standard error (in parenthesis) from at least three independent cultures, assayed in triplicate. nd, not determined.

Figure 6. Heme-stained membrane proteins from cells of B. japonicum wild type (WT; lanes 1 and 4), regR mutant strain 2426 (lanes 2 and 5), and regS mutant strain 2409 (lane 3) cultured in BSN medium under anoxic conditions or 2% initial $O_2$. About 20 $\mu$g membrane proteins were loaded per lane. Heme-stained c-type cytochromes identified previously are specified at the right margin along with their predicted mass. Note that all the samples were run in parallel on the same gel.

extension analyses of norC, performed by using [$\gamma^{[32]}$P]ATP and the subsequent detection of extension products in denaturing polyacrylamide gels, only revealed the presence of the FixK$_{j}$-dependent start site P1 but not the RegR-dependent start site P2 [41]. This apparent discrepancy could be due to the different growth conditions and methodological approaches used by Mesa and colleagues (2002) [41] and in this work. Anoxia and nitrate are required for RegR-dependent induction of nor genes. This is in line with microarray experiments performed previously to characterize the B. japonicum RegR regulon where nor genes were not among RegR-regulated genes in cells grown in PSY medium under microoxic conditions (max. 0.5% oxygen throughout cell cultivation) [25]. Those authors identified RegR-dependent genes in either free-livingoxic or microoxic and symbiotic conditions and concluded that this protein contributes to redox regulation in B. japonicum. As shown here, RegR has also a regulatory role under anoxic conditions, and the presence of nitrate or a nitrogen oxide generated from nitrate reduction was crucial for RegR control of nor genes. Analogous to our findings, the presence of nitric oxide (NO) is required for ResDE-dependent anaerobic induction of Bacillus subtilis nasDE and hmp genes which encode a nitrite reductase and a NO-detoxifying flavohemoglobin, respectively. In this bacterium, NO inactivates the NO-sensitive NsrR transcriptional repressor of nasDE and hmp [58] leading to anaerobic induction of nasDE and hmp by ResDE. B. japonicum genome lacks genes coding for an obvious NsrR homolog [59], which, however, does not exclude that in addition to RegR also other regulators contribute to the control of B. japonicum nor genes under denitrifying conditions.

RegSR two-component regulatory system comprises the membrane-associated RegS histidine protein kinase and its cognate RegR response regulator [39]. The regulatory mechanism has been well-studied in the orthologous RegBA system of R. capsulatus [46,60]. In this bacterium, the membrane-localized ubiquinone pool and the redox-active cytochrome (Cys$^{207}$) function as redox sensors that regulate RegB kinase activity which auto-phosphorylates and transfers the phosphoryl group to the RegA response regulator [61–64]. In this work, we made the intriguing observation that regulation of norC differed in regS and regR mutants. While deletion of regR abolished activation of norC under anoxic conditions in BSN medium, mutation of regS resulted in wild type-like expression norC. This is in line with previously described phenotypic differences between regR and regS mutants of B. japonicum [20], regB and regA mutants of R. capsulatus [65], or regS and norR mutants of Pseudomonas aeruginosa [66]. It might be possible that in the B. japonicum regS mutant, RegR is phosphorylated via cross-talk by an alternative sensor kinase. In fact, the two-component regulatory system encoded by B. japonicum genes blr1154 and blr1155 shows pronounced similarity to RegSR (H.M. Fischer, unpublished data), and thus is a candidate for the postulated cross-talk.

Supporting Information

Table S1 List of primers used for qRT-PCR experiments and EMSA assays.

Table S2 Anoxically induced genes (as compared to oxic conditions) whose expression differed in the RegR strain relative to the wild type.

Table S3 Differentially expressed genes by a factor of ≤5 or ≥5 in the RegR strain grown anoxically and their putative operon members.
