We study an LC-circuit implemented using a current-biased Josephson junction (CBJJ) as a tunable coupler for superconducting qubits. By modulating the bias current, the junction can be tuned in and out of resonance and entangled with the qubits coupled to it. One can thus implement two-qubit operations by mediating entanglement. We consider the examples of CBJJ and charge–phase qubits. A simple recoupling scheme leads to a generalization to arbitrary qubit designs.

Significant successes in manipulating the quantum state of superconducting qubits once more make them prime candidates for a solid-state quantum computer. Since the experiments yield single-qubit coherence times close to the accepted limits, one can focus on other steps towards realizing the potential of quantum information processing in these systems. The critical next step is controlled coupling of, at least, two qubits.

Several coupling mechanisms are possible, e.g., capacitive coupling for charge, charge–phase, and current-biased Josephson-junction (CBJJ) qubits. Importantly, it is simple to implement and recently enabled entangling two charge qubits. Also, this type of coupling can be turned on and off by tuning the qubits’ level spacings in and out of resonance if the interaction Hamiltonian is off-diagonal in the computational basis.

In this case, universal quantum computing is still possible, but imperfect refocusing introduces errors and the threshold for fault tolerance is not yet known.

We propose to capacitively couple superconducting qubits to a CBJJ, implementing an LC-circuit and acting as a tunable bus. This parallels cavity QED (the CBJJ and qubits playing the roles of the cavity and atoms respectively) and ion traps. LC-circuits can also be coupled to flux qubits (inductively) and other superconducting devices. In another scheme to entangle qubits through an LC-circuit, the latter’s virtual states mediate an effective qubit–qubit interaction.

The CBJJ’s kinetic inductance depends on the bias and modifies the circuit’s overall inductance. It thus acts as a tunable anharmonic LC-circuit, which guarantees a non-uniform level spacing, reducing leakage to higher states. However, for anharmonic oscillators, transitions from |n⟩ to |n±2⟩ etc. can cause leakage; this is minimized for suitable system parameters (see below).

For illustration, we first consider a pair of CBJJs, coupled by a capacitance Cc (Fig. 1 cf. Ref. [17]). One plays the role of the qubit and the other of the tunable bus. Controlled coupling of charge–phase qubits follows. Coupling of a charge qubit to a CBJJ was studied in Ref. [18].

A Josephson junction biased by a dc current has the well-known washboard potential. Close to the critical bias Ic, there are few levels in each washboard well. We consider a large junction with a bias such that there are only three such levels. Then, the two lowest levels in one of the wells form the qubit’s computational subspace |0⟩, |1⟩. State |n⟩ has decay rate Γn to the continuum. The |0⟩ ⋱ |1⟩ transition frequency is Ω.

The circuit of Fig. 1 has the Hamiltonian

$$\mathcal{H} = \frac{\hbar^2}{2C_{q1}} E_{q1} \cos \phi_q - \frac{\hbar^2}{2\pi} I_q \phi_q + \frac{\hbar^2}{2C_{p1}} E_{p1} \cos \phi_p - \frac{\hbar^2}{2\pi} I_p \phi_p + \frac{\hbar^2}{2C_c} I_{q1} I_{p1} \cos \phi_{qp} \cos \phi_q \cos \phi_p$$

where $p_i$ is the charge at node $i$ and $\phi_i$ the phase difference across junction $i$. ‘q’ (‘p’) denotes qubit (bus). The effective capacitances are $C_{q1} = C_{p1} + (C_{q1}^{-1} + C_c^{-1})^{-1}$.
$C_{jb} + (C_{jq}^{-1} + C_{jb}^{-1})^{-1}$, and $\tilde{C}_c = C_{jq} C_{jb} (C_{jq}^{-1} + C_{jb}^{-1} + C_{jb}^{-1})$. Below we take both junctions identical: $C_{jq} = C_{jb} \equiv C_j$ and $E_{jq} = E_{jb} \equiv E_j$.

For near-critical potentials, the washboard potentials are well approximated by cubic ones [20] and the junctions can be treated as anharmonic oscillators. Using this analogy, the charge at node $i$ is $p_i = \frac{e}{2\pi} \sqrt{m \omega_i / 2} (a_i^+ - a_i)$, with the ‘mass’ $m = \tilde{C}_i (\Phi_i / 2\pi)^2$ and the plasma frequency $\omega_{pi} = \sqrt{2 \pi / \tilde{C}_i \Phi_0^2 [1 - (E_{bias,i}/I_c)^2]^{1/4}}$. $a_i^{(1)}$ is an annihilation (creation) operator [10, 20].

Expressing $1$ in the basis $\{|0_{q_{1b}}, |1_{q_{1b}}\}$, we find the coupled eigenstates. First, focus on the Hamiltonian $H_2$ in $L$, the span of $\{|0_{q_{1b}}, |1_{q_{1b}}\}$: to first order in the anharmonicity,

$$H_2 = \begin{pmatrix} E_{q0} + E_{b1} & \gamma / 2 \\ \gamma / 2 & E_{q1} + E_{b0} \end{pmatrix},$$

where the coupling coefficient is $\gamma \equiv \hbar \sqrt{\omega_{pin} \omega_{ph}} \tilde{C}_j / \tilde{C}_c$ and $E_{bi}$ is the energy level $k$. Without coupling, $\{|0_{q_{1b}}, |1_{q_{1b}}\}$ are degenerate for bias currents such that $E_{q1} - E_{q0} = E_{b1} - E_{b0}$. A non-zero $\gamma$ lifts the degeneracy, and the new (maximally entangled) eigenstates are

$$|\psi_{\pm}\rangle \equiv (|0_{q_{1b}}\rangle \pm |1_{q_{1b}}\rangle) / \sqrt{2}.$$  

In resonance, $H_2$ thus acts as $e^{-i \omega \gamma \tau / 2\hbar}$ in $L$ and as phase factors outside. Hence, for a system prepared in $|1_{q_{1b}}\rangle$, the probability to find the qubit in $|1_{q_{1b}}\rangle$ oscillates with period $T_{Rabi} = h / \gamma$. For a single CBJJ such oscillations only occur under current bias at frequency $\Omega$ [2, 3]. Oscillations for the coupled qubit and bus without applied resonant perturbation on them individually then demonstrate their entanglement.

Anharmonicity is crucial here as it keeps other relevant level pairs out of resonance, suppressing leakage out of $L$. However, $p_{q_{1b}}/\tilde{C}_c$ in $\Omega$ causes non-resonant leakage, in particular to $|2_{q(b)}\rangle$. These states are closer to the top of the potential barrier, so $\Gamma_{2,q(b)}$ are large. Hence, poisoning of $|\psi_{\pm}\rangle$ with $|2_{q(b)}\rangle$ shortens the coherence time.

We evaluate the extent of this leakage numerically. The Hamiltonian of each anharmonic oscillator is expressed in terms of about 20 harmonic-oscillator eigenstates and diagonalized. For each junction, we use $C_j = 6pF$ and $I_c = 21\mu A$ [2]. With $I_{bias} = 20.8\mu A$, each contains three levels. We take $C_c = 25fF$, minimizing leakage while keeping a reasonable $T_{Rabi} \approx 40$ns (see below) [2].

We find that $|2_{q(b)}\rangle$ poisons $|\psi_{\pm}\rangle$ with a small probability ($P_2 \sim 10^{-6}$) only, as expected. The coupled system’s other states also have weak poisoning by $|2_{q(b)}\rangle$: worst is the eigenstate close to $|1_{q_{1b}}\rangle$, with $P_2 \sim 10^{-4}$. Roughly, the lifetime of a state with poisoning $P_2$ is $(P_2 T_{Rabi})^{-1}$. Since $\Gamma_{2}/\Gamma_1 \sim 10^3$ [2], then $P_2 \lesssim 10^{-4}$ should hardly change the lifetime of the qubit or bus.

When the bus is not tuned to the qubit’s frequency $\Omega_q$, the two are decoupled. For this, we keep the qubit’s bias constant, and for the bus decrease it to 20.43$\mu A$; each well then contains about 11 levels. The eigenstates are now computed as $0.007 |0_{q_{1b}}\rangle + 0.999 |1_{q_{1b}}\rangle$ and $0.999 |0_{q_{1b}}\rangle + 0.007 |1_{q_{1b}}\rangle$, where poisoning by higher states with probabilities $\lesssim 10^{-6}$ has been omitted.

One can choose a $C_c$ optimizing the effective quality of the coupled qubits, as shown in Fig. 2. To avoid further leakage and gate errors, the qubit–bus coupling should be turned on faster than $T_{Rabi}$ but adiabatically with respect to the bus interlevel spacing, corresponding to $\sim \text{Ins}^2$; this leaves a suitable window of turn-on time.

Let us turn to a pair of charge–phase qubits coupled through a CBJJ (Fig. 3). For the qubits, only two levels are considered. To be able to couple the bus to only one qubit at a time, we assume $\Omega_1 \neq \Omega_2$ for their level spacings. Similarly to the above, tuning the bus in resonance with $\Omega_i$ causes coherent oscillations between it and qubit $i$, while the other qubit is hardly affected.

As before, the interaction Hamiltonian couples the bus charge to the qubit-island charge and, in the logical basis for the qubit $1$, takes the form $\sigma_{x} p_{1b}/\tilde{C}_c$. The qubit–bus coupling coefficient is $\gamma’ \equiv \sqrt{\beta} (2\epsilon_1) \times \left(2\pi/\Phi_0\right)^2 \sqrt{m e \omega_{ph}/\tilde{C}_c}$, where $\tilde{C}_c$ now depends on the total capacitances of both qubits $C_{\Sigma,i} = C_{g1} + 2C_{ji}$. The number $\beta$ depends on the ratio of the qubit island’s charging and Josephson energies; we take $\beta = 1.16$, corresponding to the parameters of Ref. [1].

For two-qubit operations, the qubits should interact sequentially with the bus which, at the end of the operation, should be disentangled from them. This can be done as follows. Assume the qubits are in an arbitrary state $\rho_0 = I/2$.

\begin{equation}
|\psi_{\pm}\rangle = T_{dec}^\dagger T_{Rabi}^\dagger |\psi_i\rangle
\end{equation}

\begin{equation}
Q_{dec} = T_{dec} T_{Rabi}^\dagger
\end{equation}

\begin{equation}
T_{dec} = T_{q,bias} T_{Rabi}^\dagger
\end{equation}

\begin{equation}
T_{Rabi} = T_{bias}^\dagger T_{bias}
\end{equation}

\begin{equation}
Q_{bias} = T_{bias}^\dagger T_{bias}
\end{equation}

\begin{equation}
Q_{bias} = T_{bias}^\dagger T_{bias}
\end{equation}
has been given in Refs. [21]. Here we study them for the coupled system near the degeneracy point. Consider, e.g., the CBJJs in Fig. 1. Major sources of decoherence are the qubit δIq(t) and bus δIb(t) bias noises. These correspond to two separate environments, leading to independent fluctuations of ωpq and ωpb. Near degeneracy, focus again on the subspace L. First rewrite $H_2$ as $H_2 = \frac{1}{4} (\sigma_x \cos \theta + \sigma_z \sin \theta)$, where $\cos \theta = (\Omega_{q} + \Omega_{b})/\epsilon$, $\sin \theta = \gamma/\epsilon$, and $\epsilon = \sqrt{(\Omega_{q} + \Omega_{b})^2 + \gamma^2}$. Then, expand $H_2$ to $O(\delta I)$, obtaining the system–bath Hamiltonian $H_{SB} = \tau_z (X_q + X_b) + \tau_x (X_q' + X_b')$. The $\tau_n$ are Pauli matrices in the eigenbasis of $H_2$ and $X_1'$(t) are bath operators.

For an environment represented by real impedances $Z(\omega) = R_I$ in parallel to each junction, the spectral density of the bath operators is $J(\omega) = J_x(\omega) + J_z(\omega)$, where

$$\frac{R_I J_z(\omega)}{\omega} = \left[ \frac{\omega_{pq} I_{bias,q}}{4(I_{c,q}^2 - I_{bias,q}^2)} \left( \frac{\gamma \sin \theta}{2 \omega_{pq}} - h \cos \theta \right) \right]^2 + \left[ \frac{\omega_{pb} I_{bias,b}}{4(I_{c,b}^2 - I_{bias,b}^2)} \left( \frac{\gamma \sin \theta}{2 \omega_{pb}} + h \cos \theta \right) \right]^2$$

and similarly for $J_x$. Thus $J(\omega)$ remains $\propto \omega$ even under microwave resonances.

The relaxation and dephasing rates now become

$$T_1^{-1} = J_z(\epsilon/h) \coth(\epsilon/2k_BT)/2h$$

$$T_2^{-1} = T_1^{-1}/2 + 2\pi\alpha k_BT/h$$

where $\alpha = J_z(\omega)/2\pi h\omega$ for $\omega \rightarrow 0$. For the CBJJ, long coherence times require an environment with sufficiently high impedance, engineered to be Re $Z(\omega) \approx 500k\Omega$ in Ref. [21] (instead of the standard $\approx 100\Omega$ at microwave frequencies). With this $R_I$, $T = 25mK$, and the above parameters for two CBJJs, $T_{1,2} \sim 1ms$ at exact resonance. Out of resonance, $T_1$ grows while $T_2$ stays the same order. This lower bound on $T_{1,2}$ is $>10^3\times$ the decoherence time of the decoupled system [21]. So $\delta I_{q,b}$ should hardly affect the coherence.

For a charge–phase qubit at the working point, voltage fluctuations $\delta V$ across the coupling-bus impedance $Z_b(\omega)$ affect the qubit island through $H_{SB} \sim e\delta V(C_c/C_2)\tau'_z$. Here, $\tau'_z$ is a Pauli matrix in the single-qubit eigenbasis. As is clear from the general [21] and [1], there is no dephasing since $H_{SB}$ does not couple to $\tau'_z$. Moreover, in the case of a purely resistive $Z_b(\omega)$, and for now considering only the junctions’ capacitance [21], the spectrum of $\delta V$ is centered at $\omega = 0$. With, e.g., a large Re $Z_b(\omega) \approx 500k\Omega$ as above, this spectrum is very narrow and its weight at $\Omega_{1,2}$ small. The relaxation due to $Z_b$ is therefore weak [21].

Finally, let us generalize to other qubit designs. The above holds if the interaction Hamiltonian is completely off-diagonal in the computational basis. If it is of the form $\sigma_{zq} \otimes \phi_b$, recoupling can be used [21]. Start from the
relations $H\sigma_z H = \sigma_z$ and $H\sigma_x H = \sigma_z$ for the Hadamard gate $H$. Since $H_q(B_{xz}\sigma_x + \Omega_b \sigma_z + \frac{\gamma}{2} \sigma_x \otimes p_b)H_q = B_{xz}\sigma_x + \Omega_b \sigma_z + \frac{\gamma}{2} \sigma_x \otimes p_b$, applying $H$ on the qubit before and after the qubit–bus interaction (realized here by taking the single-qubit Hamiltonian as $B_{xz}\sigma_x$ with $B_{xz} = \Omega_b$) the coupled system will behave as if it had an off-diagonal interaction. All our results then apply.

In conclusion, we have considered a CBJJ acting as a tunable LC-circuit to mediate entanglement between superconducting qubits and perform logic operations. The method allows coupling qubits not just with different parameters, but of different kinds: the two qubits in Fig. 3 need not be the same. It allows to switch the coupling on and off without tuning individual qubits. Estimates show that no significant additional relaxation or dephasing is introduced into the system. Leakage to higher states can be minimized by choosing the junction parameters and coupling capacitances. The issue of leakage has been addressed previously [25], and this should be adapted to apply here. Since the qubits and LC-circuit can be optimized independently, this gives reason for optimism. Our approach thus has the potential to lead to a universal coupling scheme for solid-state qubit registers.

As this article was being finalized, a paper investigating capacitive coupling between charge qubits through an LC-circuit appeared on the LANL preprint server. In Ref. [27], coupling between the qubits is realized using both on- and off-resonant pulses with the LC-circuit.
