Abstract
Ultracold polar molecules, in highly anisotropic traps and interacting via a repulsive dipolar potential, may form one-dimensional chains at high densities. According to classical theory, at low temperatures there exists a critical value of the density at which a second-order phase transition from a linear to a zigzag chain occurs. We study the effect of thermal and quantum fluctuations on these self-organized structures using classical and quantum Monte Carlo methods, by means of which we evaluate the pair correlation function and the static structure factor. Depending on the parameters, these functions exhibit properties typical of a crystalline or of a liquid system. We compare the thermal and the quantum results, identifying analogies and differences. Finally, we discuss experimental parameter regimes where the effects of quantum fluctuations on the linear–zigzag transition can be observed.

(Some figures in this article are in colour only in the electronic version)

1. Introduction

The experimental realization of strongly interacting atomic ensembles at ultralow temperatures allows the observation of self-organization into ordered patterns. Prominent examples are Coulomb crystals of laser-cooled ions in Paul and Penning traps [1]. In these systems laser cooling allows one to access the crystalline regime, which emerges from the competition of the long-range Coulomb interaction and the trapping potential at low temperature. Different structures are found depending on the trap geometry and the number of atoms [1–4]. In one of the early experimental works [2, 3], the phase diagram of the various low-dimensional crystalline structures was determined as a function of the trapping frequency of the harmonic confinement and of the number of atoms [1–4]. In one of the early experimental works [2, 3], the phase diagram of the various low-dimensional crystalline structures was determined as a function of the trapping frequency of the harmonic confinement and of the number of atoms, starting from a set-up with the ions arranged in a linear chain. Later works, concerned about the possibility of measuring quantum fluctuations affecting the structure of these systems, pointed out that the ground state of ion crystals is essentially classical [5]. Recent theoretical works, nevertheless, predicted that for chains of few ions quantum fluctuations, such as single-particle tunnelling at the structural transition linear–zigzag, may be observed [6].

Under this perspective, ultracold dipolar gases of atoms or polar molecules are interesting systems, as the nature of the dipolar interaction allows one to observe the interplay between quantum degeneracy and long-range forces. Dipolar gases of ultracold atoms have been experimentally realized with chromium atoms [7, 8]. In these experiments the strength of the s-wave scattering interaction is conveniently controlled by tuning the Feshbach resonance and can be made vanishing, thus leading to the realization of purely dipolar systems. Stability against collapse is warranted by polarizing the gas in a two-dimensional geometry, such that the dipolar interactions can be considered as purely repulsive [9, 10]. Several theoretical works have studied the phases of dipolar gases of atoms or polar molecules as a function of density and dimensionality [11–16]. In the context of this paper, studies which predicted the creation of self-organized structures in a two-dimensional bulk system are particularly relevant, showing that the ground state may exhibit the typical features of a crystal or of a quantum fluid depending on the density [9, 10].

One-dimensional dipolar gases can be experimentally realized in highly anisotropic traps [17]. In this limit, the Luttinger liquid models describe the long-range properties of dipolar gases at ultralow temperatures [18]. In this case, by
tuning the density, the phase of the gas undergoes a crossover from a Tonks–Girardeau gas to a crystal-like phase [19]. Differing from Coulomb systems, the crystal-like phase is energetically favourable at large densities, as it is typical of short-range interacting systems.

In [20] we presented a theoretical study of low-dimensional dipolar gases focusing on the effects of quantum fluctuations on the formation of transverse correlations at the classical critical point from a linear to a planar distribution, where the one-dimensional structure is unstable with respect to increasing the atomic density and/or to decreasing the transverse potential. In this paper, we provide further details of that study and extend it to consider thermal effects in the formation of quasi-crystalline structures in the classical domain. The analysis of the thermal and quantum fluctuations is performed numerically, by means of Monte Carlo simulations. The pair correlation function and the structure form factor for the linear and zigzag chains for the classical case at finite temperature and the quantum case at $T = 0$ are compared, and analogies and differences are discussed.

This paper is organized as follows. In section 2, we introduce the theoretical model for a two-dimensional gas of dipolar bosons in the presence of tight transverse confinement. In section 3 we discuss the mechanical stability of a one-dimensional array of dipoles, assuming classical dynamics and neglecting thermal fluctuations. In section 4, the numerical methods applied for simulating the thermal and quantum fluctuations are described. The effect of thermal fluctuations on the quasi-crystalline phase is discussed in section 5. The phase diagram for the quantum ground state is introduced and discussed in section 6 while the numerical results for the pair correlation function and structure form factor of linear and zigzag phases are presented in section 7. The conclusions are drawn in section 8, and details of the calculations are reported in the appendices.

2. The model

We consider $N$ bosonic atoms or molecules of mass $m$ at ultralow temperatures. The particles have an induced or permanent dipole and are confined by an external harmonic potential on the plane $x-y$ at $z = 0$ by means of a very tight confinement along the $z$-axis, while their dipoles are aligned along the $z$-direction by means of an external field, such that their mutual interaction is always repulsive. By appropriately tuning an external magnetic field to the top of a Feshbach resonance, the s-wave scattering can be made negligible so that the particles interact exclusively through the repulsive long-range dipolar interaction potential, which here reads as

$$V_{\text{int}} = \frac{C_{\text{dd}}}{4\pi |\rho_1 - \rho_2|^3},$$

(1)

where $C_{\text{dd}}$ is the dipolar interaction strength and $\rho_j = (x_j, y_j)$ is the particle position vector in the $x-y$ plane.

The Hamiltonian of the dipoles contains the kinetic energy, the harmonic confinement and the dipole–dipole interaction:

$$H = \sum_j \left[\frac{p_j^2}{2m} + \frac{1}{2} m v_j^2 \gamma_j^2 \right] + \frac{1}{2} \sum_{j=1}^N \sum_{\ell=1}^N \frac{C_{\text{dd}}}{3\pi |\rho_j - \rho_\ell|^3},$$

(2)

where $p_j$ is the conjugate momentum of the coordinate $\rho_j$ and $v_j$ is the confinement frequency of the particles along the $y$-direction. In the following, we will consider a homogeneous system along the $x$-direction with periodic boundary conditions. For the classical regime, where the particles are distinguishable, this will correspond to imposing $\rho_{j+N} = \rho_j$. In the quantum regime, this consists in imposing that the ground-state wavefunction fulfills the condition $\psi(x_1, \ldots, x_j + L, \ldots, x_N, y_1, \ldots, y_N) = \psi(x_1, \ldots, x_j, \ldots, x_N, y_1, \ldots, y_N)$ for all $j$, where $L$ is the size of the system along the $x$-direction.

3. Mechanical stability of a classical chain of dipoles

In this section, the dipolar system is studied in the classical regime. We first consider the equilibrium positions of the dipoles as determined by the trap and the repulsive dipolar interaction:

$$\frac{\partial V}{\partial x_i} |_{\rho = \rho^{(0)}} = -3r_0 \sum_j (x_i - x_j) |\rho_i - \rho_j|^3 |_{\rho = \rho^{(0)}} = 0,$$

(6)

and

$$\frac{\partial V}{\partial y_i} |_{\rho = \rho^{(0)}} = -3r_0 \sum_j (y_i - y_j) |\rho_i - \rho_j|^3 |_{\rho = \rho^{(0)}} = 0.$$  

(7)

We assume the interparticle distance along the $x$-axis to be uniform and given by the length

$$a = 1/n,$$

(8)
where \( n \) is the linear density and we denote by \( \tilde{n} = n \sqrt{E_{bo}/mv_{f}^{2}} \) the rescaled density. Within the assumption of equispaced dipoles, equation (6) is automatically satisfied. In order to find a solution of equation (7), we assume the ansatz \( \tilde{q}_{j}^{0} = (j \tilde{a}, (-1)^{j}/\tilde{b}, 2/), \) with \( \tilde{a} = 1/\tilde{n} \), and which for \( \tilde{b} = 0 \) corresponds to a linear arrangement of the dipoles, while for \( \tilde{b} \neq 0 \) it gives a zigzag structure. Using this ansatz, equation (7) becomes
\[
\tilde{b} \left[ 1 - \sum_{l=1}^{N/2} \frac{12 \tilde{r}_{0}}{(2l-1)^{2} \tilde{a}^{2} + \tilde{b}^{2}} \right] = 0, \tag{9}
\]
which relates the value of \( \tilde{b} \) to \( \tilde{a} \). Note that \( \tilde{b} = 0 \) is always a solution of equation (9). Values of \( \tilde{b} \neq 0 \) are solutions of equation (9) provided that the linear density \( \tilde{n} \) is larger than some critical value \( \tilde{n} > \tilde{n}_{c} \) where
\[
\tilde{n}_{c} = \sqrt{E_{bo}}^{1/5} \tag{10}
\]
is the critical density which depends on the trap frequency \( \nu_{L}, E = (8/9 \zeta(4))^{1/5} = 0.6078 \ldots \) is a constant and \( \zeta \) is the Riemann zeta function. The values of \( \tilde{b} \), computed by solving equation (9) numerically for different values of \( \tilde{n} \), are shown in figure 1 and compared to values of \( \sqrt{\langle y^{2} \rangle} \) obtained by classical Monte Carlo simulations (see section 4 for details on the numerical simulations).

The dispersion relations of the dipolar chain inside a harmonic potential have been determined in [22]. In this work we consider a simpler situation, assuming that there is no harmonic potential along the \( x \)-direction and periodic boundary conditions are imposed at the edges. In this geometry, the frequencies of the phononic modes of the harmonic crystal are simply found using a phonon-wave ansatz; see for instance [21, 23]. This ansatz solves exactly the equations of motion for the longitudinal and transverse displacements from the equilibrium positions, \( \tilde{q}_{j} = \tilde{x}_{j} - j \tilde{a} \) and \( \tilde{w}_{j} = \tilde{y}_{j}, \) respectively, which read as
\[
\tilde{q}_{j} = -12 \tilde{r}_{0} \sum_{j \neq 0} \frac{1}{j^{3} \tilde{a}^{2}} (\tilde{q}_{j} - \tilde{q}_{j+i}) \tag{11}
\]
\[
\tilde{w}_{j} = - \tilde{w}_{j} + 3 \tilde{r}_{0} \sum_{j \neq 0} \frac{1}{j^{3} \tilde{a}^{2}} (\tilde{w}_{j} - \tilde{w}_{j+i}). \tag{12}
\]
One finds two branches, for the axial and transverse excitations, which are given by
\[
\omega_{\perp}^{2}(k) = \frac{48 \tilde{r}_{0}}{a^{4}} \sum_{j \geq 0} \frac{1}{j^{3}} \sin^{2} \frac{kja}{2} \tag{13}
\]
\[
\omega_{\parallel}^{2}(k) = 1 - \frac{12 \tilde{r}_{0}}{a^{5}} \sum_{j \geq 0} \frac{1}{j^{3}} \sin^{2} \frac{kja}{2}, \tag{14}
\]
where \( k = 2 \pi l / Na \) with \( l = 0, 1, 2, \ldots, N - 1 \). The two branches are analogous to an acoustic (\( \omega_{\perp} \)) and an optical (\( \omega_{\parallel} \)) branch. A few relevant modes are depicted in figure 2.

The acoustic branch, equation (13), is characterized by a sound velocity \( c = \sqrt{12 \tilde{r}_{0} \zeta(3)/a^{3}}. \) This value is consistent with the value found from the relation [24]
\[
mc^{2} = n \partial \mu / \partial n, \tag{15}
\]
where \( \mu \) is the chemical potential, \( \mu = \partial E / \partial N \) and \( E \) is the ground-state energy, which at large densities is equal to \( E = (N^{2}/L^{2}) \zeta(3)C_{dd}/4 \pi \) (see appendix A and [19]). From the dispersion relation of the optical branch, equation (14), one finds the stability condition of the linear chain configuration. In fact, equation (14) gives imaginary values of the transverse frequency for values of the linear density \( \tilde{n} > \tilde{n}_{c} \), with \( \tilde{n} = 1/\tilde{a} \)
and \( \tilde{n}_k \) being the critical density. Its value is found by solving the relation \( \min_k (\omega_{1k}) = 0 \), which gives \( \tilde{n}_k \) in equation (10) and \( k = \pi/a \). The corresponding mode whose frequency becomes zero at \( \tilde{n}_k \) is the zigzag mode (see figure 2c),

\[
\psi_{\tilde{\nu}} = (-1)^j \tilde{b}/2, \tag{16}
\]

where \( \tilde{b} \) is the amplitude of the mode when the chain is stable. When one can assume that the dipolar chain exhibits long-range order (at very large interaction strengths), the structural instability at \( \tilde{n} = \tilde{n}_k \) can be characterized as a classical second-order phase transition, applying a straightforward extension to dipolar interactions of the analysis presented in [21] for Coulomb interactions. The details are reported in appendix A.

### 4. Monte Carlo methods

The numerical study of the properties of a many-body system is carried out using Monte Carlo methods. The advantage of these methods is that they allow evaluation of multidimensional integrals over the phase space. In a classical system of dimensionality \( D \), this corresponds to an integral over \( 2 \times N \times D \) variables \( R = \{ r_1, \ldots, r_N; v_1, \ldots, v_N \} \) with \( r_j \) and \( v_j \) being the position and velocity of a particle \( j \) respectively, with \( j = 1, \ldots, N \). In a quantum system, the dimensionality of the phase space is \( N \times D \) with \( R = \{ r_1, \ldots, r_N \} \) in coordinate representation. The average of some quantity of interest \( A(R) \) has the form

\[
\langle A \rangle = \frac{\int \ldots \int A(R) p(R) \, dR}{\int \ldots \int p(R) \, dR}, \tag{17}
\]

with \( p(R) \) being the probability density function. In a classical system, at thermal equilibrium position and velocity are independent variables. For a quantity \( A(R) = A(r_1, \ldots, r_N) \) depending only on particle coordinates, the velocities in equation (17) can be integrated out. As a result the average of interest is performed by only integrating over the position variables, using the averaging weight

\[
p_{CLS}(r_1, \ldots, r_N) = \exp \left\{ -\frac{V(r_1, \ldots, r_N)}{k_B T} \right\}. \tag{18}
\]

where \( V \) is the potential, \( T \) is the temperature and \( k_B \) is the Boltzmann constant.

In the quantum case, the averages are performed using the coordinate representation. In a variational (VMC) calculation, the probability distribution is defined by the modulus squared of the trial wavefunction \( \psi_T(r_1, \ldots, r_N) \):

\[
p_{VMC}(r_1, \ldots, r_N) = |\psi_T(r_1, \ldots, r_N)|^2. \tag{19}
\]

The trial wavefunction \( \psi_T \) depends usually on some variational parameters, which can be optimized by minimizing the variational energy of the system. Once the optimal parameters are known, this wavefunction is used as a guiding wavefunction in diffusion Monte Carlo (DMC) calculations. The DMC method solves the imaginary-time Schrödinger equation for the product of the wavefunction \( \psi \) and the guiding wavefunction \( \psi_T \). For large values of imaginary times, the DMC method allows one to sample the probability distribution

\[
p_{DMC}(r_1, \ldots, r_N) = \psi_T(r_1, \ldots, r_N) \phi_0(r_1, \ldots, r_N). \tag{20}
\]

where \( \phi_0(r_1, \ldots, r_N) \) is the ground-state wavefunction (more details on the DMC method can be found, for example, in [25]).

In both cases, classical (18) and quantum (19), the probability distribution is known analytically and can be written explicitly. This allows one to perform its sampling using the Metropolis algorithm [26]. A trial move converting the probability from \( p \) to \( p' \) is always accepted if \( p' > p \) (in a classical system this means that energy in the new configuration has a lower energy or, being the same, it has a larger value of the wavefunction in the quantum case), otherwise the move is accepted with probability \( p'/p \). We generate a new configuration by displacing one particle by a random distance, which we draw from a Gaussian distribution. The width of the Gaussian distribution is adjusted so that on average, we have a 50% acceptance rate. Under these conditions, the Metropolis algorithm guarantees that the generated set of configurations (Markov chain) has the desired distribution and the average \( \langle A \rangle \) is stochastically evaluated as an average over the Markov chain.

We use the Bijl–Jastrow construction [27] of the trial wavefunction:

\[
\psi_T(r_1, \ldots, r_N) = \prod_{i=1}^{N} f_1(r_i) \prod_{j<k} f_2(|r_j - r_k|). \tag{21}
\]

The one-body term is chosen in a Gaussian form \( f_1(r) = \exp \left\{ -\alpha r^2 \right\}. \) In the limit of a quasi-one-dimensional system, where the excitations of the radial harmonic confinement levels are absent, the optimal value \( \alpha = 1/2 \) corresponds to the ground-state wavefunction of a harmonic oscillator. If the system leaves the quasi-one-dimensional regime, the system spreads in the radial direction, and accordingly the value of \( \alpha \) is reduced. The two-body term is the same as that used in [10, 20]:

\[
f_2(r) = \begin{cases} 
C_1 K_0(2\sqrt{3}a_0 r/\sqrt{T}), & 0 < r < R_{par} \\
C_2 \exp[-C_3 a_0 \times [1/r + 1/(L_x - r)]], & R_{par} \leq r < L/2 \\
1, & L/2 \leq r, 
\end{cases} \tag{22}
\]

with \( K_0(r) \) being the modified Bessel function of the second kind. Coefficients \( C_1, C_2, C_3 \) are fixed by the conditions of the continuity of the wavefunction and its first derivative. The parameter \( 0 < R_{par} < L/2 \) is free and is fixed by a variational procedure (the dependence of the energy on this parameter is rather weak and in many cases the choice \( R_{par} = L/4 \) is sufficient). When the distance between the two particles is small, the influence of other particles can be neglected. As a result, \( f_2(r) \) is well approximated by the solution of the two-body scattering problem (see the short-distance behaviour of (22)). This makes the calculation stable even for a divergent interaction potential. We symmetrize the argument of the long-range part as \( 1/r + 1/(L_x - r) \). In this way, we ensure the zero derivative of the trial wavefunction at the boundary \( r = L_x/2 \) according to the periodic boundary conditions.

DMC averaging (20) provides exact estimators for operators commuting with the Hamiltonian. In particular, the ground-state energy is found in a statistically exact way. Instead, density profiles and other functions of particle
Figure 3. Contour plot of the mean transverse size of the system $(\gamma^2)$ at (a) $T = 10^{-5} \hbar \nu_t / k_B$ and (b) $T = \hbar \nu_t / k_B$ as a function of the parameters $\bar{\rho}_0$ and $\bar{\phi}$ respectively. The contour lines correspond to fixed values of $(\gamma^2)$ (in units of $\alpha_0^2$); the scale is reported on the right side of the plot. The dashed line, obtained from solving equation (10), separates the linear from the zigzag structures; the solid line separates the zigzag from the multiple chain structures. The calculations are made for a system of $N \times M$ with a grid of 50×50 of the plot. The dashed line, obtained from solving equation (10), separates the linear from the zigzag structures; the solid line separates the zigzag from the multiple chain structures. The calculations are made for a system of $N \times M$ with a grid of 50×50 size, each point corresponding to a run with a different choice of parameters. Effects of the finite grid are visible in Monte Carlo data in the vicinity of the dashed line.

positions are obtained as ‘mixed’ estimators $\langle A \rangle_{\text{DMC}} = \langle \psi_T | A | \phi_0 \rangle / \langle \psi_T | \phi_0 \rangle$ which are biased by a particular choice of the trial wavefunction. Ideally, one has to find a pure estimator, i.e. averages over the ground state $\langle A \rangle = \langle \phi_0 | A | \phi_0 \rangle / \langle \phi_0 | \phi_0 \rangle$. The optimized trial wavefunction is expected to be close to the true ground-state wavefunction, so that the difference $|\psi_T - \psi_0| \approx 0$ small and one can use the mixed estimator together with the variational one $\langle A \rangle_{\text{VMC}} = \langle \psi_T | A | \psi_T \rangle / \langle \psi_T | \psi_T \rangle$ (obtained according to (19)) to extrapolate the pure estimator. The two extrapolation procedures

\[
\langle A \rangle \approx 2 \langle A \rangle_{\text{DMC}} - \langle A \rangle_{\text{VMC}} \tag{23}
\]

\[
\langle A \rangle \approx \langle A \rangle_{\text{DMC}} / \langle A \rangle_{\text{VMC}} \tag{24}
\]

have the same order of accuracy and contain errors which are quadratic in $|\psi_T - \psi_0|$. Alternatively, for local quantities one can use more involved techniques of pure estimators [28]. For simplicity, we will use rules (23) and (24) and check that both estimators agree within the accuracy of interest.

5. Thermal fluctuations around the classical equilibrium positions

The structures discussed in section 3 were determined by simply evaluating the classical equilibrium positions of the potential energy, equation (4), as a function of the linear density and of the transverse trapping frequency. In this case, we identified a sharp condition, $\tilde{n}_c = \tilde{E}_0^{-1/5}$, as given by equation (10), such that for $\tilde{n} < \tilde{n}_c$ the equilibrium positions are along a line (linear chain), otherwise they are arranged along multiple lines. For an interval $\tilde{n}_c < \tilde{n} < \tilde{n}_M$, with $\tilde{n}_M$ being a fixed value, the structure is a zigzag chain. Thermal fluctuations will smear the sharp transition at $\tilde{n}_c$. In this section, we compute their effect around $\tilde{n}_c$ for various values of the temperature using a classical Monte Carlo calculation.

For later convenience, we report the temperature in units of the energy $E_{2h_0}$, which we set $E_{2h_0} = \hbar \nu_t$. In order to study the transition linear–zigzag structure, we evaluate the transverse variance $\langle \gamma^2 \rangle$ and report the numerical results as a function of the linear density $\tilde{n}$ and the interaction strength $\tilde{\rho}$ in a contour plot for two different values of the temperature; see figure 3. In addition, in the figures we plot two lines corresponding to the transition from a linear to a zigzag (dashed line) and from a zigzag to a multiple chain (solid line), as obtained by finding the classical equilibrium positions of the potential (4) and plotted for comparison.

Figure 3(a) reports the result obtained setting $T = 10^{-5} \hbar \nu_t / k_B$. Here, one can still identify a sharp transition from linear to zigzag and from zigzag to multiple chains, according to the predictions given by equation (10). Such situations could be found in set-ups with extremely high transverse frequencies, although it is questionable whether such a trap could be experimentally realized. Figure 3(b) displays the case $T = \hbar \nu_t / k_B$, showing that at this temperature the transition is completely smeared out.

We now study how thermal effects modify the pair correlation function, which is related to the probability of finding two particles separated by a distance $(x, y)$, and is here defined as

\[
g_2(x, y) = \langle \mathcal{N}(\rho_1) \mathcal{N}(\rho_2) \rangle, \tag{25}
\]

where $\mathcal{N}(\rho) = \sum_{i=1}^{2} \delta(\rho - \rho_i)$ is the two-dimensional density and $g_2(x, y)$ depends only on the relative distances $x = x_1 - x_2$ and $y = y_1 - y_2$. Here, integrating out the radial coordinate from the two-dimensional density gives the linear density.
The pair distribution function \( \langle \tilde{n}(\varrho) \tilde{n}(0) \rangle \) (left) and static structure factor \( S(k) \) for the linear structures (right). Temperatures are (rows from top to bottom) \( T = 0.05, T = 0.1, T = 0.2 \) and \( T = 0.5 \hbar \nu / k_B \). Number of particles is \( N = 20, \tilde{r}_0 = 7.5, \tilde{n} = 0.4 \).

\[
\int N(\rho) \, dy = n(x)
\]

and its average is equal to the linear density \( \langle n(x) \rangle = n \).

The pair correlation function is displayed in figure 4 for various values of the temperature. Here, the ‘hole’ for \( x = 0 \) and \( y = 0 \) is due to the hard-core repulsive interaction potential, which forbids two particles from being at the same position. There is a clear strong correlation between neighbouring particles, which is lost as the temperature and the interparticle distance increase. This is a manifestation of the absence of a true crystalline order.

Information over the properties of the system can be inferred by means of Bragg spectroscopy, giving access to the static structure factor.

\[
S(k) = \frac{1}{N} \langle N_k N_{-k} \rangle,
\]

where \( N_k = \int e^{ik\rho} N(\rho) \, d\rho = \sum_{i=1}^{N} \exp[ik\rho_i] \) is the Fourier transform of the two-dimensional density \( N(\rho) \). The right column of plots in figure 4 displays the static structure factor, corresponding to the pair correlation function plotted on the left side. Here, one sees the appearance of a high peak, at \( k_x = 2\pi/a \), and of a second peak, at \( k_x = 4\pi/a \), at low temperatures. The peaks would correspond to Bragg scattering by an ordered structure at interparticle spacing \( a \), and are thus signatures of very strong correlations in the system. Their height diminishes, while they become broader, as temperature increases and the axial structure is lost. The disappearance of the second peak at higher temperatures is typical of a gas phase.

Figure 5 displays the pair correlation function and the structure form factor in the parameter regime, in which the zigzag structure is expected at ultralow temperatures. As before, the plots of \( g_2(x, y) \) show a hole for the zero separation, caused by the dipolar repulsion. Moreover, one finds a crystal-like ordering at very low temperatures, \( T \approx 0.05 \hbar \nu / k_B \), which disappears as the temperature is increased by a factor of 10. In addition, at low temperatures one observes a large probability of finding two particles with the same transversal displacement, such that \( y_i - y_j = 0 \), with doubled periodicity with respect to the linear chain. One
also observes additional peaks corresponding to correlations in the $y$-direction, corresponding to the doubled chain (zigzag) structure. As in one-half of the cases the particle of reference belongs to the upper (lower) chain, there are peaks in $g_2(x, y)$ for $y = -2b$ ($y = 2b$). The peaks at $y = 0$ have larger amplitudes as they are a sum of the contributions from both upper and lower chains.

The static structure factor is plotted as a function of the two-dimensional wavevector $(k_x, k_y)$. We note that different boundary conditions in $x$ and $y$ lead to different accessible values of momentum. At low temperatures, the static structure factor recalls the geometry of a two-dimensional crystal and naturally shows how a one-dimensional structure transforms into a two-dimensional one. There is a number of directions in which well-defined peaks are observed. The peaks in direction $(k_x, k_y) = (\pi/a, 0)$ are similar to those shown in figure 4 for the linear chain. The peaks in the transverse direction $(k_x, k_y) = (0, \pi/b)$, in diagonal directions $(k_x, k_y) = (\pi/a, \pi/b)$, etc, are signatures of the realization of a zigzag structure. As the temperature is increased, the number of peaks is decreased until only the central peak is left. We note, however, that the presence of the central peak is somehow trivial as it counts the number of particles in the system.

Finally, we study how the ordering in the linear chain is destroyed as the temperature is increased from $T = 10^{-3}\hbar\nu_t/k_B$ up to $T = 0.1\hbar\nu_t/k_B$, by looking at the features of the structure form factor. In figure 6 $S_k$ is plotted as a function of $k_x$ for $N = 20$ particles, for various values of the temperature. The peak at $k = 0$ counts the number of particles and its height is equal to 20 in all cases. The height of the other peaks, at multiples of $2\pi/a$, diminishes as $T$ is increased. In particular, it decreases with the number of the peak. Moreover, the height of the peaks seems to
follow a power-law dependence as a function of the peak number. These observations will be compared with the effect of quantum fluctuations on ordering at $T = 0$.

6. The quantum ground state

The definition of a one-dimensional ground-state density distribution of dipoles in the quantum regime requires the existence of an energy gap for exciting the transverse motion, such that at $T = 0$ the relevant excitations of the dipolar gas are essentially along the longitudinal axis. In order to quantify this statement, we first introduce the characteristic lengths of the system. The confinement in the transverse direction sets the characteristic length (oscillator length)

$$a_0 = \sqrt{\hbar/m\nu_t},$$

which determines the width of the single-particle ground-state wave packet and which we choose as unit length. We extend the classical model of equation (3) by taking the unit energy $E_{00} = \hbar\nu_t$ in which now the classical variables $\rho$ and $\tau$ are replaced by the corresponding quantum conjugate operators. The potential energy $\tilde{V}$ is given by equation (4). For a one-dimensional configuration, when the transverse excitations are frozen out, the parameter $r_0$ gives the characteristic length scale of interactions, and has to be compared to the length scale of quantum fluctuations set by $n^{-1}$, where $n$ is the linear density. The system is in a gas or quasi-crystal phase depending on whether the product $nr_0$ is much smaller or much larger than unity. For $nr_0 \gg 1$ the dipolar gas is in the quasi-ordered phase with ground-state energy $E^{1D}_{\varphi} = N(nr_0)^{3}\zeta(3)\hbar^3/(nr_0^2)$, which is the potential energy of a classical crystal [19] (see also appendix A). In the quantum gas regime, for $nr_0 \ll 1$, the properties of the system are well described by the Tonks–Girardeau model [29] with ground-state energy $E^{1D}_{TG} = N\pi^2\hbar^2n^2/(6m)$ (the expression for $E^{1D}_{TG}$ does not depend on the strength of the dipolar interaction, as in this regime the interparticle distance is large and the potential interaction enters only through the positions of the nodes of the ground-state wavefunction, while the potential energy can be neglected). These two regimes are shown in the phase diagram in figure 7, displaying the various phases of the ground state of the dipolar system as a function of $\bar{r}_0$ and $\bar{n} = n\theta_{\text{D}}$, and are separated by the grey short-dashed line, which indicates the curve $nr_0 = \bar{n}\bar{r}_0 = 1$.

Dynamically, the system is one dimensional when the chemical potential $\mu$ is much smaller than the level spacing of the transverse oscillator, $\mu \ll \hbar\nu_t$. In this regime, the quantum state of the system can be described within the Luttinger liquid formalism, as was shown in [18], and no true long-range order is found at finite densities [30]. The curve $E^{1D}_{\varphi}/N = \hbar\nu_t$ separates the one- and two-dimensional phases and is shown in figure 7 by the black dashed line. In the quasi-ordered phase, for $nr_0 \gg 1$, this corresponds to the inequality $E^{1D}_{\varphi}/N \ll \hbar\nu_t$, which leads to the relation $n \ll r_0^{-1/3}$. In the quantum gas regime, for $nr_0 \ll 1$, the condition of being one dimensional is $E^{1D}_{TG}/N \ll \hbar\nu_t$, which is equivalent to the requirement $n\theta_{\text{D}} \ll 1$.

The phase diagram in figure 7 can be experimentally explored by changing the density $\bar{n}$, moving vertically, and by varying the transverse frequency $\nu_t$, moving parallel to the straight short-dashed line. Typical parameters of experiments with one-dimensional gases are given for instance in [17]: for $\theta_{\text{D}} \approx 35$ nm, 60–400 atoms per tube of length varying between 15 and 50 $\mu$m, one finds $r_0 \approx 0.07$, $\theta_{\text{D}} \approx 0.04$–0.3. Among all atom species with which condensation has been reached, $^{52}$Cr has the largest value of $r_0 = 2.4$ nm [8]. Larger values of $r_0$ can be reached using polar molecules such as CO, ND$_3$, HCN, CsCl with $r_0 = 5$ nm–340 $\mu$m, allowing one to cover regions of the phase diagram up to the classical region ($\bar{n}\bar{r}_0 \gg 1$).

7. Effects of quantum fluctuations on ordering

In this section we present numerical results for the pair correlation function and the structure form factor of the quantum gas of bosons at $T = 0$, focusing on the solid-like regime and studying in particular the parameter regimes where classically the linear and zigzag chains are observed. Now, the structural properties are defined from the interplay
among the quantum kinetic term, dipolar interactions and the confinement potential in the Hamiltonian (3). The results are compared with the classical case at finite temperature, discussed in section 5.

Figure 8 displays the pair correlation function and the static structure factor of the quantum system at zero temperature. For the same parameter regimes in a classical system, we observed at very low temperature quasi-crystalline linear structures; see figure 4. The results in figure 8 hence clearly show that quantum fluctuations significantly modify the phase of the system. No features of quasi-ordering can be observed: the pair correlation function is almost uniform at short distances, which is in agreement with the behaviour of the two-body Jastrow term has to vanish at short distances. Consequently, the pair correlation function has to vanish when two particles meet in both classical and quantum systems. In a classical approach to an ultracold system, the low-momentum part is described by phonons. The static structure factor grows linearly with $k$ for small momenta (see figure 8):

$$S(k) = \frac{\hbar k}{2mc}, \quad k \to 0,$$

where $c$ is the speed of sound; see also equation (15). At zero temperature in the $k \to 0$ limit, the static structure factor vanishes $S(k) \to 0$.\(^5\) The low-moment behaviour is important as it reflects the number fluctuations in a large system, which is described in detail in appendix B; refer to equation (B.3). On the other hand, the number fluctuations at finite temperature are related to the isothermal compressibility \(^{32}\) $c_\text{Th}^2 = -\frac{V^2}{N\langle \delta\mathcal{V}/N\rangle}$ as

$$\langle (\delta N)^2 \rangle = -\frac{k_B T \frac{N^2}{V^2} \left( \frac{\partial \mathcal{V}}{\partial P} \right)_T}{\frac{N k_B T}{mc^2}} = Nk_B T \frac{N}{mc^2}.$$

This means that at finite temperatures, $S(k)$ no longer vanishes in the zero momentum limit; instead it goes to a constant value $S(k) \rightarrow k_B T / mc^2$, $k \rightarrow 0$, defined by the temperature and the compressibility (15). Moreover, the effects of the temperature in quantum Bose systems on the low-momentum part of the static structure factor can be found analytically \(^{33}\), and $S(k)$ is given by the following expression:

$$S(k) = \frac{\hbar k}{2mc} \text{cth} \frac{\hbar k c}{2k_B T} = \frac{k_B T}{mc^2} + \frac{\hbar^2 k^2}{12mc^2 k_B T} + \ldots, \quad |k| \ll k_B T / \hbar c.$$

\(^{5}\) Note that from definition (26), the value of $S(k)$ is discontinuous at zero momentum where it gives the number of particles for $k = 0$. For a gas $S(k) = -N\delta(k)$ is instead continuous.

---

\(^4\) As discussed in section 5, the hole comes from the short-range divergence of the repulsive potential. This can be easily understood by considering the lower limit of the integral giving the potential energy of dipolar interactions:

$$\int V(r)g_2(r) dr \propto \int g_2(r)|r|^3 dr.$$  

This energy diverges if $g_2(r)$ does not vanish at short distances. Consequently, the pair correlation function has to vanish when two particles meet in both classical and quantum systems. In a quantum system this also means that the two-body Jastrow term has to vanish at short distances, which is in agreement with the behaviour of the two-body scattering solution used in the construction of the trial wavefunction (22).

---

\(^5\) Note from the definition (26), the value of $S(k)$ is discontinuous at zero momentum where it gives the number of particles for $k = 0$. For a gas $S(k) = -N\delta(k)$ is instead continuous.
Figure 8. Pair distribution function $g_2(x, y)$ (left) and static structure form factor $S(k, 0)$ for the quantum gas of dipolar bosons at $T = 0$, with $N = 20$ particles, $\tilde{n} = 0.4$ and $\tilde{r}_0 = 7.5$. The results are obtained with a quantum Monte Carlo simulation; see section 4. Extrapolation (23) is used to remove bias due to a particular choice of the trial wavefunction.

Figure 9. Same as in figure 8, but with $\tilde{r}_0 = 100$. The static structure form factor is displayed as in figure 5.

The low-momenta dependence is no longer linear, but a quadratic one with the coefficient of proportionality entirely defined by the temperature.

The one-dimensional case has been studied in the literature [18, 30, 34], and evidence has been given that one-dimensional dipolar systems manifest Luttinger liquid behaviour even if the interactions are of long-range type [18]. From Haldane’s approach [35], it is possible to write asymptotic expressions for the one-dimensional pair correlation function $g_2(x)$. Although this effective description is valid only at large distances, it is sufficient to predict the behaviour of the peaks in the static structure factor using properties of the Fourier transformation (26). The static structure factor has been computed for various values of $\tilde{n}\tilde{r}_0$ in [30, 34], showing that at large values multiple peaks appear. Their height decays with the peak order according to a power law decay (with the exponent depending on the Luttinger parameter and hence on the linear density [34]), showing interesting analogies with the classical case at finite temperatures. Clear important differences between quantum mechanical and thermal effects in the structure form factor are identified in its behaviour at low values of $k$, as the value of the static structure factor at zero momentum is related to the integral of the density fluctuations over the whole volume of the system. In the quantum mechanical case, it grows from zero linearly in $k$ (see figure 8) while in the classical case at finite $T$ it no longer vanishes at zero momentum; instead, it goes to a constant value, defined by the temperature and compressibility (see appendix B for details). This can lead us back to the issue on how number fluctuations $\langle (\delta N)^2 \rangle$ increase with the volume size $L^D$, $D$ being the dimensionality of the homogeneous space. Indeed, thermal fluctuations increase linearly with the volume, while fluctuations in quantum systems at zero temperature follow the anomalous law $\langle (\delta N)^2 \rangle \propto L^{D-1} \ln CL$ [36, 37], where $C$ is a constant. In particular, in a one-dimensional system (and also in a quasi-one-dimensional geometry), the fluctuations follow the logarithmic dependence $\langle (\delta N)^2 \rangle \propto \ln L$ [38].

8. Conclusions

We have discussed the properties of the classical and quantum distributions of a low-dimensional gas of dipolar particles at thermal equilibrium, by computing numerically the pair correlation function and the static structure form factor, focusing on the regime where one would expect quasi-ordered structures of dipoles in a linear or zigzag structure. Thermal and quantum fluctuations tend to destroy ordering, bringing further evidence that a true self-organized crystal cannot exist at finite temperature or (in a quantum system) at a finite interaction strength. Analogies and differences between the effects of thermal and quantum fluctuations on the phase diagram, the pair correlation function and the static structure factor are discussed. The behaviour of the static structure factor for small momenta is addressed. In the limit of large dipolar interaction strengths or of large linear density, the transition from a one-dimensional to a planar configuration occurs with the creation of a mesoscopic structure in the transverse direction, which exhibits the main features of the transition from a single to a double and then a multiple chain distribution of dipoles, while quasi-order is observed also in the transverse pair correlation function at large densities. Such patterns are characterized by non-local correlations, which
arise from zero-point fluctuations and which may be important resources for the realization of quantum simulators [39, 40].

Appendix A. Transition from the linear chain to the zigzag structure

For very large interaction strengths, the linear chain becomes unstable for \( \tilde{n} > \tilde{n}_c \). Under this condition one can show that, within a certain interval of densities, the stable configuration is a planar zigzag structure. The zigzag structure is composed of two chains, one shifted with respect to the other by a lattice distance \( a \), so that with respect to the linear chain the periodicity doubles from \( \pi/a \) to \( 2\pi/a \).

We identify the order parameter of the zigzag as the distance \( b/2 \) of the dipoles from the trap axis \( x \) and the control parameter as the density \( \tilde{n} \) while the transverse trap frequency \( v_t \) remains fixed. A similar analysis can be performed using the transverse frequency as the control parameter and fixing the density; see [21]. In order to study the behaviour close to the instability point, we expand equation (4) up to the fourth order around the equilibrium positions of the chain, \( \tilde{V} = \sum_{\ell=0}^{4} \tilde{V}^{(\ell)} \), where \( \ell \) labels the order. Here, \( \tilde{V}^{(0)} \) is the ground-state energy in the limit of strong correlations, which for \( N \gg 1 \) reads as

\[
\tilde{V}^{(0)} \equiv N \tilde{\rho}_0 \tilde{\zeta}(3) \frac{\tilde{n}}{\tilde{a}^3}.
\]

Moreover, as we expand close to the equilibrium positions of the linear chain, the first-order term \( \tilde{V}^{(1)} \) vanishes. Using the decomposition into the eigenmodes of the linear chain, the quadratic term takes the form

\[
\tilde{V}^{(2)} = \frac{1}{2} \sum_{k} \sum_{k=\pm} (\alpha(k)^2 \Theta_k^{(2)} + \alpha(k) \Psi_k^{(2)}),
\]

where

\[
\alpha(k) = 1 - \frac{12 \tilde{\rho}_0}{a^5} \sum_{j=0}^{3} \frac{1}{j!} \sin^2 \frac{kja}{2} - \frac{3}{2}
\]

and it coincides with \( \tilde{w}_j(k)^2 \); equation (14), for \( \tilde{n} < \tilde{n}_c \), while the normal modes \( \Theta_k^{(3)} \) and \( \Psi_k^{(3)} \) are related to axial and transverse displacements by the relation

\[
\tilde{q}_j = \sqrt{\frac{3}{N}} \sum_{k} (\Theta_k^{(3)} \cos kja + \Theta_k^{(-)} \sin kja)
\]

\[
\tilde{w}_j = \sqrt{\frac{3}{N}} \sum_{k} (\Psi_k^{(3)} \cos kja + \Psi_k^{(-)} \sin kja)
\]

with \( k = 2\pi l/Na \) for \( l = 0, 1, 2, \ldots, N/2 \), and the subscript \( \pm \) indicates the parity by the reflection \( k \rightarrow -k \). For convenience, we denote by \( \Psi_0 \) the mode of the linear chain at wavevector \( k_0 = \pi/a \) (zigzag mode). The linear chain becomes mechanically unstable when, by varying \( \tilde{n} \), the frequency of the zigzag mode with wavevector \( k = \pi/a \), equation (16), vanishes. Around the instability point, the zigzag mode is significantly coupled to other quasi-degenerate modes by the third- and fourth-order terms \( \tilde{V}^{(3)} \) and \( \tilde{V}^{(4)} \) respectively. These quasi-degenerate modes are long-wavelength axial modes \( \Theta_{k\pm} \) at wavevectors \( \delta k \), such that \( |\delta k|a \ll 1 \), and short-wavelength transverse modes \( \Psi_{k\mp} \) at wavevector \( k = k_0 + \delta k \), with \( |\delta k|a \ll 1 \). At lowest order in the expansion in \( \delta ka \), the effective potential for the modes which are relevantly coupled at the instability reads as

\[
\tilde{V}_{\text{eff}} = \frac{1}{2} \alpha_0 \Psi_0^2 + \frac{1}{2} \sum_{\delta k > 0} \alpha_{\delta k} \left( \Psi_{\delta k}^+ + \Psi_{\delta k}^- \right) + \tilde{V}^{(4)}_{\delta k},
\]

where for brevity we denote \( \alpha_{\delta k} \equiv \alpha(k_0 - \delta k) \) and \( \Psi_{\delta k} \equiv \Psi_{k_0 + \delta k} \). The fourth-order potential for the relevant modes is given by

\[
\tilde{V}^{(4)}_{\delta k} = A \Psi_0^4 + 6 A \Psi_0^2 \sum_{\delta k > 0} \left( \Psi_{\delta k}^+ + \Psi_{\delta k}^- \right)^2 + A \Psi_0 f \left( \Psi_{\delta k_1}^+, \Psi_{\delta k_2}^-, \Psi_{\delta k_3}^-, \Psi_{\delta k_4}^+ \right) + O(\delta k^2 a^2),
\]

where

\[
A = \frac{30 \tilde{\rho}_0 \tilde{\eta}^2}{N} \left( 1 - \frac{1}{2^7} \right) \tilde{\zeta}(7)
\]

and the function \( f \) contains a sum of products of three amplitudes \( \Psi_{\delta k} \) for \( \delta k \neq 0 \), whose precise form is not important for the present discussion. We now allow the linear density \( \tilde{n} \) to take values in the interval \( [\tilde{n}_c - \delta, \tilde{n}_c + \delta] \), such that \( a \delta k \) may take only small but negative values, and for \( \delta k < 0 \) we determine the corrections \( \Psi_{\delta k}^{(2)} \) to the equilibrium positions of the linear chain using equation (A.6), assuming that the role of the fourth-order potential \( \tilde{V}^{(4)}_{\delta k} \) is to give rise to a small displacement \( b \ll a \) with respect to the equilibrium interparticle distance \( a \). Using a stability analysis of the zigzag configuration in a similar way as that used for the linear–zigzag transition in low-dimensional ion crystals [21], we find that the stable solution has \( \Psi_{\delta k} = 0 \) for \( \delta k > 0 \) and

\[
\Psi_0 = \left( \frac{\alpha_0}{4 A} \right)^{1/2},
\]

where \( \alpha_0 = 1 - (\tilde{n}/\tilde{n}_c) \). Correspondingly, the spatial displacement \( b \) reads as \( b = 2 \Psi_0 \sqrt{N} \) and, using equations (10) and equation (A.8), it can be written as

\[
b = B a \frac{1}{\tilde{n}_c^5} \left( \frac{\tilde{\rho}_0}{\tilde{n}_c} \right)^5
\]

where we have introduced the dimensionless constant

\[
B = \frac{8}{5} \frac{31 \tilde{\zeta}(5)}{127 \tilde{\zeta}(7)} = 0.634 \ldots
\]

Note that the expression for \( b \) found in equation (A.10) corresponds to the second-order expansion of equation (9) in the parameter \( b/a \). The exact result found by solving
equation (9) numerically and the approximated result equation (A.10) are compared in figure 1.

The jump in the classical ground-state energy at the transition point is given by the difference between the potentials of the soft mode at each side of the critical points. We denote by

$$\tilde{V}^\text{soft} = \frac{1}{2} a_0 \Psi_0^2 + A \Psi_0^4$$

(A.12)

the effective potential for the soft mode, where A is given by equation (A.8). At zero temperature, for $\tilde{n} = \tilde{n}_c - \delta$, with $\delta > 0$, $\tilde{V}^\text{soft} = 0$, while for $\tilde{n} = \tilde{n}_c + \delta$, $\tilde{V}^\text{soft} \neq 0$. Letting $\delta \to 0^+$, we find that the energy difference per particle is given by

$$\Delta \tilde{E} = \frac{1}{N} \tilde{V}^\text{soft}(\tilde{n} \to \tilde{n}_c^+) - \frac{1}{N} \tilde{V}^\text{soft}(\tilde{n} \to \tilde{n}_c^-) = -\frac{1}{2} \tilde{c}(\tilde{n}_c - \tilde{n})^2,$$

(A.13)

where $\tilde{c} = [4650(\xi(5))/[1127(\xi(7))] = 37.65 \ldots \ldots$ Note that the second derivative of $\Delta \tilde{E}$ with respect to $\tilde{n}$ is discontinuous at the critical point. At zero temperature, this means that the phase transition is of second order.

Appendix B. Static structure form factor and thermodynamic properties

Small momentum behaviour is directly related to the density fluctuations in the system. Indeed, the number fluctuations in volume $L$ are related to the integral of the pair correlation function:

$$(\delta N)^2 = \int_L \frac{d^3 x_1}{L} \frac{d^3 x_2}{L} \langle \delta n(x_1) \delta n(x_2) \rangle$$

$$= N + \int_L \frac{d^3 x_1}{L} \frac{d^3 x_2}{L} \langle g_2(x_1 - x_2) - n^2 \rangle.$$

(B.1)

Here we consider the case of a linear chain considering it as a one-dimensional object so that the volume is linear L and the pair correlation function saturates to a constant value, $g_2(x) \to n^2$ as $|x| \to \infty$. The static structure factor is related by the Fourier transformation to $g_2(x)$ according to the relation $g_2(x) = n^2 + n \int (S(k) - 1) e^{-i k x} dk/2\pi$, which is inverse to equation (26). By substituting this expression into equation (B.1), one gets

$$(\delta N)^2 = N + n \int_L \frac{d^3 x_1}{L} \frac{d^3 x_2}{L} \int_0^\infty \frac{dk}{2\pi} \langle S(k) - 1 \rangle e^{-i k x_1}.$$  

(B.2)

Changing to the relative motion and centre-of-mass variables $x = x_1 - x_2$; $X = (x_1 + x_2)/2$ one separates spatial integrals into two. One is trivial $\int_0^L dX = L$. The second gives the $\delta$-function $\int e^{i k x} dx = 2\pi k \delta(k)$ leading to a simple relation

$$\langle (\delta N)^2 \rangle = NS(0).$$
