SMOOTHING SINGULAR EXTREMAL KÄHLER SURFACES 
AND MINIMAL LAGRANGIANS

OLIVIER BIQUARD AND YANN ROLLIN

Abstract. Given a complex surface $\mathcal{X}$ with singularities of class $T$ and no nontrivial holomorphic vector field, we consider smoothings $(\mathcal{M}_t, \Omega_t)$, where $\Omega_t$ is a Kähler class on $\mathcal{M}_t$ degenerating to $\Omega_0$. Under an hypothesis of non degeneracy of the smoothing at each singular point, we prove that if $\mathcal{X}$ admits an extremal metric in $\Omega_0$, then $\mathcal{M}_t$ admits an extremal metric in $\Omega_t$ for small $t$.

In addition, we construct small Lagrangian stationary spheres which represent Lagrangian vanishing cycles when $t$ is small.

1. Introduction

Let $\mathcal{X}$ be a normal compact complex surface with singularities of class $T$. Such singularities are isolated and of orbifold type $\mathbb{C}^2/\Gamma$ for some finite group $\Gamma \subset \mathrm{U}_2$. The possible singularities are either rational double points ($\Gamma \subset \mathrm{SU}_2$) or cyclic quotient singularities of type $\frac{1}{dn}(1, dna - 1)$, for positive integers $d, n, a$ such that $a$ and $n$ are relatively prime.

Since there is no general answer to the existence problem of constant scalar curvature Kähler metrics (CSCK for short), numerous constructions relying on gluing techniques have been made (cf. for instance [8, 1, 2]). In the case of canonical singularities (rational double points), the idea is to start from a CSCK orbifold metric on $\mathcal{X}$ and to deduce a smooth CSCK metric on the minimal resolution $\hat{\mathcal{X}}$ by perturbation theory. The exceptional divisor of $\hat{\mathcal{X}} \to \mathcal{X}$ is a union of holomorphic $-2$ spheres, whose configuration is described by the Dynkin diagram of a complex semisimple Lie algebra $\mathfrak{g}_\mathbb{C}$ determined by $\Gamma$ (this is a part of the McKay correspondence).

In this work we consider smoothings of singularities rather than resolutions. We prove, under natural hypotheses, that $\mathbb{Q}$-Gorenstein smoothings admit CSCK metrics.

In the special case of Kähler-Einstein metrics, the desingularizations cannot carry Kähler-Einstein metrics unless $c_1(\mathcal{X}) = 0$, since they contain holomorphic $-2$ spheres. But smoothings may carry Kähler-Einstein metrics, and our result gives a construction of those Kähler-Einstein metrics close to the singular ones. Also it is interesting to note that for general singularities of class $T$, the smoothings are not diffeomorphic to the minimal resolution.

If the homology class of a $-2$ sphere of the desingularization is Lagrangian in the smoothing, we prove that it can be represented by a small Hamiltonian stationary sphere. This gives a concrete construction of the Lagrangian minimizer, whose existence is proved by Schoen and Wolfson [9].

1.1. CSCK metrics. We now give precise statements. Let $\mathcal{X}$ be a normal complex surface with quotient singularities. We consider a $\mathbb{Q}$-Gorenstein smoothing...
of $\mathcal{X}$, denoted $p : \mathcal{M} \to \Delta$, where $\Delta$ is an open disc centered at the origin in $\mathbb{C}$. This means that a multiple of the canonical divisor of $\mathcal{M}$ is Cartier and $\mathcal{M}$ is Cohen-Macaulay. Moreover, the central fiber is the given $\mathcal{X}$, and the general fiber $\mathcal{M}_t$ is smooth.

Kollár and Shepherd-Barron [7] proved that the singularities which appear must be of class $T$; this class subdivides into two classes:

- canonical singularities of type $\mathbb{C}^2/\Gamma$ for a finite subgroup $\Gamma \subset \text{SU}_2$; one gets the list $A_d$ ($d \geq 1$), $D_d$ ($d \geq 4$), $E_d$ ($d = 6, 7, 8$);
- cyclic quotients obtained by a quotient of an $A_{dn-1}$ singularity by $\mathbb{Z}_n$.

The local theory of smoothings of such a singularity is well understood: there is an (explicit) hypersurface $\mathcal{Y} \subset \mathbb{C}^3 \times \mathbb{C}^d$, such that the projection $p : \mathcal{Y} \to \mathbb{C}^d$ is a $\mathbb{Q}$-Gorenstein smoothing of $\mathcal{Y}_0 \simeq \mathbb{C}^2/\Gamma$. Moreover, any $\mathbb{Q}$-Gorenstein smoothing of $\mathcal{Y}_0$ is isomorphic to the pull-back of $p$ under a germ of holomorphic maps $f : \mathbb{C} \to \mathbb{C}^d$. The fibers $\mathcal{Y}_t = p^{-1}(t)$ over the discriminant locus $\mathcal{D} \subset \mathbb{C}^d$ are singular. This leads us to introduce a non degeneracy condition in the following way. As recalled below, there is a particular ramified covering map $\pi : \mathbb{C}^d \to \mathbb{C}^d$ associated to the singularity. This map is ramified exactly above $\mathcal{D}$, and moreover the ramification locus $\pi^{-1}(\mathcal{D})$, which turns out to be a union of linear hyperplanes:

$$\pi^{-1}(\mathcal{D}) = \bigcup H_i.$$ 

Up to taking a ramified covering (which we choose of smallest possible degree), the germ $f : \mathbb{C} \to \mathbb{C}^d$ can be lifted to $\hat{f} : \mathbb{C} \to \mathbb{C}^d$ such that $f = \pi \circ \hat{f}$. The following definition is a way to say that the deformation is transversal to the discriminant locus:

**Definition 1.** We say that a smoothing $\mathcal{X} \hookrightarrow \mathcal{M} \to \Delta$ is non degenerate at the singular point $x \in \mathcal{X}$ if the corresponding $\hat{f}$ satisfies $\frac{\partial \hat{f}}{\partial x}(0) \notin \bigcup H_i$.

**Example.** Consider the $A_k$-singularity $w^{k+1} = xy$, desingularized by the family

$$xy = w^{k+1} + a_{k-1}w^{k-1} + a_{k-2}w^{k-2} + \cdots + a_0.$$

A deformation is given by a map $f(z) = (a_0(z), \ldots, a_{k-1}(z))$. It is easy to check that if $\frac{\partial w}{\partial z} \neq 0$ then the deformation is non degenerate.

To state the theorem, we need to fix a Kähler class. Along a ray to the origin in $\Delta$, the Gauss-Manin connection identifies $H^2(\mathcal{M}_t, \mathbb{R})$ with a fixed vector space; going to the origin, we identify this vector space with

$$H^2_{\text{orb}}(\mathcal{X}, \mathbb{R}) \oplus \bigoplus_{x \text{ singular}} \mathbb{R}^{e_x},$$

where $e_x$ is the dimension of the real $H^2$ of the local smoothing of the singularity at $x$. As we shall see later, if $d_x$ is the dimension of the space of smoothings of the singularity at $x$,

$$e_x = \begin{cases} d_x & \text{for a canonical singularity}, \\ d_x - 1 & \text{for other singularities}. \end{cases}$$

(One cannot get such an identification on the whole disk, because of the monodromy of the Gauss-Manin connection; but since the data of a Kähler class is real, it is natural to give it only on a ray).

The simplest form of our results can now be stated:
Theorem A. Suppose that we are given

- a normal complex surface \( X \), with no holomorphic vector fields, and a \( \mathbb{Q} \)-Gorenstein smoothing \( X \hookrightarrow \mathcal{M} \to \Delta \), which is non degenerate at each singular point;
- along the ray \( t \in \mathbb{R}_+ \cap \Delta \), a Kähler class \( \Omega_t \in H^2(\mathcal{M}_t, \mathbb{R}) \), depending smoothly on \( t \), such that \( \Omega_0 \) is an orbifold Kähler class on \( X \), containing an orbifold CSCK metric.

Then for small \( t > 0 \) the class \( \Omega_t \) contains a CSCK metric on \( \mathcal{M}_t \).

The behavior of the CSCK metric for \( t \) small is well understood: outside the singularities it converges to the orbifold CSCK metric on \( X \), but near a singularity \( x \) some rescaling converges to an ALE Kähler Ricci flat space, which appears as the ‘bubble’ at \( x \).

One special case is when the smoothing is given with a polarization \( \Omega \), resulting in a constant \( \Omega_t \). This covers in particular the Kähler-Einstein case: when \( \Omega_t = \pm c_1(\mathcal{M}_t) \) our result gives a construction of the Kähler-Einstein metric on the smoothing of \( X \), as well as a concrete description of its degeneracy to an orbifold Kähler-Einstein metric. This Kähler-Einstein picture is recently obtained in the case of \( A_1 \) singularities by Spotti [10].

Complex orbifold singularities of codimension at least 3 are rigid by a result of Schlessinger. However, it would be interesting to extend our results in dimension 3 or more, allowing orbifold singularities of codimension 2. A natural problem would be to remove the triviality assumption of the automorphism group: one may expect the existence of the CSCK metric to be related to a K-stability property, like in [12].

One can replace the non degeneracy hypothesis on the smoothing \( \mathcal{M}_t \) by a weaker non degeneracy hypothesis on the data \( (\mathcal{M}_t, \Omega_t) \) of the smoothing with the Kähler class. This requires slightly more material that we now explain.

Let us come back to the \( \mathbb{Q} \)-Gorenstein smoothing \( \mathcal{Y} \to \mathbb{C}^d \) of a canonical singularity. The parameter space \( \mathbb{C}^d \) can be identified with \( h_{\mathbb{C}}/W \), where \( h_{\mathbb{C}} \) is a Cartan subalgebra of the Lie algebra \( g_{\mathbb{C}} \) associated to \( \Gamma \) by the McKay correspondence (\( g_{\mathbb{C}} \) is exactly the \( A_d \), \( D_d \) or \( E_d \) simple Lie algebra), and \( W \) is the Weyl group. Here the canonical projection \( h_{\mathbb{C}} \to \mathbb{C}^d \) is ramified over the discriminant locus \( D \subset \mathbb{C}^d \).

The real 2-cohomology is isomorphic to the real Cartan subalgebra \( h_{\mathbb{R}} \) (actually, the smoothing is diffeomorphic to the minimal resolution, whose \(-2\) spheres give a basis of \((h_{\mathbb{R}})^*)\). But there is some ambiguity in this identification, because the monodromy of the Gauß-Manin connection is given by the action of \( W \).

In the smoothing \( \mathcal{Y} \to \mathbb{C}^d = h_{\mathbb{C}}/W \), the general fiber is smooth, but there are singular fibers, given by the walls of the Weyl chambers of \( h_{\mathbb{C}} \). Nevertheless, there exist a simultaneous resolution of singularities \( \hat{\mathcal{Y}} \to h_{\mathbb{C}} \) (Brieskorn, Slodowy). Then all the fibers are smooth and their real 2-cohomology can be identified to \( h_{\mathbb{R}} \).

The case of the other \( T \) singularities is similar: they are quotients of \( A_{dn-1} \) singularities by a \( \mathbb{Z}_n \) action, and one obtains the same structure by taking the \( \mathbb{Z}_n \) fixed points of the \( A_{dn-1} \) simultaneous resolution: the space of parameters is therefore \( \mathbb{R}^{\mathbb{C}} \simeq \mathbb{C}^d \), and the real 2-cohomology is \( h_{\mathbb{Z}_n}^{\mathbb{R}} \simeq \mathbb{R}^{d-1} \).

Now come back to our setup of a smoothing \( \mathcal{M} \to \Delta \) with a family of Kähler classes \( \Omega_t \). At a singular point \( x \in X \), the smoothing is induced from the standard
smoothing $\mathcal{Y}$ by a map (we denote the dependence in $x$ by an index $x$)

$$f_x : \Delta_c \rightarrow ((\mathfrak{h}_C)_x/W_x)^{G_x},$$

where $G_x = 1$ for a canonical singularity, and $\Delta_c \subset \Delta$ is a smaller disk of radius $c$. Up to a finite ramified covering $\Delta_b \rightarrow \Delta_c$, we can lift this map into a map into $(\mathfrak{h}_C)_x^{G_x}$:

$$(\zeta_c)_x : \Delta_b \rightarrow (\mathfrak{h}_C)_x^{G_x}.$$

Up to taking a higher degree covering, we can take the same covering $\Delta_b \rightarrow \Delta_c$, say of order $d$, for all singular points. Adding the data $(\zeta_r)_x$ of the Kähler class in a neighborhood of the singularity, we obtain at each singularity a map

$$\zeta_x : \Delta_b \rightarrow (\mathfrak{h}_R)_x^{G_x} \oplus (\mathfrak{h}_C)_x^{G_x}, \quad \zeta_x = ((\zeta_r)_x, (\zeta_c)_x),$$

which represents the deformation of both the Kähler parameter and the complex parameter. We consider the Kähler class as depending smoothly on the parameter on $\Delta_b$ (since $\Delta_b$ is a covering, this is more general than the setting of Theorem A). Then at the origin we have for some integer $p$

$$\zeta_x(t) = t^p \dot{\zeta}_x + O(t^{p+1}).$$

We can now define an extended notion of non degeneracy:

**Definition 2.** We say that $(M_t, \Omega_t)$ is non degenerate at the point $x$ if $p \leq d$ and $\dot{\zeta}_x$ does not belong to a wall of a Weyl chamber.

The above definition is clearly a generalization of Definition 1. We now extend Theorem A under the form:

**Theorem B.** Suppose that we are given

- a normal complex surface $\mathcal{X}$, with no holomorphic vector fields, and a $\mathbb{Q}$-Gorenstein smoothing $\mathcal{X} \hookrightarrow \mathcal{M} \rightarrow \Delta$;
- along the ray $t \in \mathbb{R}_+ \cap \Delta_b$, a Kähler class $\Omega_t \in H^2(\mathcal{M}_t, \mathbb{R})$, such that $\Omega_0$ is an orbifold Kähler class on $\mathcal{X}$, containing an orbifold CSCK metric.

If $(\mathcal{M}_t, \Omega_t)$ is non degenerate at each singular point in the sense of Definition 2, then for small $t > 0$ the class $\Omega_t$ contains a CSCK metric on $M_t$.

There is a final extension of the results in the case of canonical singularities: then we do not need the initial family $\mathcal{M}$ to be a smoothing. Indeed suppose that $\mathcal{X} \hookrightarrow \mathcal{M} \rightarrow \Delta$ is any deformation of a surface with rational double points, then near each singularity $x$, the family is still induced by some map $\Delta_c \rightarrow (\mathfrak{h}_C)_x/W_x$ (because this is a semi-universal deformation), which can again be lifted to $(\zeta_c)_x : \Delta_b \rightarrow (\mathfrak{h}_C)_x$. Pulling back $\widehat{\mathcal{Y}} \rightarrow (\mathfrak{h}_C)_x$ near each singular point, we obtain a simultaneous resolution $\widehat{\mathcal{M}} \rightarrow \Delta_b$ of the singularities of $\mathcal{M} \rightarrow \Delta$ and we can apply our method in this setting to obtain:

**Theorem C.** Suppose that we are given

- a normal complex surface $\mathcal{X}$, with no holomorphic vector fields, with only rational double points, and a deformation $\mathcal{X} \hookrightarrow \mathcal{M} \rightarrow \Delta$; let then $\widehat{\mathcal{M}} \rightarrow \Delta_b$ the simultaneous resolution of singularities as above;
- along the ray $t \in \mathbb{R}_+ \cap \Delta_b$, a Kähler class $\Omega_t \in H^2(\widehat{\mathcal{M}}_t, \mathbb{R})$, such that $\Omega_0$ is an orbifold Kähler class on $\mathcal{X}$, containing an orbifold CSCK metric.
If \((\hat{\mathcal{M}}_t, \Omega_t)\) is non degenerate at each singular point in the sense of Definition 2, then for small \(t > 0\) the class \(\Omega_t\) contains a CSCK metric on \(\hat{\mathcal{M}}_t\).

This result covers the known case of minimal resolutions, but also the case of partial resolutions which are not smoothings. It is not valid for \(T\) singularities because the deformations include other components that are not induced from the \(\mathbb{Q}\)-Gorenstein smoothing \(\mathcal{Y}\).

### 1.2. Hamiltonian stationary spheres

Suppose we are under the hypothesis of Theorem B. As we have seen,

\[ H^2(\mathcal{M}_t, \mathbb{R}) = H^2_{\text{orb}}(\mathcal{X}, \mathbb{R}) \oplus \oplus_x \text{singular} (\theta_R)^{G_x}. \]

Fix a singular point \(x\), and a system \(\mathcal{R}_x^+ \subset (\mathcal{H}_C)_x^+\) of positive roots. If \(x\) is a rational double point \((G_x = 1)\), a root \(\theta \in \mathcal{R}_x^+\) represents an integral homology class on \(\mathcal{M}_t\); in general, \(\theta\) represents a homology class in the local \(G_x\)-covering, so after projection still represents a (possibly zero) homology class in \(\mathcal{M}_t\).

Remind that the deformation \((\mathcal{M}_t, \Omega_t)\) is given near the singular point \(x\) by a map \(\zeta_x = (\zeta_x^\nu + (\zeta_x^c)_x) : \Delta \rightarrow (\theta_R)^{G_x} \oplus (\mathcal{H}_C)^{G_x}\), in which \((\zeta_x^\nu)_x(t)\) represents the class of the restriction of \(\Omega_t\) near the singularity. Therefore the homology class defined by \(\theta\) is \(\Omega_t\)-Lagrangian if \(\langle \theta, (\zeta_x^\nu)_x(t) \rangle \equiv 0\), which implies in particular \(\langle \theta, (\zeta_x^\nu)_x \rangle = 0\).

**Theorem D.** Suppose that we are under the hypothesis of Theorem B or C. Fix a singular point \(x \in \mathcal{X}\) and a root \(\theta \in \mathcal{R}_x^+\), such that \(\langle \theta, (\zeta_x^\nu)_x \rangle = 0\), and \(\theta\) is primitive for this property (that is cannot decompose as \(\theta_1 + \theta_2\) with \(\theta_i \in \mathcal{R}_x^+\) satisfying the same property). Finally suppose that for all \(t > 0\), one has \(\langle \theta, (\zeta_x^\nu)_x(t) \rangle \equiv 0\), that is the homology class represented by \(\theta\) remains \(\Omega_t\)-Lagrangian. Then:

1. If \(x\) is a rational double point, then the homology class in \(\mathcal{M}_t\) (or \(\hat{\mathcal{M}}_t\) in the setting of Theorem C) corresponding to \(\theta\) is represented by a smooth Hamiltonian stationary sphere \(S_\ell\), which is also a global Lagrangian minimizer of the area in its homotopy class.
2. If \(G_x = \mathbb{Z}_n\), and if the homology class defined by \(\theta\) is nonzero, then it is represented by a smooth Hamiltonian stationary sphere \(S_\ell\).

Moreover (see section 5), one gets an explicit description when \(t \to 0\): after dilations, the Hamiltonian stationary representative of \(\theta\) converges to a special Lagrangian sphere in the ALE Kähler Ricci flat space obtained at the limit.

In the second case \((G_x = \mathbb{Z}_n)\), if the homology class defined by \(\theta\) in the quotient vanishes, one can still get in some cases a Hamiltonian stationary embedded \(S^2\) or \(\mathbb{R}P^2\), see section 6.2. We do not state a minimizing property which is less clear, because the models in the ALE Kähler Ricci flat space are not calibrated.

For example, from Theorem A we recover Kähler-Einstein metrics on certain 4-point blowup of \(\mathbb{C}P^2\) constructed by Tian [13], and Theorem D provides a construction of stationary Lagrangian spheres (cf §7.1).

### 1.3. Organization of the paper

In most of the article, we suppose that \(\mathcal{X}\) has only canonical singularities and we prove directly Theorem C, which implies Theorem A, Theorem B) and Theorem D. At the end, we explain the case of general singularities of the class \(\mathcal{T}\): there is not much change, because they are obtained as cyclic quotients of canonical singularities and all our constructions pass to the quotient.
One of the main points in the paper is the construction of ‘good’ Kähler metrics on the deformations: this is not obvious, because the complex structure changes. It turns out that what is needed is an extension to the singular setting of the theorem of Kodaira on the stability of the Kähler condition under complex deformations. This is done in section 3, after the introduction of the ‘tangent graviton’ in section 2. In section 4, we extend arguments in the literature to produce the CSCK metrics, so we only point out the new features in our situation. In section 5, we produce the Hamiltonian stationary Lagrangian spheres. The case of general singularities is explained in section 6, and some applications are given in section 7.

1.4. Acknowledgements. The authors would like to thank Claude LeBrun for some stimulating discussions.

2. Deformations of singular surfaces and Kähler classes

In this section, $X$ will always denote a compact complex surface with canonical singularities endowed with an orbifold Kähler metric $g$ with Kähler form $\omega$ and Kähler class $\Omega_0$. We consider a flat deformation $X \hookrightarrow M \rightarrow \Delta$ of $X$.

2.1. Complex deformations near singularities. Our first goal is to understand a simultaneous resolution $\hat{X} \hookrightarrow \hat{M} \rightarrow \Delta_d$ of the deformation, focusing near the singular points. For this purpose, we choose a set of adapted isomorphisms $U_i \cong \Delta^2_\varepsilon/\Gamma_i$ near each singularity $x_i \in X$. Actually, for simplicity of notations we will suppose that there is only one singular point $x_0$, and we will point out from place to place what changes for several singular points. So near $x_0$, one can choose local coordinates $z$ with values in $\Delta^2_\varepsilon$ defined modulo $\Gamma$, such that the pullback of $\omega$ on the disc is expressed as

$$dd^c(|z|^2 + \eta)$$

where $|z|$ is the Euclidean distance to the origin in $\mathbb{C}^2$ and $\eta$ is a smooth $\Gamma$-invariant real function such that $\eta = O(|z|^4)$. Up to scaling the metric, and shrinking the open set $U$, we may assume that $\varepsilon = 1$. In the sequel, we shall always assume that the identification $U \cong \Delta^2/\Gamma$ is chosen in such a way.

By restricting $M$ to a suitable neighborhood of the singular point $x_0$, we deduce a flat deformation

$$\Delta^2/\Gamma \hookrightarrow N \rightarrow \Delta_c$$

of the singularity $U = N_0$. The singularity $U$ admits a semi-universal flat family of deformations by a result of Kas-Schlessinger [6]: there is a deformation

$$\mathbb{C}^2/\Gamma \hookrightarrow \mathcal{Y} \rightarrow \mathfrak{h}_\mathbb{C}/W,$$

where $\mathfrak{h}_\mathbb{C}$ is a Cartan subalgebra of the complex semisimple Lie algebra associated to the Dynkin diagram of the singularity (this is the Lie algebra associated to the finite group $\Gamma$ by the McKay correspondence), and $W$ is the Weyl group. Then, $N$ is induced by some holomorphic map $\psi : \Delta_c \rightarrow \mathfrak{h}_\mathbb{C}/W$. Thus, there is a
Such that the restriction $\Psi : N_t \to Y_{\psi(t)}$ is an embedding for every $t \in \Delta_c$.

A remarkable feature of canonical singularities is that $\mathbb{C}^2/\Gamma \hookrightarrow Y \twoheadrightarrow \mathfrak{hC}/W$ admits a simultaneous resolution $\hat{\mathbb{C}}^2/\Gamma \hookrightarrow \hat{Y} \twoheadrightarrow \mathfrak{hC}$ given by a diagram

$$
\begin{array}{ccc}
\mathbb{C}^2/\Gamma & \xrightarrow{\psi} & \mathbb{C}^2/\Gamma \\
\downarrow & & \downarrow \\
N & \xrightarrow{\psi} & Y \\
\downarrow & & \downarrow \\
\Delta_c & \xrightarrow{\psi} & \mathfrak{hC}/W
\end{array}
$$

where the map $\mathfrak{hC} \to \mathfrak{hC}/W$ is the canonical projection (Brieskorn, Slodowy).

A priori, one cannot lift the map $\psi : \Delta_c \to \mathfrak{hC}/W$ to $\mathfrak{hC}$. The obstruction is the monodromy of $\psi$, which lies in $W$. By taking a ramified cover, with order $d$ equal to the order of the monodromy of $\psi$, we obtain a lifting

$$
\begin{array}{ccc}
\Delta_d & \xrightarrow{\psi} & \mathfrak{hC} \\
\downarrow & & \downarrow \\
\Delta_c & \xrightarrow{\psi} & \mathfrak{hC}/W
\end{array}
$$

If there are several singular points, one has to take the order to be the least common multiple of the orders at each point.

Thus, the family of deformations $N' = \Delta_d \times_{r_k} N$ admits a simultaneous resolution $\hat{N} \to N'$ and we have a commutative holomorphic diagram

$$
\begin{array}{ccc}
\hat{Y} & \xrightarrow{\psi} & Y \\
\downarrow & & \downarrow \\
\hat{N} & \xrightarrow{\psi} & N \\
\downarrow & & \downarrow \\
\mathfrak{hC} & \xrightarrow{\pi} & \mathfrak{hC}/W
\end{array}
$$
where the maps $\Psi$ and $\hat{\Psi}$ restrict to fiberwise embeddings. Here we should point out that the maps also commute with the embeddings $\Delta^2/\Gamma \hookrightarrow \hat{\mathcal{N}}$, $\Delta^2/\Gamma \hookrightarrow \mathcal{N}$, $\hat{C}^2/\Gamma \hookrightarrow \hat{\mathcal{Y}}$, $C^2/\Gamma \hookrightarrow \mathcal{Y}$ and the canonical inclusion $\Delta^2 \hookrightarrow \mathbb{C}^2$.

**Remark 3.** The fact that deformations of simple singularities do admit simultaneous resolutions after passing to a sufficiently high ramified cover, as recalled above, is the essential ingredient used in [6] to construct a simultaneous resolution for deformations of compact complex surfaces with canonical singularities.

**Remark 4.** Conversely, if the simultaneous resolution $\hat{\mathcal{Y}} \hookrightarrow \hat{\mathcal{M}} \to \Delta_d$ is already given as a data, the preimage $\hat{\mathcal{N}}$ of $\mathcal{N}$ via the map $\hat{\mathcal{M}} \to \mathcal{M}$ provides a simultaneous resolution of the deformation of the singularity for free. However, by a universal property of simultaneous resolutions of canonical singularities [4], it turns out that $\Delta^2/\Gamma \hookrightarrow \hat{\mathcal{N}} \to \Delta_d$ must be given by the above construction.

### 2.2. Kronheimer’s gravitons.

The simultaneous resolution $\hat{\mathcal{Y}} \to \mathfrak{h}_C$ of the semiuniversal family of deformations $\mathcal{Y} \to \mathfrak{h}_C/W$ is explicitly constructed by Kronheimer. At this point, we need more details. Kronheimer actually constructs a family $Y_\zeta$ of hyperKähler manifolds, parameterized by a triple $\zeta = (\zeta_1, \zeta_2, \zeta_3) \in \mathfrak{h} \otimes \mathbb{R}^3$. To explain its properties, we choose a positive root system $\mathfrak{R}^+ \subset \mathfrak{h}^*$, and for a root $\theta \in \mathfrak{R}^+$ we define a hyperplane of $\mathfrak{h}$ by

$$D_\theta = \ker \theta.$$  

Then the family $(Y_\zeta)$ has the following properties:

1. $Y_\zeta$ is a smooth manifold if
   $$\zeta \notin D = \cup_{\theta \in \mathfrak{R}^+} \mathbb{R}^3 \otimes D_\theta;$$

2. all $(Y_\zeta)_{\zeta \notin D}$ are diffeomorphic to the minimal resolution $\hat{\mathcal{C}}^2/\Gamma$ of $\mathcal{C}^2/\Gamma$; the diffeomorphism
   $$F_\zeta : \hat{\mathcal{C}}^2/\Gamma \sim \to Y_\zeta$$
   can be chosen so that the metric is asymptotic to the Euclidean metric: actually there is an asymptotic development at any order
   $$F_\zeta^* g_\zeta = g^{\text{eucl}} + \sum_{i=2}^{k-1} g_\zeta^i R^{-2i} + \mathcal{O}(R^{-2k}),$$
   where $g_\zeta^i$ is a homogeneous polynomial in $\zeta$ of degree $i$; in the sequel, we will suppose that such a diffeomorphism is chosen (this is possible smoothly in the $\zeta$ parameter because $\mathfrak{h} \otimes \mathbb{R}^3 - D$ is simply connected);

3. $H^2(Y_\zeta, \mathbb{R})$ is identified with $\mathfrak{h}$ in such a way that the homology classes of the $-2$ curves of the resolution get identified with the simple roots of $\mathfrak{h}$ (and so $H_2(Y_\zeta, \mathbb{Z})$ is identified with the root lattice of $\mathfrak{h}$); under this identification, the cohomology classes of the three Kähler forms $(\omega_1, \omega_2, \omega_3)$ of $Y_\zeta$ are $\zeta_1$, $\zeta_2$ and $\zeta_3$;

4. there is a $SO_3$ action which for $u \in SO_3$ identifies isometrically
   $$Y_\zeta \to Y_{u(\zeta)},$$
   permuting $(\omega_1, \omega_2, \omega_3)$ to $u(\omega_1, \omega_2, \omega_3)$;
when we want to underline the holomorphic symplectic structure \((I_1, \omega_2 + i\omega_3)\) of \(Y_\zeta\), we use the notation \(Y_{\zeta,r,c}\), where \(\zeta_r = \zeta_1\) and \(\zeta_c = \zeta_2 + i\zeta_3 \in \mathbb{C}\); then there is a \(\mathbb{C}^*\)-action, giving for \(\lambda \in \mathbb{C}^*\) an isomorphism of holomorphic symplectic manifolds, which is actually also an isometry,

\[
H_\lambda : Y_{\zeta_r,c} \rightarrow \frac{1}{|\lambda|^2} Y_{|\lambda|^2 \zeta_r, \lambda^2 \zeta_c};
\]

Here the leading fraction means that the metric has been rescaled by a factor \(\frac{1}{|\lambda|^2}\).

(6) if \(\zeta_r \notin \cup_{\theta \in \mathbb{R}_+} D_\theta\), then there is a map \(Y_{\zeta_r,c} \rightarrow Y_{0,c}\) which is a minimal resolution of singularities, actually \(Y_{\zeta_r,c}\) and \(Y_{0,c}\) are the fibers \(\hat{Y}_c\) and \(Y_{c}\) of the simultaneous resolution \((2.2)\).

**Remark 5.** In this paper, the notation \(O(R^k)\) for a function \(f\) on \(\mathbb{C}^2\), or more generally a tensor, means that when \(R\) goes to \(\infty\), then for any integer \(l = 0, 1, \ldots\), one has \(\nabla^l f = O(R^{k-l})\).

We now point out the statement which will be central in this paper: it gives the geometric meaning of the walls \(D_\theta\).

**Lemma 6.** Suppose \(\theta\) is a root and \(\zeta \notin D\), so \(\theta\) corresponds to some homology class in \(H_2(Y_\zeta, \mathbb{Z})\).

1) If \(\zeta_1 \in \ker \theta\), then \(\theta\) is a Lagrangian homology class for \(Y_{\zeta_1,c}\).

2) If \(\zeta_c \in \ker \theta\), then \(\theta\) is represented by a holomorphic cycle in \(Y_{\zeta_1,c}\); moreover if \(\theta\) is primitive for this property (that is cannot be written as \(\theta_1 + \theta_2\), with \(\theta_i \in \mathbb{R}^+\) and \(\zeta_c \in \ker \theta_1\)), then \(\theta\) is represented by a holomorphic sphere.

The condition \(\zeta \notin D_\theta\) can now be understood in terms of this lemma: indeed, if \(\zeta \in D_\theta\), then both \(\zeta_r, \zeta_c \in \ker \theta\) which means that \(\theta\) would represent at the same time a Lagrangian class and a holomorphic cycle, which is impossible, so \(Y_{\zeta_r,c}\) has to be singular.

The first part of the lemma is obvious from (iii). The second part is basically contained in the work of Brieskorn and Slodowy on Kleinian singularities. By property (vi), the holomorphic map \(Y_{\zeta_r,c} \rightarrow Y_{0,c} = Y_c\) is a minimal resolution of singularities, but the semi-universal deformation \(\mathcal{Y}\) is explicit and its singularities are completely understood: the discriminant locus \(\mathcal{D} \subset C^k = h/W\), that is the set of \(v \in C^k\) such that \(Y_v\) is singular, is exactly the branch locus of the projection \(h_C \rightarrow h_C/W\), i.e. the projection of the kernels of the roots. (And the monodromy representation \(\pi_1(C^k - \mathcal{D}) \rightarrow \text{Aut} H^2(\mathcal{Y}_{\nu_0}, C)\) is the standard representation of \(W\) on \(h_C\)).

If \(\zeta_c \in \ker \theta\) for only one root \(\theta\) (this is the generic case), then \(Y_c\) has a singular point with a singularity of type \(C^2/\mathbb{Z}_2\), giving a \(-2\) holomorphic sphere in the minimal resolution \(Y_{\zeta_r,c}\) in the homology class corresponding to \(\theta\). For a general \(\zeta_c \in \ker \theta\), then of course \(\theta\) is still represented by a holomorphic cycle in \(Y_{\zeta_r,c}\), which might be a union of several curves if it can be decomposed as a sum of roots \(\theta = \theta_1 + \cdots + \theta_l\) such that \(\zeta_c \in \ker \theta_1\).

**Remark 7.** The \(A_k\)-gravitational instantons are known explicitly (multi-Eguchi-Hanson metrics given by the Gibbons-Hawking ansatz). In that case one can see explicitly the holomorphic cycles of Lemma 6.
2.3. The tangent graviton. We come back to our setting of a flat deformation \( \mathcal{X} \hookrightarrow \mathcal{M} \to \Delta \) of a Kähler orbifold surface \( \mathcal{X} \) with a simultaneous resolution \( \tilde{\mathcal{X}} \hookrightarrow \tilde{\mathcal{M}} \to \Delta_d \) after passing to a ramified cover. We deduce a family of deformations of the singularity \( \Delta^2 / \Gamma \hookrightarrow \mathcal{N} \to \Delta_c \) and a simultaneous resolution \( \hat{\Delta}^2 / \hat{\Gamma} \hookrightarrow \hat{\mathcal{N}} \to \Delta_d \). As explained in \( \S 2.1 \) we have a morphism

\[
\begin{array}{ccc}
\hat{\mathcal{N}} & \xrightarrow{\hat{\psi}} & \hat{\mathcal{Y}} \\
\Delta_d & \xrightarrow{\hat{\psi}} & \mathbb{C}
\end{array}
\]

The cohomology class \( \Omega_t \) defined for \( t \in \Delta_d \cap \mathbb{R}^+ \), restricted to \( \hat{\mathcal{N}}_t \) defines a class on \( \hat{\mathcal{Y}} \) identified to an element \( \zeta_r(t) \in \mathfrak{h} \). So that the whole data \( (\hat{\mathcal{N}}_t, \zeta_r(t)) \) is exactly that of the Kronheimer graviton

\[
\zeta : \Delta_d \cap \mathbb{R}^+ \to \mathfrak{h} \oplus \mathfrak{h}_\mathbb{C} \\
t \mapsto (\zeta_r(t), \zeta_c(t))
\]

does not vanish at infinite order at \( t = 0 \) and introduce the first nonzero derivative \( \dot{\zeta} \) for some order \( p > 0 \). This means that

\[
\zeta(t) = t^p \dot{\zeta} + O(t^{p+1}) \tag{2.7}
\]

for some \( p > 0 \) and \( \dot{\zeta} \neq 0 \).

The domain \( \hat{\mathcal{N}}_t \) identifies to a small domain of \( Y_{\zeta(t)} \). Zooming by a factor \( \varepsilon^{-1} = t^{-p/2} \), and multiplying the Kähler class by a factor \( \varepsilon^{-2} = t^{-p} \), we obtain by (2.6) that this domain is identified via \( H_{t^{-p/2}} \) with a larger and larger domain in \( Y_{e^{-2\zeta(t)}} \), which converges to \( Y_{\zeta} \) on compact subsets.

This discussion motivates:

**Definition 8.** The Kronheimer space \( Y_{\zeta} \) is called the tangent graviton to the deformation \( (\hat{\mathcal{N}}, \Omega_t|_{\hat{\mathcal{N}}}) \).

**Remark 9.** There are choices in the construction of \( \dot{\zeta} \):

- the choice of lifting to the simultaneous resolution is done up to the action of the Weyl group \( W \), acting on the parameter \( \zeta_c(t) \): but this does not change the space \( Y_{\zeta_r(t), \zeta_c(t)} \);
- the choice of a coordinate in the disc: since we have chosen a real ray, the ambiguity is the rescaling by a real \( \lambda > 0 \), but in view of (2.6), this amounts to rescale the graviton.

**Remark 10.** If the restriction of \( \Omega_t \) to \( \hat{\mathcal{N}}_t \) is identically zero, then \( \zeta_r(t) \equiv 0 \). In this case, as \( \zeta \) is a holomorphic map and the nonzero derivative \( \dot{\zeta} \) can be defined without restricting to a particular ray in \( \Delta_d \). Thus, all the above definition make
sense if we allow $t \in \Delta_d$. This property is of special interest in the case of polarized smoothings.

3. Representing Kähler classes

The one point blowup of a complex manifold endowed with a Kähler metric $\omega$, carries a family of Kähler metric $\omega_\varepsilon$. This is a very nice argument due to Kodaira in which the metric $\omega_\varepsilon$ can be constructed almost explicitly. The construction of $\omega_\varepsilon$ is done by cut and paste, where the Burns-Simanca metric defined on a neighborhood of the exceptional divisor is glued with the original metric. As $\varepsilon \to 0$, the metrics $\omega_\varepsilon$ converge smoothly away from the exceptional divisor toward the original metric $\omega$.

The aim of the current section is to prove a similar result for families of deformations of a Kähler orbifold surface with isolated singularities. In particular, we shall prove the following proposition.

**Proposition 11.** Let $X \hookrightarrow M \to \Delta$ be a family of deformations of a compact complex surface with canonical singularities. Let $\omega$ be an orbifold Kähler metric on $X$ with Kähler class $\Omega_0$ and $\Omega$ a family of Kähler classes supported by a simultaneous resolution $\hat{X} \to \hat{M} \to \Delta_d$ degenerating toward $\Omega_0$, such that the variation of Kähler class and complex structure is non degenerate in the sense of Definition 2.

Then, there exists a family of Kähler metrics $g_t$ with Kähler forms $\omega_t$ defined for $t \in \Delta_d \cap (0, +\infty)$ and a smooth trivialization $\phi: \Delta_d \times \hat{X} \to \hat{M}$ defining all the fibers $M_t$ with the property that

- $[\omega_t] = \Omega_t$;
- the family of metrics $g_t$ converges in the $C^2$-sense toward the orbifold metric $\mathcal{G}$ on every compact set of $X = \hat{X} \setminus E$, where $E$ is the exceptional divisor of $\hat{X} \to X$.

**Remark 12.** The above proposition also holds if $\Omega$ is only assumed to be a family of $(1,1)$-classes (instead of Kähler). As a corollary, under the assumptions of admissibility, $\Omega_t$ must be a Kähler class for $t \in (0, +\infty)$ sufficiently small.

The rest of the section will be devoted to prove the proposition as well as giving more accurate results about the behavior of $\omega_t$ as $t \to 0$.

3.1. Summary of the setup. We use the notations introduced at §2. As in §2.1, we shall assume to keep the notations simple that there is exactly one singularity in $Y$ with a neighborhood $U$ identified to $\Delta^2 / \Gamma$. The minimal resolution of the singularity will be denoted $\tilde{U} \to U$ and $\tilde{X} \to X$. The case when several singularities occur is a straightforward generalization of the constructions explained below.

The smooth manifold or orbifold deduced from $\tilde{X}$ and $X$ will be denoted $\hat{X}$ and $X$, and $X$ will denote the complement of the singularity in $\overline{X}$, or equivalently, the complement of the exceptional divisor in $\tilde{X}$.

Using a smooth trivialization $\phi: \Delta_d \times \tilde{X} \to \hat{M}$ of the simultaneous resolution $\hat{X} \hookrightarrow \hat{M} \to \Delta_d$, we have a family of complex structures $J_t$ defined on $\tilde{X}$ deduced from $\hat{M}_t$ and $\phi$. The degenerating family of Kähler classes $\Omega_t$ on $(\tilde{X}, J_t)$ also provides a cohomology class $\Omega_t|_{\tilde{U}} \in H^2(\tilde{U}, \mathbb{R}) \simeq H^2(\mathbb{C}^2 / \Gamma, \mathbb{R})$. As explained in §2.3, this is the Kähler class of a Kähler Ricci-flat metric $\mathcal{G}_{\xi(t)}$ compatible with the complex structure $I_{\xi(t)}$ on $\mathbb{C}^2 / \Gamma$ provided by Kronheimer’s construction.
If the variation of the deformation is non-degenerate, there is a scaling parameter \( \varepsilon = t^{p/2} \) defined for some \( p \geq 1 \), and homotheties \( H_{-1} \) by a factor \( t^{-p/2} = \varepsilon^{-1} \) such that we have the following properties: \( H_{-1} \) induces a map \( \hat{U} \to \Delta^2_{e_{-1}} / \Gamma \) such that the image of the Kähler structure \( (I_{\zeta(t)}, g_{\zeta(t)}) \) is \( (I_{e^{-2}\zeta(t)}, \varepsilon^2 g_{e^{-2}\zeta(t)}) \). Up to rescaling the metric by a factor \( \varepsilon^{-2} \), the family of Kähler structure converges to the tangent graviton graviton \( Y_0 \) which is smooth (not in Kronheimer’s wall).

Thus by \( 2.2 \) (ii), we have uniform estimates in \( t \) as \( R \to +\infty \) of the form

\[
g_{e^{-2}\zeta(t)} = g^{\text{euc}} + \xi_t \quad \text{with} \quad \xi_t = O(R^{-4})
\]

where \( g^{\text{euc}} \) is the Euclidean metric on \( \mathbb{C}^2 / \Gamma \), and \( R \) is the Euclidean distance to the origin. The function \( R \) is related to \( r \) by the scaling factor \( r = \varepsilon R \). Similar estimates hold for the complex structures

\[
I_{e^{-2}\zeta(t)} = \text{euc} + O(R^{-4}),
\]

where \( \text{euc} \) is the canonical complex structure of \( \mathbb{C}^2 / \Gamma \).

### 3.2. Background Hermitian metrics

Let \( \overline{\mathcal{Y}} \) be the orbifold Kähler metric on \( (\overline{\mathcal{X}}, J_0) \) with Kähler form \( \overline{\omega} \). Recall that the isomorphism between \( U \) and \( \Delta^2 / \Gamma \) is chosen so that the Kähler form can be written as \( (3.1) \). We modify \( \overline{\mathcal{Y}} \) so that it is flat near the the singularity. For this purpose, we need to choose a gluing scale of the form

\[
b = \varepsilon^\beta = t^{p\beta/2}
\]

where \( \beta \) is a constant very close to \( \frac{1}{2} \), and such that \( 1 > \beta > \frac{1}{2} \). The precise value of this constant will be decided later on (cf. \( (\ref{eq:beta}) \)).

We also need to define suitable cut-off functions. We fix a standard bump function \( \chi : \mathbb{R} \to \mathbb{R} \), that is a smooth non-decreasing function such that \( \chi(x) = 0 \) for \( x \leq 0 \) and \( \chi(x) = 1 \) for \( x \geq 1 \). Then we choose a pair of real parameters \( (x_1, x_2) \) such that \( 0 < x_1 < x_2 \) and define

\[
\chi(x_1, x_2)(x) = \chi \left( \frac{x - x_1}{x_2 - x_1} \right)
\]

(3.1)

Let \( r \) be the function on \( U \) corresponding to the Euclidean distance to the origin via the isomorphism \( U \simeq \Delta^2 / \Gamma \). Then we define

\[
\omega_{B,t} = \overline{\omega} \quad \text{away from the domain} \quad r \leq 4b \quad \text{of} \quad U
\]

\[
\omega_{B,t} = d\hat{e}_{\xi_0}(r^2 + \chi(2b, 4b)(r)\eta) \quad \text{on the domain} \quad r \leq 4b \quad \text{of} \quad U
\]

so that \( \omega_{B,t} \) is the Kähler form of a Kähler orbifold metric on \( (\overline{\mathcal{X}}, J_0) \) for \( t \) small enough.

Similarly, we modify the model metric \( g_{e^{-2}\zeta(t)} \) on \( \mathbb{C}^2 / \Gamma \) as follows:

\[
g_{A,t} = g_{e^{-2}\zeta(t)} \quad \text{on the domain} \quad R \leq b / \varepsilon
\]

\[
g_{A,t} = g^{\text{euc}} \quad \text{on the domain} \quad 2b / \varepsilon \leq R,
\]

\[
g_{A,t} = g^{\text{euc}} + (1 - \chi(b / \varepsilon, 2b / \varepsilon)(R))\xi_t \quad \text{on the annulus} \quad b / \varepsilon \leq R \leq 2b / \varepsilon.
\]

Hence \( g_{A,t} \) defines a Riemannian metric on \( \mathbb{C}^2 / \Gamma \) for \( t \) small enough.

The homothety \( H_{-1} \) identifies the annuli \( b \leq r \leq 4b \) and \( b / \varepsilon \leq R \leq 4b / \varepsilon \). By construction \( g_{B,t} \) is Euclidean at \( r = 2b \) and so is \( g_{A,t} \) near \( R = 2b / \varepsilon \). Identifying
the annuli via $H_{\varepsilon}^{-1}$, we define a Riemannian metric on $\tilde{X}$ by

$$\tilde{h}_t = \varepsilon^2 H_{\varepsilon}^{-1} g_{A,t} \text{ on the domain } r \leq 2b \text{ of } \tilde{U}$$
$$= g_{B,t} \text{ outside the domain } r \leq 2b \text{ of } \tilde{U}$$

By definition, the metric $\tilde{h}_t$ is $J_t$-Hermitian on the domain $r \leq b$ of $\tilde{U}$ and $J_0$-Hermitian on the complement of $r \leq 2b$. We construct a globally $J_t$-Hermitian metric on $\tilde{X}$ by introducing its projection

$$h_t(u,v) = \frac{1}{2}(\tilde{h}_t(u,v) + \tilde{h}_t(J_t u, J_t v)). \quad (3.2)$$

Similarly, one can construct $I_{\varepsilon-2\zeta(t)}$-Hermitian metrics $h_{A,t}$ on $\mathbb{C}^2/\Gamma$ deduced from $g_{A,t}$.

3.3. Hölder spaces. Elliptic operators, Laplacians for instance, may not be Fredholm on a singular or noncompact manifold. At this point, we ought to introduce suitable weighted Hölder spaces to deal with this issue.

Hölder spaces for ALE spaces. We consider a radius function $\rho_A$ on $\mathbb{C}^2/\Gamma$. That is a smooth function such that $\rho_A > 0$ with the property that $\rho_A = R$, say on the domain $R \geq 2$. For $\delta \in \mathbb{R}$, we define the weighted Hölder $C_{\delta,\alpha}^k$-norm given by

$$\|f\|_{C_{\delta,\alpha}^k(\mathbb{C}^2/\Gamma,t)} = \sum_{j=0}^k \sup_{x,y} |\rho_A^{-\delta} \nabla^j f| + \|\rho_A^{-\delta-\alpha} \nabla^k f\|_\alpha$$

where $(i_0 > 0$ being fixed and chosen smaller than the injectivity radius)

$$\|f\|_\alpha = \sup_{d(x,y) \leq i_0} \frac{|f(x) - f(y)|}{d(x,y)^\alpha}.$$ 

Here, $f$ can be any tensor, and the pointwise norms are taken with respect to the metric $g_{\varepsilon-2\zeta(t)}$ (or alternatively $g_{A,t}$).

Remark 13. All the norms on $\mathbb{C}^2/\Gamma$ obtained in such a way are commensurate uniformly in $t$. Thus, any of these norms could be used in the estimating process.

Hölder spaces on orbifold. Similarly, we define a radius function $\rho_B$ on $\tilde{X}$, that is a smooth function such that $\rho_B > 0$ and $\rho_B = r$ on $U$. We define $C_{\delta,\alpha}^k(\tilde{X})$ with the same formula as above, using instead the metric $\mathcal{F}$ (or alternatively $g_{B,t}$).

Hölder spaces on the gluing. Finally a third weighted norm can be defined on $\tilde{X}$ itself. For this purpose, we define a weight function $\rho$ (depending on the parameters $t$) on $\tilde{X}$ as follows: put $\rho = \rho_B$ on the complement of $\tilde{U}$, $\rho = r$ on the domain $b \leq r \leq 1$ of $\tilde{U}$ and $\rho = \varepsilon H_{\varepsilon}^{-1} \rho_A$ on the rest. Using the same formula as above with metrics $h_t$ (or alternatively $\tilde{h}_t$), we define a norm $\|f\|_{C_{\delta,\alpha}^k(\tilde{X},t)}$ on $\tilde{X}$.

Given a $m$-form $f$ on $\tilde{X}$, we can interpret a $C_{\delta,\alpha}^k(\tilde{X})$-estimate on $f$ as an estimate on each piece of the manifold. We decompose $f = f_A + f_B$ where $f_A = (1 - \chi_{(b,2b)}(\rho))f$ and $f_B = \chi_{(b,2b)}(\rho)f$. Then $f_A$ is supported on the domain $\rho \leq 2b$ and $f_A = f$ on the domain $\rho \leq b$. Similarly $f_B$ is supported in the domain $\rho \geq b$ and
\[ f = f_B \text{ on the domain } \rho \geq 2b. \] Then \( \|f\|_{C^{k,\alpha}_\delta}(\tilde{X},\tilde{t}) \) is uniformly commensurate with the norms
\[
\|f_B\|_{C^{k,\alpha}_\delta}(\tilde{X},\tilde{t}) + \varepsilon^{-m-\delta}\|(H_{\varepsilon^{-1}})_*f_A\|_{C^{k,\alpha}_\delta}(\tilde{X},\tilde{t})
\] (3.3)
where \( m \) is the degree of the form \( f \) and \( H_{\varepsilon^{-1}} \) is used to identify the domain \( \rho \leq 2b \) with the domain \( \rho_A \leq 2b/\varepsilon \).

**Remark 14.** The asymptotics of the metrics \( \overline{\mathcal{F}} \), \( g_{\varepsilon^{-2}\zeta(t)} \) and complex structures \( I_{\varepsilon^{-2}\zeta(t)} \), together with the naturality of the constructions of the metrics \( g_A \), \( g_B \), \( h_A \), \( \tilde{h}_t \), \( h_t \) and the fact that the functions \( \chi(c,2c) \) are uniformly bounded in \( C^0_\alpha \)-norm imply that the Hölder norms defined using any of these metrics lead to uniformly commensurate norms. Therefore, we could use any of these metrics for estimating the \( C^{k,\alpha}_\delta \)-norms.

### 3.4. Background Laplacian

The Cauchy-Riemann operator on \((\tilde{X}, J_t)\) is denoted \( \partial J_t \) or \( \overline{\partial} J_t \). Its adjoint deduced from the Hermitian metric \( h_t \) is denoted \( \tilde{\partial} J_t^* \). Then the Dolbeault Laplacian is given by
\[
\Box_t = \tilde{\partial} J_t^* \partial J_t + \tilde{\partial} J_t \tilde{\partial} J_t^*
\]
for \((p, q)\)-forms on \((\tilde{X}, J_t)\).

**Error terms.** It should be pointed out that the Dolbeault Laplacian \( \Box_t \) need not agree with the Riemannian Laplacian \( \Delta_t \) of \( h_t \). Indeed, the metric \( h_t \) is not necessarily Kähler. Thus, \( h_t \) is Hermitian, by construction, but its Kähler form \( \varpi_t = h_t(J_t\cdot,\cdot) \) is not a priori closed. In this section, we investigate how close \( h_t \) is to be Kähler. In particular, we prove the following lemma:

**Lemma 15.** For every \( k \geq 0 \), there exist a constant \( C_k > 0 \) such that for every \( \delta < 0 \) sufficiently close to \(-2 \), \( t > 0 \) and \( \beta = \frac{2}{2-\delta} \), we have
\[
\|d\varpi_t\|_{C^{k,\alpha}_\delta(t)} \leq C_k \varepsilon^2.
\]
Similarly, we have an estimate
\[
\|\nabla^{LC} J_t\|_{C^{k,\alpha}_\delta(t)} \leq C_k \varepsilon^2.
\]

**Proof.** On the compact domain \( \tilde{X} \setminus \tilde{U} \), the family of complex structure \( J_t \) converges smoothly to \( J_0 \), and \( |J_t - J_0| = O(d^4) \) where \( d \) is the order of the covering \((2.3)\). By assumption, the variation is non degenerate \((d \geq p)\), hence \( |J_t - J_0| = O(\varepsilon^2) \) on the compact domain. It follows that \( \varpi_t \) converges smoothly to \( \varpi \), the Kähler form of the orbifold metric \( \overline{\mathcal{F}} \). Since \( \varpi = 0 \), the estimate \( \|d\varpi_t\|_{C^{1,\alpha}} = O(\varepsilon^2) \) on this domain follows.

On the domain \( r \leq b \), the metric \( \tilde{h}_t \) is \( J_t \)-Hermitian. In fact it agrees with the model metric \( g_{\varepsilon^{-2}\zeta(t)} \) up to a scaling factor \( \varepsilon^2 \). Therefore \( \tilde{h}_t = h_t \) and the \( J_t \)-Hermitian metric is Kähler on this domain. In particular \( d\varpi_t = 0 \).

On the domain \( 2b \leq r \leq 1 \), we have \( \tilde{h}_t = g_{B,t} \) and \( J_t = I_{\varepsilon^{-2}\zeta(t)} = H_{\varepsilon^{-1}}I_{\varepsilon^{-2}\zeta(t)} \). However \( I_{\varepsilon^{-2}\zeta(t)} = \text{euc} + O(R^{-4}) \) it follows that \( J_t = J_0 + O(\varepsilon^4 R^{-4}) \). Since \( g_{B,t} \) is Kähler w.r.t. the complex structure \( J_0 \), we have \( \tilde{h}_t = g_{B,t} + O(\varepsilon^4 R^{-4}) \) and \( \varpi_t = \omega_{B,t} + O(\varepsilon^4 R^{-4}) \). Thus, \( d\varpi_t = O(\varepsilon^4 R^{-4}) \) hence \( r^{-1-\delta}d\varpi_t = O(\varepsilon^{4-\beta(5+\delta)}) \) on the domain \( 2b \leq r \leq 1 \). That is to say \( \|d\varpi_t\|_{C^{1,\alpha}} = O(\varepsilon^{4-\beta(5+\delta)}) \) on the annulus.
2b \leq r \leq 1. We see that if delta is sufficiently close to –2 then the error term is a \( O(\varepsilon^2) \).

On the domain \( b \leq \rho \leq 2b \), we can rescale via the homothety \( H_t \) and look at the construction on the annulus \( b/\varepsilon \leq R \leq 2b/\varepsilon \) of \( \mathbb{C}^2/T \). Up to a scaling factor \( \varepsilon^2 \), the metric \( \tilde{h}_t \) corresponds to \( g_{A,t} \). On the other hand, we have \( g_{A,t} = g_{\varepsilon^{-2}\zeta(t)} + O(R^{-3}) \). It follows that the \( \varepsilon^{-2}\zeta(t) \)-Hermitian metric \( h_{A,t} \) deduced from \( g_{A,t} \) satisfies the estimate \( h_{A,t} = g_{\varepsilon^{-2}\zeta(t)} + O(R^{-4}) \) and we have a similar estimate for the corresponding Kähler forms \( \omega_{A,t} \) and \( \omega_{\varepsilon^{-2}\zeta(t)}^{\text{mod}} \) defined using \( \varepsilon^{-2}\zeta(t) \). Hence \( d\omega_{A,t} = O(R^{-5}) \). Using the homothety again, we obtain the estimate \( d\omega_t = O(\varepsilon^4 r^{-5}) \) (there is an factor \( \varepsilon \) coming from the fact that we are taking the norm of a 3-form for the rescaled metric) on the annulus \( b \leq r \leq 2b \). As in the previous case, we deduce an estimate \( \|d\omega_t\|_{C^{0,\alpha}} = O(\varepsilon^{4-\beta(5+\delta)}) \) on the annulus \( b \leq r \leq 2b \) as well.

From now on, we shall fix the gluing scale \( b = \varepsilon^\beta \), with the convention

\[
\beta = \frac{2}{2-\delta}
\]

(3.4)
as in the above lemma. The point is that for \( \delta \in (-2,0) \), we have \( \beta \in (\frac{1}{7},1) \), \( \lim_{\delta \to -2} \beta = \frac{1}{7} \).

Then we deduce that the Kähler form \( \omega_t \) is almost harmonic in the sense of the following corollary:

**Corollary 16.** For \( \delta < 0 \) sufficiently close to \(-2\) there exists a constant \( C > 0 \) such that for all \( t > 0 \)

\[
\|\Box_t \omega_t\|_{C_{\delta+2}^{0,\alpha}}(t) \leq C \varepsilon^2,
\]

and

\[
\|\Delta_t \omega_t\|_{C_{\delta+2}^{0,\alpha}}(t) \leq C \varepsilon^2.
\]

**Proof.** Using Lemma 15, together with the fact that \( \star \omega_t = \omega_t \) we deduce an estimate

\[
\|d^* \omega_t\|_{C_{\delta+1}^{1,\alpha}}(t) \leq C_1 \varepsilon^2.
\]

Therefore we have an estimate on \( dd^* \omega_t \) and \( d^* d\omega_t \) in \( C_{\delta-2}^{0,\alpha}(t) \)-norm and the result follows for \( \Delta_t \omega_t \).

The same proof works with the Dolbeault Laplacian. We merely use the fact that the norm of \( \star \partial_t \omega_t \) is controlled by the norm of \( d\omega_t \). The pointwise norm of this tensor is controlled by the pointwise norm of \( \nabla_t^{\text{Chern}} \star \partial_t \omega_t \). The metric being Hermitian, we only have \( \nabla_t^{\text{Chern}} = \nabla_t^{\text{LC}} + T \) where \( T \) is a tensor such that \( T = O(\nabla_t^{\text{LC}} J_1) \). Using again 15, we conclude that

\[
|\nabla_t^{\text{Chern}} \star \partial_t \omega_t | \rho^{\delta-2} \leq |\nabla_t^{\text{LC}} \star \partial_t \omega_t | \rho^{\delta-2} + (|T| \rho)(| \star \partial_t \omega_t | \rho^{1-\delta}).
\]

The estimate follows and we have the control on \( \Box_t \omega_t \) with the \( C_{\delta-2}^{0,\alpha} \)-norm. \( \square \)
The Laplacian and gravitons. The space $\hat{C^2}/\Gamma$ is endowed with a complex structure $\mathcal{I} = \epsilon^{-2}\zeta(t)$ and Kähler metric $g_{\epsilon^{-2}\zeta(t)}$. The parameter $t = 0$ corresponds to the tangent graviton. Each of these spaces has a corresponding Laplacian $\Box^A_t = \frac{1}{2}\Delta^A_t$. If $\delta$ is not an indicial root, the operator $\Box^A_t : C^{2,\alpha}_\delta \rightarrow C^{2,\alpha}_{\delta-2}$ defined on $(p,q)$-forms with respect to $g_{\epsilon^{-2}\zeta(t)}$ is Fredholm.

Indicial roots are well understood for such operators

Lemma 17. Every $\delta \in (-2,0)$ is not an indicial root. In the case of 1-forms every $\delta \in (-3,1)$ is not an indicial root.

Proof. For the first part, see [8]. For the second part, one has to check that 0 is not an indicial root. This boils down to check that there are no $\Gamma$-invariant parallel 1-forms on $\hat{C^2}$. By duality, it follows that $-2$ is not an indicial root either. □

Harmonic forms on ALE spaces. The space of harmonic forms of type $(p,q)$ on the ALE space, denoted $\mathcal{H}^{p,q}_{A,t}$, is defined as the kernel of $\Box^A_t C^{2,\alpha}_\delta \rightarrow C^{2,\alpha}_{\delta-2}$, for $\delta \in (-2,0)$. Since there are no indicial root in the interval, it follows that the definition for $\mathcal{H}^{p,q}_{A,t}$ is independent of the choice of $\delta \in (-2,0)$. For 1-forms we could also choose $\delta \in (-3,1)$ as there are no indicial roots in this interval by Lemma 17.

If we choose $\delta$ sufficiently close to $-2$, we see that harmonic forms are in $L^2$. In fact, the decay is even better according to the following lemma

Lemma 18. Any harmonic form $\gamma \in \mathcal{H}^{p,q}_{A,t}$ satisfies $\gamma = \mathcal{O}(R^{-3})$.

Proof. It suffices to understand the case of a harmonic function $\gamma \in C^{2,\alpha}_\delta$. The standard theory for Laplacian on ALE spaces shows that $\gamma = cR^{-2} + \mathcal{O}(R^{-3})$ since there are no indicial roots in $(-3,-2)$. The coefficient $c$ is a constant multiple of $\int \Box^A_t \text{vol} = 0$ (cf. [5, Theorem 8.3.6]) and the lemma follows. □

We recall some standard results for Hodge theory on ALE spaces (cf. [5] for instance): The canonical map $\mathcal{H}^{p,q}_{A,t} \rightarrow H^{p+q}(\hat{C^2}/\Gamma, \mathbb{C})$ is injective with image denoted $H^{p,q}_t$. In addition

$$H^k(\hat{C^2}/\Gamma, \mathbb{C}) = \bigoplus_{j=0}^k H^{j,j-k}_t$$

for all $0 < k < 4$. In particular we see that $\mathcal{H}^{1,0}_{A,t} = \mathcal{H}^{0,1}_{A,t} = 0$.

We also have the following result

Lemma 19.

$$\mathcal{H}^{2,0}_{A,t} = \mathcal{H}^{0,2}_{A,t} = 0$$

and

$$\mathcal{H}^{1,1}_{A,t} \simeq H^2(\hat{C^2}/\Gamma, \mathbb{C})$$

for all $t$ sufficiently small.
For every \( \xi \)' we construct a form \( \gamma \) with its Laplacian. Alternatively, we can look at the manifold \( X \), the smooth locus of \( X \) and the Laplacian defined between weighted Hölder spaces.

Laplacian and orbifold. One can consider the Kähler orbifold \((X, J_0, g)\) together with its Laplacian. Alternatively, we can look at the manifold \( X \), the smooth locus of \( X \) and the Laplacian defined between weighted Hölder spaces

\[
\Box^B : C^2,\alpha_\delta \to C^2,\alpha_{\delta-2}
\]

acting on \((p, q)\)-forms with respect to \( J_0 \).

Like on the ALE space, this operator is Fredholm for \( \delta \in (-2, 0) \), and for \( \delta \in (-3, 1) \) in the case of 1-forms. Moreover, its kernel \( H^0_B \) corresponds to smooth harmonic forms on \( X \).

3.5. Approximate kernel. One can construct an approximate kernel of the operator \( \Box_\delta \) on \((\tilde{X}, J_0, h_t)\) as follows. The spaces \( H_{A,t}^{1,1} \) are the fibers of a smooth (trivial) vector bundle over the base \( t \in [0, d) \). Given \( \gamma_{A,t} \in H_{A,t}^{1,1} \) and \( \gamma_B \in H_B^{0,q} \), we construct a form \( \gamma'_t \) on \( \tilde{X} \) by requiring that \( \gamma'_t = H^*_{\varepsilon-1} \gamma_{A,t} \) on the domain \( \rho \leq b \), \( \gamma'_t = \gamma_B \) on the domain \( \rho \geq 4b \) and

\[
\gamma'_t = (1 - \chi(2b, b)(r)) H^*_{\varepsilon-1} \gamma_{A,t} + \chi(2b, 4b)(r) \gamma_B
\]

Then we call \( \gamma_t \) the projection of \( \gamma'_t \) onto forms of type \((1, 1)\) for the complex structure \( J_t \). Thus we have constructed a linear map

\[
\Phi_t : H_{A,t}^{1,1} \oplus H_B^{0,q} \to \Omega_{J_t}^{1,1}(\tilde{X})
\]

(3.5)

For every \( t > 0 \) small enough, the linear map (3.5) is injective and its image will be denoted \( \mathcal{K}_t^{1,1} \).

Alternatively, using the isomorphisms \( H^2(\mathbb{C}^2/\Gamma, \mathbb{C}) \simeq H_{A,t}^{1,1} \) and \( H^1(X) \simeq H_B^{1,1} \), the map \( \Phi_t \) can be thought of as an isomorphism

\[
\Psi_t : H^2(\mathbb{C}^2/\Gamma, \mathbb{C}) \oplus H^1(X) \to \mathcal{K}_t^{1,1}.
\]

In the case of 1-forms, we have \( H_{A,t}^{1,0} = 0 \) and \( H_B^{0,1} = 0 \). A similar construction gives linear maps

\[
\Phi_t : H_B^{0,1} \to \Omega_{J_t}^{1,0}(\tilde{X}), \quad \Phi_t : H_B^{1,0} \to \Omega_{J_t}^{1,0}(\tilde{X})
\]

These maps are injective for \( t \) small enough and their images are denoted \( \mathcal{K}_t^{0,1} \) and \( \mathcal{K}_t^{1,0} \). Then, we define isomorphisms \( \Psi_t : H^{0,1}(X) \to \mathcal{K}_t^{0,1} \), \( \Psi_t : H^{1,0}(X) \to \mathcal{K}_t^{1,0} \).

Let \( \| \cdot \|_A \) be an arbitrary norm on the cohomology \( H^*(\mathbb{C}^2/\Gamma, \mathbb{C}) \) and \( \| \cdot \|_B \) an arbitrary norm on the cohomology \( H^*(\tilde{X}, \mathbb{C}) \). We introduce a family of norms \( \| \cdot \|_{\delta,t} \) on \( H^2(\mathbb{C}^2/\Gamma, \mathbb{C}) \oplus H^2(\tilde{X}, \mathbb{C}) \simeq H^2(\tilde{X}, \mathbb{C}) \) given by

\[
\| \Omega_A \oplus \Omega_B \|_{\delta,t} = \varepsilon^{-2-\delta} \| \Omega_A \| + \| \Omega_B \|
\]
Lemma 20. Given $k \geq 0$, there are constants $c_1, c_2 > 0$ such that for every $\delta \in (-2, 0)$ sufficiently close to $-2$ and every $t > 0$ sufficiently small, we have for all $\Omega \in H^2(\hat{C}^2/\Gamma, \mathbb{C}) \oplus H^{1,1}(X)$

$$c_1 \|\Omega\|_{\delta,t} \leq \|\Psi_t(\Omega)\|_{C^{k,\alpha}_\delta(\hat{X},\hat{t})} \leq c_2 \|\Omega\|_{\delta,t}.$$ 

For cohomology classes $\Xi \in H^{0,1}(X)$, we have a similar result with the estimate

$$c_1 \|\Xi\|_B \leq \|\Psi_t(\Xi)\|_{C^{k,\alpha}_\delta(\hat{X},\hat{t})} \leq c_2 \|\Xi\|_B.$$ 

**Proof.** The injection $\mathcal{H}_B^{1,1} \to \mathcal{K}_t^{1,1}$ induced by $\Phi_t$ allows to pull-back the $C^{k,\alpha}_\delta(\hat{X},\hat{t})$ norm. It is readily checked that this norm is uniformly commensurate with the $C^{k,\alpha}_\delta(\hat{X})$-norm.

Similarly, the injection $\mathcal{H}_t^{1,1} \to \mathcal{K}_t^{1,1}$ induced by $\Phi_t$ allows to pull-back the $C^{k,\alpha}_\delta(\hat{C}^2/\Gamma, t)$ norm. This norm is uniformly commensurate with the $C^{k,\alpha}_\delta(X)$-norm up to a factor $\varepsilon^{-2^{-2}}$ by (3.3).

The proof of the second part of the statement goes along the same lines, except that we do not have to deal with harmonic forms on the ALE space.

**Uniform elliptic estimates.** A key step in order to construct Kähler forms is Hodge theory. More precisely, we should control the first eigenvalues of the Dolbeault Laplacian between weighted Hölder spaces:

**Proposition 21.** There exists a constant $c > 0$ such that for all $t > 0$ sufficiently small and every $(1,1)$-form $\gamma$ on $(\hat{X}, J_1)$, we have

$$c \|\gamma\|_{C^{2,\alpha}_\delta(t)} \leq \|\gamma\|_{C^{0,\alpha}_\delta(t)} + \|\Box t \gamma\|_{C^{0,\alpha}_{\delta-2}(t)}.$$ 

If in addition $\gamma$ is $L^2$-orthogonal to the space $\mathcal{K}_t^{1,1}$ and $\delta \in (-2, 0)$ sufficiently close to $-2$, we have

$$c \|\gamma\|_{C^{2,\alpha}_\delta(t)} \leq \|\Box t \gamma\|_{C^{0,\alpha}_{\delta-2}(t)}.$$ 

Similarly, if $\gamma$ is a $(0,1)$-form orthogonal to $\mathcal{K}_t^{0,1}$, we have an estimate

$$c \|\gamma\|_{C^{2,\alpha}_{\delta+1}(t)} \leq \|\Box t \gamma\|_{C^{0,\alpha}_{\delta-1}(t)}.$$ 

**Proof.** The first part of the proposition is standard. For the second part, let us argue by contradiction. If the proposition is not true, there are weights $\delta \in (-2, 0)$ arbitrarily close to $-2$ with and families of parameter $t_j \to 0$ and $(1,1)$-forms $\gamma_j$ on $(\hat{X}, J_1)$ such that

$$\|\gamma_j\|_{C^{0,\alpha}_{\delta}(t_j)} = 1, \text{ and } \|\Box t_j \gamma_j\|_{C^{0,\alpha}_{\delta-2}(t_j)} \to 0.$$ 

The first part of the proposition provides a uniform $C^{2,\alpha}$ estimate on $\gamma_j$.

Then, up to extraction of a subsequence, we may assume that $\gamma_j$ converges in the $C^{0,0}$ sense on every compact set of $X$ toward a form $\gamma$ on $X$ which is $\overline{\partial}^*$-harmonic and in $C^{2,\alpha}_\delta(X, t_j)$. This implies that $\gamma$ extends as a smooth orbifold form on the orbifold $\hat{X}$. Since each $\gamma_j$ is orthogonal to $\mathcal{K}_t$ and $\delta > -3$, it follows that $\gamma$ is orthogonal to $\mathcal{H}_B^{1,1}$. This forces $\gamma = 0$.

Similarly, we can transport $\gamma_j$ on the domain $R \leq 4b_j/\varepsilon_j$ of $\hat{C}^2/\Gamma$ using the homothety $H_j = H_{b_j^{-1}}$. Put $\mu_j = \varepsilon^{-2-\delta}H_j^* \gamma_j$. By definition of the norm we obtain a uniform $C^{2,\alpha}$ bound on $\mu_j$. Up to extraction, we may assume that $\mu_j$ converge on
every compact set of $C^2/\Gamma$ to a harmonic form $\mu \in C^2_{\delta}$. Again, the fact that harmonic forms must have a strong decay forces $\mu \in C^2_{-3}$ by Lemma 18. Then, the fact that $\gamma_j$ is orthogonal to $K_{\mu}^{1,1}$ implies that $\mu$ is orthogonal to $K_{\mu}^{1,1}$. We conclude $\mu = 0$.

Let $m_j$ be a point where the function $|\rho_j^{-\delta} \gamma_j|$ is maximal equal to 1 (cf. assumption (3.6)). Up to extraction of a converging subsequence, we have either

1. $\rho_j(m_j) \leq 2b_j$
2. $\rho_j(m_j) \geq 2b_j$

for all $j$.

Case (ii): If $\rho_j(m_j)$ is bounded away from zero we clearly have a contradiction. Indeed, after further extraction, we may assume that $\rho_j$ converges to a point in $X$. But we know that $\gamma_j$ converges to 0 on every compact set of $X$ hence $|\rho_j^{-\delta} \gamma_j|(m_j) \to 0$ which is impossible.

So we may assume up to extraction that $\lim \rho_j(m_j) = 0$. Using homotheties and rescaling for $\gamma_j$ again, we can extract a converging subsequence on every compact set of the cone $C^2(0)/\Gamma$ such that the limit is nonvanishing, harmonic and in $C^2_{\delta}$ on the cone. This is not possible for $\delta$ is not an indicial root of the Laplacian.

Case (i): If $\rho_j(m_j)/\epsilon_j$ is bounded, we have a contradiction. The proof is the same as in the first case, using the rescaled forms $\mu_j$ instead.

If it is not bounded, we may assume that it goes to infinity after extraction. Then we use rescaling to extract a harmonic limit on the cone, exactly as in the first case.

□

From approximate kernel to harmonic forms. The spaces $K_\mu$ consist of forms which are approximately harmonic in the sense of the following lemma.

**Lemma 22.** Fix $-2 < \delta < 0$ sufficiently close to $-2$. There is a constant $c > 0$ such that for all $\Omega_A \in H^2(C^2,\mu)$, $\Omega_B \in H^{1,1}(X)$ and $\Omega = \Omega_A \oplus \Omega_B$, we have

$$c \|\Box_t \Psi_t(\Omega_A)\|_{C^0_{\delta-2}} \leq \epsilon^{2-\beta(\delta+4)} \|\Omega_A\|_A$$

and

$$c \|\Box_t \Psi_t(\Omega_B)\|_{C^0_{\delta-2}} \leq \epsilon^{-\delta} \|\Omega_B\|_B$$

In particular

$$c \|\Box_t \Psi_t(\Omega)\|_{C^0_{\delta-2}} \leq \epsilon^{\beta_1} \|\Omega\|_{\delta,l}$$

where $\beta_1 = \min(-\beta, 4 + \delta - \beta(\delta + 4))$ is very close to 1, by definition.

Similarly, if $\Xi \in H^{0,1}(X)$, we have

$$c \|\Box_t \Psi_t(\Xi)\|_{C^0_{\delta-1}} \leq \epsilon^{-\beta(\delta+1)} \|\Xi\|_B.$$

**Proof.** The proof is similar to the one for Lemma 15 and Corollary 16. Let $\gamma_{t,A} \in H_{A}^{1,1}$ be a family of harmonic $(1,1)$-forms on the family of ALE representing $\Omega_A$. Then, we have uniform estimates $\gamma_{t,A} = O(R^{-4})$ on the annulus $b/\epsilon \leq R \leq 4b/\epsilon$. Using the rescaled metric, we deduce an estimate $\|\Psi_t(\Omega_A)\| = O(\epsilon^{2-\delta})$ on the annulus $b \leq r \leq 4b$. Hence $\Box_t \Psi_t(\Omega_A) = O(\epsilon^{2-\delta})$ so $\Box_t \Box_t \Psi_t(\Omega_A) = O(\epsilon^{2-\delta})$, that is to say $\Box_t \Box_t \Psi_t(\Omega_A) = O(\epsilon^{2-\delta})$ on the annulus. The first part of the lemma follows.
For the second part of the statement, we start with the uniform estimate \( \Psi_t(\Omega_B) = \mathcal{O}(1) \) on the annulus \( b \leq r \leq 4b \). It follows that \( |r^{2-\delta} \Box t \Psi_t \Omega_B| = \mathcal{O}(e^{-\beta \delta}) \) on the annulus.

On the annulus \( 4b \leq r \leq 1 \) we have the estimate \( |J_0 - J_t| = \mathcal{O}(r^{-4}) = \mathcal{O}(e^{-4r^{-4}}) \). It follows that \( |\Box t \Psi_t(\Omega_B)| = \mathcal{O}(e^{4r^{-6}}) \) on this annulus. Thus \( |r^{2-\delta} \Box t \Psi_t(\Omega_B)| = \mathcal{O}(e^{-4-\beta(4+\delta)}) \) on the annulus \( 4b \leq r \leq 1 \). We see that \( 4 - \beta(4 + \delta) \) goes to 3 as \( \beta \) is close to \(-2 \) and \( \delta \) close to 1/2.

On the compact part, we have an estimate \( J_0 - J_t = \mathcal{O}(\varepsilon^2) \). So the estimate \( |\Box t \Psi_t(\Omega_B)| = \mathcal{O}(\varepsilon^2) \) on the compact domain follows.

The second part of the lemma follows. The third inequality is obvious.

For the last statement, we just notice that the same estimates hold in the case of 1-forms. We merely have to replace \( \delta \) by \( \delta + 1 \). So we have the estimate \( \mathcal{O}(\varepsilon^{-\beta(\delta+1)}) \) on the annulus \( b \leq r \leq 4b \), the estimate \( \mathcal{O}(\varepsilon^{4-\beta(5+\delta)}) \) on the annulus \( 4b \leq r \leq 1 \) and \( \mathcal{O}(\varepsilon^2) \) on the compact domain.

Let \( P_t: \mathcal{H}^{1,1}(\hat{X}, J_t) \to K_t^{1,1} \) be the \( L^2 \)-orthogonal projection (deduced from \( h_t \)) on the space \( K_t^{1,1} \). Similarly, we denote \( P_t: \mathcal{H}^{0,1}(\hat{X}, J_t) \to K_t^{0,1} \). This projection is very close to the identity in the sense of the following corollary.

**Corollary 23.** Suppose \(-2 < \delta < 0 \) with \( \delta \) sufficiently close to \(-2 \). There exists a constant \( c > 0 \) such that for all \( \gamma_t \in \mathcal{H}^{1,1}(\hat{X}, J_t) \)
\[
\|\gamma_t - P_t(\gamma_t)\|_{C^2,\alpha} \leq c e^{\beta \delta} \|P_t(\gamma_t)\|_{C^2,\alpha}.
\]

Similarly, if \( \gamma_t \) denote a family \( \gamma_t \in \mathcal{H}^{0,1}(\hat{X}, J_t) \) we have
\[
\|\gamma_t - P_t(\gamma_t)\|_{C^2,\alpha} \leq c e^{-\beta(\delta+1)} \|P_t(\gamma_t)\|_{C^2,\alpha}.
\]

**Proof.** We write \( P_t(\gamma_t) = \Psi_t(\Omega_t) \) and consider the form \( \eta_t = P_t(\gamma_t) - \gamma_t \). By definition \( \eta_t \) is orthogonal to \( K_t \) and \( \Box t \eta_t = \Box t P_t(\gamma_t) = \Box t \Psi_t(\Omega_t) \). Lemma 22 applied to \( \Psi_t(\Omega_t) \) followed by Lemma 20 and Proposition 21 give the result. \( \square \)

In conclusion, \( P_t \) is an isomorphism and the operator norm \( \|P_t - \text{id}\|_{C^2,\alpha} \) is \( \mathcal{O}(\varepsilon^\beta) \) (and \( \mathcal{O}(\varepsilon^{-\beta(\delta+1)}) \) in the case of 1-forms) and the proposition below follows.

**Proposition 24.** For all \( k \geq 0 \) there exists a constant \( c > 0 \) such that for all \( \delta \in (-2, 0) \) sufficiently close to \(-2 \), \( t > 0 \) and every \((1,1)\)-form \( \beta \) orthogonal to harmonic forms on \((\hat{X}, J_t, h_t)\), and we have
\[
c\|\beta\|_{C^{2+k,\alpha}_t(t)} \leq \|\Box t \beta\|_{C^{k-2,\alpha}_t(t)}.
\]

In the case of \((0,1)\)-forms orthogonal to harmonic forms, we have a similar estimate with
\[
c\|\beta\|_{C^{2+k,\alpha}_{t+1}(t)} \leq \|\Box t \beta\|_{C^{k,\alpha}_{t-1}(t)}.
\]

### 3.6. Background Kähler structure.

Recall that \((J_t, h_t)\) is a Hermitian structure on \( \hat{X} \). However \( h_t \) is not a priori Kähler. We shall look for a nearby Hermitian metric which is Kähler.

For \( t > 0 \), the Kähler form \( \omega_t \) of \( h_t \) admits a decomposition of the form
\[
\omega_t = \omega^H_t + \omega^\perp_t
\]
where \( \omega^H_t \) is a \( \Box_t \)-harmonic \((1,1)\)-form on \((\hat{X}, J_t)\) and \( \omega^\perp_t \) is \( L^2 \)-orthogonal to \( \Box_t \)-harmonic forms.
From this point, one can prove that the following proposition

**Proposition 25.** Assuming that \( \delta \in (-2,0) \) and sufficiently close to \(-2\), we have \( \| \varpi_t - \varpi^H_t \|_{C^2,\alpha(\hat{X},t)} = O(\varepsilon^2) \).

**Proof.** By definition, \( \varpi_t - \varpi^H_t = \varpi^\perp_t \) and \( \Box_t \varpi^\perp_t = \Box_t \varpi_t \). by Proposition 24, we have
\[
\| \varpi_t - \varpi^H_t \|_{C^2,\alpha(\hat{X},t)} = O(\| \Box_t \varpi_t \|_{C^{0,\alpha}(\hat{X},t)}).
\]

The proposition follows from Corollary 16.

By definition \( \partial_t \varpi^H_t = 0 \) but it is not a priori \( d \)-closed. We remedy to this problem with the following lemma

**Lemma 26.** There exists a (1,1)-form \( \gamma_t \) on \((\hat{X}, J_t)\) in the cohomology class of \( \varpi^H_t \) such that \( d \gamma_t = 0 \) and \( \| \gamma_t - \varpi^H_t \|_{C^2,\alpha(\hat{X},t)} = O(\varepsilon^2) \).

**Proof.** Since \((\hat{X}, J_t)\) is Kähler, the Fröhlicher exact sequence degenerates at the first page. In particular \( \partial_t \varpi^H_t = \partial_t \alpha_t \), for \( \alpha_t \) a \((2,0)\)-form w.r.t \( J_t \). Here we may choose a form such that \( \partial_\hat{t} \alpha_t = 0 \) and \( \alpha_t \) is orthogonal to \( \Box_t \)-harmonic forms.

So \( \partial_\hat{t} \alpha_t = 0 \) because we are working in complex dimension 2. So \( \alpha_t \) defines a class in \( H^{0,2}(\hat{X}, J_t) \) and we can write \( \alpha_t = \mu_t + \partial_\hat{t} \beta_t \), where \( \mu_t \) is a holomorphic \((2,0)\)-form, \( \beta_t \) is a \((0,1)\)-form orthogonal to harmonic forms which satisfies \( \partial_\hat{t} \beta_t = 0 \). Put \( \gamma_t = \varpi^H_t + \partial_\hat{t} \beta_t \). Then \( \partial_t \gamma_t = \partial_t \varpi^H_t = 0 \) and \( \partial_\hat{t} \gamma_t = \partial_t \varpi^H_t + \partial_\hat{t} \partial_\hat{t} \beta_t = 0 \).

The next step is to estimate \( \beta_t \). Using the identities \( \partial_\hat{t} \partial_\hat{t} \varpi^H_t = \partial_\hat{t}^* \partial_\hat{t} \alpha_t \) and \( \partial_\hat{t}^* \alpha_t = 0 \) we obtain \( \partial_\hat{t}^* \partial_\hat{t} \varpi^H_t = \Box_t \alpha_t \).

Now
\[
\| \partial_\hat{t}^* \partial_\hat{t} (\varpi^H_t - \varpi_t) \|_{C^{0,\alpha}} = O(\varepsilon^2)
\]
according to Proposition 25. Therefore
\[
\| \partial_\hat{t}^* \partial_\hat{t} \varpi^H_t \|_{C^{0,\alpha}} \leq \| \partial_\hat{t}^* \partial_\hat{t} \varpi^H_t \|_{C^{0,\alpha}} + O(\varepsilon^2).
\]
Using Lemma 15 we obtain the estimate \( \| \partial_\hat{t}^* \partial_\hat{t} \varpi^H_t \|_{C^{0,\alpha}} = O(\varepsilon^2) \) and we deduce
\[
\| \Box_t \alpha_t \|_{C^{0,\alpha}} = O(\varepsilon^2).
\]

Proposition 24 provides the estimate
\[
\| \alpha_t \|_{C^{2,\alpha}} = O(\varepsilon^2). \tag{3.7}
\]

Eventually, we would like to estimate the \((0,1)\)-forms \( \beta_t \). We have \( \partial_\hat{t}^* \alpha_t = \partial_\hat{t}^* \partial_\hat{t} \beta_t = \Box_t \beta_t \) using the fact that \( \hat{\mu} \) is harmonic and \( \partial_\hat{t}^* \beta_t = 0 \).

The estimate \( \tag{3.7} \) provides an estimate \( \| \partial_\hat{t}^* \alpha_t \|_{C^{1,\alpha}} = O(\varepsilon^2) \) and it follows that
\[
\| \Box_t \beta_t \|_{C^{1,\alpha}} = O(\varepsilon^2).
\]
Using the fact that \( \beta_t \) is orthogonal to harmonic forms and Proposition 24, we get the estimate
\[
\| \beta_t \|_{C^{1,\alpha}} = O(\varepsilon^2).
\]

In particular this implies
\[
\| \partial_\hat{t} \beta_t \|_{C^{2,\alpha}} = O(\varepsilon^2)
\]
which proves the lemma. \( \square \)
Thus we define the real closed form $\omega'_t$ of type $(1, 1)$ on $(\hat{X}, J_t)$ by taking
\[ \omega'_t = \text{Re}(\gamma_t) \]
were $\gamma'_t$ is given by Lemma 26.

**Corollary 27.** Fix $-2 < \delta < 0$ sufficiently close to $-2$. Define $\omega'_t$ to be the real part of $\gamma_t$. Then for all $t > 0$ sufficiently small, $\omega'_t$ defines a Kähler metric $g'_t$ on $(\hat{X}, J_t)$ such that $\|\varpi_t - \omega'_t\|_{C^{2,\alpha}(t)} = O(\varepsilon^2)$.

**Proof.** By definition we have $\|\varpi_t - \omega'_t\|_{C^{2,\alpha}(t)} = O(\varepsilon^2)$. So we only need to check that the estimate is good enough to ensure that the real $(1, 1)$-form $\omega'_t$ defines a metric.

On the domain $\rho \leq 4b$ of $\hat{U}$, using the homothety $H_{\varepsilon^{-1}}$, we find an estimate
\[ \|\omega_{\varepsilon^{-2}g(t)} - \varepsilon^{-2}(H_{\varepsilon^{-1}})_{\ast}\omega'_t\|_{C^{2,\alpha}(\rho, \leq 4\varepsilon^{-1/2})} = O(\varepsilon^{2+\delta}) \]

Since $2 + \delta > 0$ the form $\omega'_t$ is definite positive for $t$ sufficiently small. A similar estimate on the domains $4\varepsilon^{-2} \leq \rho \leq 1$ and $\hat{X} \setminus \hat{U}$ proves the lemma. \qed

Although they need not agree, the Kähler class $[\omega'_t]$ is very close to $\Omega_t$ according to the following result:

**Lemma 28.** The cohomology class $[\omega'_t] \in H^2(\hat{X}, \mathbb{R})$ satisfies
\[ \|\Omega_t - [\omega'_t]\|_{\delta,t} = O(\varepsilon^2). \]

**Proof.** We have the decompositions $\Omega_t = \Omega_{t,A} + \Omega_{t,B}$ and $[\omega'_t] = [\omega'_{t,A}] + [\omega'_{t,B}]$ together with the estimate $\|\omega'_t - \varpi_t\|_{C^{2,\alpha}(t)} = O(\varepsilon^2)$. On the ALE part, the form $\varpi_t$ is closed and represents $\Omega_{t,A}$. From $[\omega'_t - \varpi_t] = O(\varepsilon^{2+\delta})$ and the fact that the spheres representing the homology classes have $\varpi_t$-volume $O(\varepsilon^2)$, we deduce that
\[ \|\omega'_{t,A} - \Omega_{t,A}\| = O(\varepsilon^{4+\delta}). \]

On the compact part, we have $[\omega'_{t,B} - \varpi_t] = O(\varepsilon^2)$ and by assumption $[\Omega_{t,B} - \Omega_0] = O(\varepsilon^2)$. Therefore
\[ [\omega'_{t,B} - \Omega_{t,B}] = O(\varepsilon^2). \]

These two estimates together prove the lemma. \qed

**3.7. Harmonic forms and Kähler form.** We shall now use the family of Kähler metrics $g'_t$ with Kähler form $\omega'_t$ on $(\hat{X}, J_t)$ provided by Corollary 27 as our favorite background metric for some $\delta \in (-2, 0)$ sufficiently close to $-2$. Its Laplacians will be denoted as well $\Box_t$ and $\Delta_t = 2\Box_t$.

The Mayer–Vietoris isomorphism $H^2(\hat{X}) \to H^2(\hat{X}) \oplus H^2(\mathbb{C}^2/\Gamma)$, gives a corresponding decomposition $\Xi_A \oplus \Xi_B$ for each cohomology class $\Xi \in H^2(\hat{X})$. The family of norms $\|\Xi_A \oplus \Xi_B\|_{\delta,t}$ defined at §3.3 provides a norm on $H^2(\hat{X})$ denoted $\|\Xi\|_{\delta,t}$ as well.

Then we have the following result

**Proposition 29.** There are constants $c_1, c_2 > 0$ such that for every family $\gamma_t$ of $g'_t$-harmonic 2-forms on $\hat{X}$ with cohomology class $\Xi_t$, we have
\[ c_1\|\gamma_t\|_{C^{2,\alpha}(t)} \geq \|\Xi_t\|_{t,\delta} \geq c_2\|\gamma_t\|_{C^{2,\alpha}(t)}. \]
Proof. The proof is done by contradiction. If the second inequality does not hold, there exists a family \( t_j \to 0 \) and \( g'_t \)-harmonic 2-forms \( \gamma_{t_j} \) such that \( \|\Xi_{t_j}\|_{\delta,t_j} \to 0 \) and \( \|\gamma_{t_j}\|_{C^{2,\alpha}_\delta(t_j)} = 1 \).

Elliptic regularity gives a uniformly \( C^{2,\alpha}_\delta \) estimate on \( \gamma_{t_j} \) by Proposition 21. Arguing exactly as in the proof of the second part of Proposition 21 by extracting converging subsequences, we show that either

1. \( \Xi_{B,t_j} \) converges to a non-vanishing cohomology class in \( H^2(\hat{X},\mathbb{R}) \)
2. or \( \varepsilon_j^{-2-\delta}\Xi_{A,t_j} \) converges to a non-vanishing cohomology class in \( H^2(\hat{X},\mathbb{R}) \).

This contradicts the fact that \( \lim \|\Xi_{t_j}\|_{\delta,t_j} = 0 \).

For the first part of the inequality, a similar proof gives the result. \( \square \)

We do not control exactly the Kähler class \([\omega'_t]\) of the Kähler metric \( g'_t \) that was just constructed. We will construct a nearby Kähler metric \( g_t \) with the Kähler class \( \Omega_t \) by perturbing \( g'_t \).

**Proposition 30.** For every \( t > 0 \) sufficiently small, the \( g'_t \)-harmonic representative \( \omega_t \) of the Kähler class \( \Omega_t \) defines a Kähler metric \( g_t \), satisfying the estimate

\[
\|\omega_t - \omega'_t\|_{C^{2,\alpha}_\delta(t)} = O(\varepsilon^2).
\]

**Proof.** According to Lemma 28

\[
\|\Omega_t - [\omega_t]\|_{\delta,t} = O(\varepsilon^2).
\] (3.8)

Then by Proposition 29 one has \( \|\omega'_t - \omega_t\|_{C^{2,\alpha}_\delta(t)} = O(\varepsilon^2) \). The worst value of the weight is \( \varepsilon^{-\delta} \), so it implies \( \varepsilon^{-\delta}|\omega'_t - \omega_t| = O(\varepsilon^2) \), that is

\[
|\omega'_t - \omega_t| = O(\varepsilon^{2+\delta}).
\]

Since \(-2 < \delta < 0\), this goes to zero and \( \omega'_t \) is a Kähler form for \( t \) small enough. The proposition follows. \( \square \)

We summarize the results of the current section in the following theorem

**Theorem 31.** Let \( X \hookrightarrow \mathcal{M} \to \Delta \) be a family of deformations of a compact complex surfaces with canonical singularities. Let \( \overline{\omega} \) be an orbifold Kähler metric on \( X \) with Kähler class \( \Omega_0 \) and \( \Omega \) a family of Kähler classes supported by a simultaneous resolution \( \hat{X} \to \hat{\mathcal{M}} \to \Delta_d \) degenerating toward \( \Omega_0 \), such that the variation of Kähler class and complex structure non degenerate.

Let \( \phi : \Delta_d \times \hat{X} \to \hat{\mathcal{M}} \) be a smooth trivialization of the family and \( h_t \) the family of Hermitian metrics on \((\hat{X}, J_t)\) with Kähler form \( \varpi_t \) constructed at §3.2 for all \( t \in \Delta_d \cap \mathbb{R}^+ \) sufficiently small.

Then, there exists a family of Kähler metrics \( g_t \) with Kähler form \( \omega_t \) on \((\hat{X}, J_t)\) defined for \( t \in \Delta_d \cap \mathbb{R}^+ \) for all \( t \) sufficiently small with the property that

- \([\omega_t] = \Omega_t\)
- for all \( \delta \in (-2,0) \) sufficiently close to \(-2\), we have \( \|\omega_t - \varpi_t\|_{C^{2,\alpha}_\delta} = O(\varepsilon^2) \).

**Proof of Proposition 11.** Since \( h_t \) converges smoothly toward \( \overline{\omega} \) on every compact set of \( X \), the proposition is an immediate corollary of Theorem 31. \( \square \)
4. CSCK metrics

Let $\mathcal{X} \hookrightarrow \mathcal{M} \to \Delta$ be a flat deformation and $\hat{\mathcal{X}} \hookrightarrow \hat{\mathcal{M}} \to \Delta_{d}$ a simultaneous resolution after passing to a ramified cover. Suppose that $\mathcal{X}$ is endowed with a CSCK orbifold metric $\overline{g}$ with Kähler class $\Omega_{0}$. Let $\Omega$ be a family of Kähler classes supported by the simultaneous resolution degenerating toward $\Omega_{0}$, with non degenerate variation at each singularity.

Let $g_{t}$ be the family of Kähler metrics on $\mathcal{M}_{t}$ with Kähler class $\Omega_{t}$ obtained in § 3. In this section, we show that $g_{t}$ can be perturbed into a CSCK metric. This kind of result is now well-known by the work of Arezzo-Pacard, see also Székelyhidi whose proof is closer to ours. Our setting is slightly different, because we vary the complex structure as well. Therefore we shall give quickly some steps of the proof, but omit most technical proofs since they are similar to that in the literature.

4.1. Scalar curvature estimates. We begin by the following estimate on the scalar curvature of the Kähler metric $g'_{t}$.

Proposition 32. Let $\kappa$ be the (constant) scalar curvature of the orbifold Kähler metric on $\overline{X}$. For all $\delta \in (-2, 0)$, the Kähler metric $g'_{t}$ with Kähler class $\Omega_{t}$ satisfies the estimate

$$\|\text{scal}(g'_{t}) - \kappa\|_{C^{0,\alpha}_{4,\delta-2}(t)} = \mathcal{O}(\varepsilon^{2}).$$

Proof. As an immediate consequence of Proposition 30 and Corollary 27, we have the estimate

$$\|\text{scal}(g'_{t}) - \text{scal}(h_{t})\|_{C^{0,\alpha}_{4,\delta-2}(t)} = \mathcal{O}(\varepsilon^{2}).$$

Then the proposition will be the consequence of the estimate

$$\|\text{scal}(h_{t}) - \kappa\|_{C^{0,\alpha}_{4,\delta-2}(t)} = \mathcal{O}(\varepsilon^{2}), \quad (4.1)$$

that we now prove.

By construction $\text{scal}(g_{B}) = \kappa$ on the domain $\rho_{B} \geq 4b$ and $\text{scal}(g_{B}) = \mathcal{O}(1)$ on the annulus $2b \leq r \leq 4b$. On the other hand $\text{scal}(g_{A,t}) = 0$ on the domain $R \leq b/\varepsilon$ and $\text{scal}(g_{A,t}) = \mathcal{O}(\varepsilon^{6}b^{-6})$ on the annulus $b/\varepsilon \leq R \leq 2b/\varepsilon$. Hence the metric $\tilde{h}_{t}$ obtained by gluing together $g_{A}$ and $g_{B}$ satisfies $|\text{scal}(\tilde{h}_{t})| = \mathcal{O}(\varepsilon^{4}b^{-6}) + \mathcal{O}(1)$ on the annulus $b \leq r \leq 2b$. Therefore $r^{2-\delta}|\text{scal}(\tilde{h}_{t})| = \mathcal{O}(\varepsilon^{4}b^{4-\delta}) + \mathcal{O}(b^{2-\delta}) = \mathcal{O}(\varepsilon^{4-\beta(2+\delta)}) + \mathcal{O}(\varepsilon^{\beta(2-\delta)})$ on the annulus. By definition $\beta\delta = 2$, hence

$$r^{2-\delta}|\text{scal}(\tilde{h}_{t}) - \kappa| = \mathcal{O}(\varepsilon^{4-\beta(2+\delta)}) + \mathcal{O}(\varepsilon^{2})$$

on the annulus $b \leq \rho \leq 4b$ which give an estimate

$$\|\text{scal}(\tilde{h}_{t}) - \kappa\|_{C^{0,\alpha}_{4,\delta-2}(t)} = \mathcal{O}(\varepsilon^{2})$$

on $\hat{X}$ for $\delta$ sufficiently close to $-2$.

The metric $h_{t}$ is obtained by projecting $\tilde{h}_{t}$ onto its $J_{t}$-invariant component. The estimate (4.1) follows from the estimates on $J_{t} - J_{0}$ with a proof along the same lines of Lemma 22. \qed
4.2. **Construction of the metrics.** It is convenient to work with the family of complex structure $J_t$ on a fixed smooth manifold $\hat{X}$ as in §3. Then, we consider

$$\omega_{t,\phi} = \omega_t + dd^c J_t \phi,$$

where $\phi$ is a function on $\hat{X}$. If $\phi$ is small enough, $\omega_{t,\phi}$ is also the Kähler form of a Kähler metric $g_{t,\phi}$ on $(\hat{X}, J_t)$ representing $\Omega_t$. More specifically, we have the following result:

**Lemma 33.** Let $C$ be a positive constant and $\delta \in (-2,0)$ sufficiently close to $-2$. Then, for every $t > 0$ sufficiently small and every function $\phi$ such that $\|\phi\|_{C^{4,\alpha}_{\delta+2}} \leq C \varepsilon^{-\beta(\delta+2)}$, the form $\omega_{t,\phi}$ is definite positive.

**Proof.** We deduce an estimate $\|\omega_t - \omega_{t,\phi}\|_{C^{4,\alpha}_{\delta}} = O(\varepsilon^{2-\beta(\delta+2)})$. The worst value of the weight is $\varepsilon^{-\delta}$ so we have an estimate $\varepsilon^{-\delta}|\omega_t - \omega_{t,\phi}| = O(\varepsilon^{2-\beta(\delta+2)})$, hence $|\omega_t - \omega_{t,\phi}| = O(\varepsilon^{(1-\beta)(\delta+2)})$. Since $(1 - \beta)(\delta + 2) > 0$, $\omega_{t,\phi}$ is definite positive for $t$ sufficiently small. □

We want to solve the equation

$$\text{scal}(g_{t,\phi}) = \text{cst} \quad (4.2)$$

where $\text{scal}(g_{t,\phi})$ is the scalar curvature of the metric $g_{t,\phi}$. The linearization of this equation at $\phi = 0$ is given by a fourth order elliptic operator $L_t$, the Lichnerowicz operator. The idea is to apply a suitable version of the implicit function theorem in order to solve (4.2).

**Proposition 34.** Suppose that $X$ does not carry any nontrivial holomorphic vector field. If $-2 < \delta < 0$, then for sufficiently small $t > 0$ the operator

$$P_t : \mathbb{R} \times C^{4,\alpha}_{\delta+2}(\hat{X}, t) \to C^{0,\alpha}_{\delta-2}(\hat{X}, t)$$

$$(v, \phi) \mapsto v + L_t \phi$$

admits a right inverse $Q_t$ with norm satisfying $\|Q_t\| \leq c \varepsilon^{-\beta(\delta+2)}$ for some constant $c$ independent of $t$.

From that and the initial control on the scalar curvature, it follows:

**Corollary 35.** Suppose that $X$ does not carry any nontrivial holomorphic vector field. For all $\delta \in (-2,0)$ sufficiently close to $-2$, there exists a constant $C > 0$ such that for all $t > 0$ sufficiently small, there is a unique solution $\phi_t$, up to a constant, to the equation $\text{scal}(g_{t,\phi}) = \text{cst}$ with the condition that $\|\phi_t\|_{C^{4,\alpha}_{\delta+2}} \leq C \varepsilon^{2-\beta(\delta+2)}$.

**Proof.** We solve the problem via the fixed point method. The equation we are interested in can be written $\text{scal}(g_{t,\phi}) + v = \kappa_0$, which can be written

$$P_t(v, \phi) + N(v, \phi) = \kappa - \text{scal}(h_t) \quad (4.3)$$

where $N$ is the non linear term of the equation.

We are looking for a solution of the form $(v, \phi) = Q_t(f)$ and the equation reads

$$f = \kappa - \text{scal}(h_t) - N_t \circ Q_t(f) =: T_t(f). \quad (4.4)$$

Applying the fixed point theorem, the Corollary is a consequence of the following claim.
Claim. There exists $C > 0$, such that for all $t > 0$ sufficiently small, the operator $T_t$ maps the ball $\|f\|_{C^{\delta}^{\alpha}_3} \leq C\varepsilon^2$ to itself and is $\frac{1}{2}$-contractant.

Let us now prove the claim. The map $N_t(v, \phi)$ depends only on $\phi$ so we can write it $N_t(\phi)$. Then there exists $c_2, C_2 > 0$ such that if

$$\|\phi\|_{C^{\delta}^{4,\alpha}_3}, \|\psi\|_{C^{\delta}^{4,\alpha}_3} \leq c_2,$$

then

$$\|N_t(\phi) - N_t(\psi)\|_{C^{\delta}^{4,\alpha}_3} \leq C_2(\|\phi\|_{C^{\delta}^{4,\alpha}_3} + \|\psi\|_{C^{\delta}^{4,\alpha}_3})\|\phi - \psi\|_{C^{\delta}^{4,\alpha}_3}$$

(4.5)

(cf. [12, Lemma 19] and notice that the condition $\delta < 0$ required there is not needed).

By Proposition 32,

$$\|\text{scal}(h_t) - \kappa\|_{C^{\delta}^{1,\alpha}_3} \leq \frac{1}{2}C\varepsilon^2$$

for some constant $C > 0$. Using Proposition 34, the bound $\|f\|_{C^{\delta}^{0,\alpha}_3} \leq C\varepsilon^2$ gives on $\phi = Q_tf$ a bound $\|\phi\|_{C^{\delta+2}_3} \leq C\varepsilon^{2-\beta(\delta+2)}$ and we deduce that

$$\|\phi\|_{C^{\delta+2}_3} \leq C\varepsilon^{2+\delta-\beta(\delta+2)} = C\varepsilon^{(\delta+2)(1-\beta)}.$$  

Since $\delta + 2 > 0$ and $1 - \beta > 0$, we conclude that $\|\phi\|_{C^{\delta+2}_3} = o(1)$. Using (4.5), we deduce that for $t > 0$ small enough, the map $T_t$ is $1/2$-contractant on the ball $\|f\|_{C^{\delta}^{0,\alpha}_3} \leq C\varepsilon^2$. The map $T_t$ preserves the ball since

$$\|T_t(f)\|_{C^{\delta+2}_3} \leq \|T_t(f) - T_t(0)\|_{C^{\delta}^{0,\alpha}_3} + \|T_t(0)\|_{C^{\delta}^{0,\alpha}_3} \leq \frac{1}{2}\|f\|_{C^{\delta}^{0,\alpha}_3} + \|\text{scal}(h_t) - \kappa\|_{C^{\delta}^{0,\alpha}_3} \leq C\varepsilon^2.$$  

\[\square\]

Proof of Proposition 34. This proposition is close to [12, Proposition 20], with the difference that the complex structure is deformed and the sign of the weight $\delta + 2$ is opposite to that of [12]. The change of complex structure just gives an additional error term in the estimates so is not a substantial change. The choice of opposite sign of the weight is more important, and we explain briefly how to deal with it.

In this kind of problem, one obtains a right inverse for $P_t$ by gluing a right inverse on the ALE space $Y_t$ with a right inverse on the orbifold part $\mathcal{X}$. The point is that we consider the weight $\delta + 2 > 0$. This immediately implies that on the ALE space $Y_t$, the operator

$$L : C^{\delta+2}_3 \rightarrow C^{\delta}_3$$

is surjective (by duality the cokernel is the kernel of $L$ in $C^{\delta+2}_3$, which is 0 because $-\delta - 2 < 0$).

Dually, the same operator $L : C^{\delta+2}_3 \rightarrow C^{\delta}_3$ on the orbifold has no kernel since $\delta + 2 > 0$ rules out the constants near the punctures, and $\mathcal{X}$ has no holomorphic vector field. But $L$ has a cokernel: since $L$ is selfadjoint, index theory in weighted
spaces gives that the index of $L$ is the opposite of the number of punctures $k$. Define a space $\hat{C}^{4,\alpha}_{\delta+2} = C^{4,\alpha}_{\delta+2} \oplus \mathbb{R}^k$ of functions of the form

$$u + \sum_{i=1}^k \lambda_i \chi_i, \quad u \in C^{4,\alpha}_{\delta+2}, (\lambda_i) \in \mathbb{R}^k,$$

where $\chi_i$ is a cutoff function which vanishes outside a small ball around the puncture $x_i$. For example, we can equip the space $\hat{C}^{4,\alpha}_{\delta+2}$ with the norm

$$\|f\|_{\hat{C}^{4,\alpha}_{\delta+2}} = \sum_{i=1}^k |f(x_i)| + \|df\|_{C^3_{\delta+1}}.$$

Then saying that $L$ has index $-k$ translates to the fact that $\tilde{L}: \mathbb{R}^k \oplus \hat{C}^{4,\alpha}_{\delta+2} \rightarrow C^{\alpha}_{\delta-2}$ has index 0. Since its kernel is now reduced to the constants, its cokernel is also reduced to the constants.

Now an inverse for this operator (orthogonally to the constants), combined with the inverses of the operators at the punctures, can be used to construct an approximate right inverse for $P_t$. One deduces that $P_t$ has a right inverse $Q_t$. The only tricky point is to estimate the norm $\|Q_t\|$, because of the constants at the punctures which appear in the space $\hat{C}^{4,\alpha}_{\delta+2}$. These constants are bounded in the space $\hat{C}^{4,\alpha}_{\delta+2}$, but on the glued manifold, they blow up in the $C^{4,\alpha}_{\delta+2}$ norm. Since they are cut around the radius $r = \varepsilon^{-\beta}$, they contribute at most by a factor $(\varepsilon^{-\beta})^{-2-\delta} = \varepsilon^{2\delta-2}$ which explains the norm estimate given for $Q_t$ in the statement of the proposition.

5. Hamiltonian stationary spheres

We now construct the Hamiltonian stationary spheres and prove Theorem D in the case of canonical singularities. The spheres are obtained as deformations of a Lagrangian sphere in the tangent graviton, which is holomorphic for another complex structure in the hyperKähler family, so is Hamiltonian stationary.

5.1. Deformation theory. As we shall now see, the deformation theory of Hamiltonian stationary spheres is our case is very simple. Let us remind some basic facts about Hamiltonian stationary surfaces in a Kähler 4-manifold $(X, \omega)$. A Hamiltonian stationary surface is a Lagrangian surface which is a critical point of the area for Hamiltonian deformations. This gives an equation that can be written in the following way: given an embedded surface $\iota_S: S \subset X$, let $H$ be its mean curvature vector and $\alpha = H \cdot \omega$, then $\alpha_S = \iota_{S^*} \alpha$ is a 1-form on $S$ satisfying the equation $d\alpha_S = \iota_{S^*} \text{Ric}$. Then $S$ is Hamiltonian stationary if on $S$ one has

$$\delta \alpha_S = 0.$$

In the hyperKähler case, one has $\alpha_S = -d\theta$, where $\theta$ is the phase defined from the holomorphic symplectic form $\Omega$ by $\iota_S^* \Omega = e^{\theta} dVol_{g_S}$, and the equation is equivalent to $\Delta \theta = 0$. If $S$ is holomorphic for another complex structure in the hyperKähler family, then $S$ is minimal so obviously Hamiltonian stationary. Moreover, in that case, one obtains readily that the linearization of the equation is given by $f \mapsto \Delta^*_S f$, where the infinitesimal deformations are parameterized by a function $f$ on $S$ (the graph of $df$ in $T^*S$ giving the infinitesimal Lagrangian
deformation). The important point here is that this linearization is automatically an isomorphism
\[ C^{k,\alpha}(S)/\mathbb{R} \to C^{k-4,\alpha}_0(S), \]
where \( C_0 \) denote the functions \( f \) on \( S \) such that \( \int_S f \text{dVol}_{g_S} = 0 \), and the quotient by \( \mathbb{R} \) is natural since constants give trivial deformations. From this we deduce immediately the following lemma:

**Lemma 36.** Suppose \( S \) is a Lagrangian sphere in a hyperKähler 4-manifold \( (X,\omega) \), which is holomorphic with respect to one of the complex structures of \( X \).

If \((Y,\xi)\) is a Kähler manifold, sufficiently close to \((X,\omega)\) in \( C^{2,\alpha} \) norm, such that \([S]\) remains a Lagrangian homology class for \( \xi \) \([\xi][S] = 0\), then in \((Y,\xi)\), in a small \( C^{3,\alpha} \) neighborhood of \( S \), there exists a unique Hamiltonian stationary sphere \( T \) such that \([T] = [S]\).

**Proof.** The proof relies on two facts: if the homology class remains Lagrangian, it can be represented by a nearby Lagrangian surface; and the linearization under Hamiltonian deformations is an isomorphism (see above). So the proof is standard, but we give a short argument where the two aspects are treated simultaneously.

We look at maps \( f : S \to X \) which are deformations of the given inclusion \( \iota_S : S \subset X \), and consider the operator
\[
\Phi(f,\xi) = (f^*\xi,\delta f^*g_\xi(Hf,\xi-\xi)),
\]
for \( \xi \) a nearby Kähler structure (the complex structure is also deformed), and \( Hf,\xi \) denotes the mean curvature vector of \( f(S) \) for the metric \( \xi \). It is clear that \( f(S) \) is Lagrangian stationary if and only if \( \Phi(f) = 0 \).

A tangent vector to the space of maps \( f : S \to X \) is a section \( n \) of the normal bundle of \( S \), but we find more convenient to represent it by the 1-form \( \alpha = n \cdot \omega \) on \( S \). Then at the inclusion \( \iota_S \) one has
\[
\frac{\partial \Phi}{\partial f}(\alpha) = (d\alpha,\delta \Delta \alpha).
\]

To avoid the difference of the orders of the differential operators, we consider instead of \( \Phi \) the operator
\[
\Psi(f,\xi) = (f^*\xi,\Delta f^*g_\xi^{-1}\delta f^*g_\xi(Hf,\xi-\xi)),
\]
so that
\[
\frac{\partial \Psi}{\partial f}(\alpha) = (d\alpha,\Delta^{-1}\delta \Delta \alpha) = (d\alpha,\delta \alpha).
\]

Then \( \Psi \) is a smooth operator \( C^{3,\alpha} \times C^{2,\alpha} \to C^{2,\eta}_0 \times C^{2,\eta}_0 \), where each time the index 0 means with zero integral over \( S \) (for the metric \( f^*g_\xi \)); here we have used the hypothesis that \( \Sigma \) remains Lagrangian, so \( \int_S f^*\xi = 0 \). The differential \( \frac{\partial \Psi}{\partial f} \) is obviously an isomorphism at \( (f,\xi) = (\iota_S,\omega) \), since it identifies with \( d + \delta : \Omega^1(S) \to \Omega^2(S)_0 + \Omega^0(S)_0 \). The result is a consequence of the implicit function theorem. \( \square \)

This lemma is useful because of the following remark:

**Lemma 37.** If \( Y_\xi \) is a gravitational instanton for some \( \zeta = (\zeta_1,\zeta_2,\zeta_3) \in \mathfrak{h} \otimes \mathbb{R}^3 \), and \( \theta \) is a positive root such that \( \zeta_1 \in \ker \theta \), then the Lagrangian homology class corresponding to \( \theta \) is represented by a holomorphic cycle for a complex structure orthogonal to \( I_1 \) (and therefore Lagrangian for \( I_1 \)).
Proof. Because $\theta(\zeta_1) = 0$, there exists an angle $\varphi$, such that
\[
u = \begin{pmatrix} 0 & -\cos \varphi & \sin \varphi \\ 1 & 0 & 0 \\ 0 & \sin \varphi & \cos \varphi \end{pmatrix} \in SO_3
\]
sends $\zeta$ to $\xi = (\xi_1, \xi_c)$ such that $\theta(\xi_c) = 0$. By the second statement in Lemma 6, the homology class corresponding to $\theta$ is represented by a holomorphic cycle for the complex structure $u^{-1}(I_1) = -\cos \varphi I_2 + \sin \varphi I_3$. □

Together with Lemma 36 we deduce:

**Corollary 38.** Under the hypotheses of Theorem C, fix a singular point $x \in X$, with tangent graviton $Y_{\zeta_1, \zeta_c}$. Let $\theta$ be a positive root, such that $\zeta \in \text{ker } \theta$ and $\theta$ is primitive for this property, so that $\Sigma$ is represented in $Y_{\zeta_1, \zeta_c}$ by a Hamiltonian stationary sphere $S_0$ (Lemma 6). Finally suppose that the 2-homology class $\Sigma \in H_2(\hat{M}_t, \mathbb{Z})$ defined by $\theta$ remains Lagrangian, that is $\Omega_1 \cdot \Sigma = 0$.

If $\omega_t$ is the CSCK metric on $X_t$ in the class $\Omega_t$, then for $t$ small enough, $\Sigma$ can be represented by a Lagrangian stationary sphere, close to $S_0$.

Here we use that $\omega_t$ is a CSCK metric only through the estimates that it satisfies. The conclusion holds also for every metric in the class $\Omega_t$ satisfying the same estimates; the CSCK metric is a canonical example of such a metric.

**Proof.** We blow up the metrics $\omega_t$: from Corollary 35, on every compact, the Kähler metrics $\frac{\omega_t}{t^p}$ converge to the gravitational instanton $Y_{\zeta_1, \zeta_c}$ in $C^{2,\alpha}$ (actually in $C^\infty$). Then we apply Lemma 36. □

5.2. **Minimizing property.** We now prove the minimizing property of the spheres that we constructed, which is stated in Theorem D. The idea is that a sequence of minimizers in the homotopy class must converge to a minimizer in the tangent graviton $Y_{\zeta_1, \zeta_c}$. But since our minimizer $S_0 \subset Y_{\zeta_1, \zeta_c}$ is calibrated, it is unique, so the sequence of minimizers must converge to $S_0$. But then in a neighborhood of $S_0$ we have a uniqueness statement for our Lagrangian stationary sphere. Of course the whole process relies strongly on the fundamental results of Schoen-Wolffson [9].

Let us now give more details. For each $t > 0$, by [9] the free homotopy class of $\Sigma$ can be represented by a $\omega_t$ Hamiltonian stationary, weakly conformal map $s_t : S^2 \to X_t$, each being area minimizing in the homotopy class.

Of course the same map works for $\varpi_t = \frac{\omega_t}{t^p}$, which we now choose as the metric on $\hat{M}_t$. Since the area of the Hamiltonian stationary sphere that we constructed is $O(t)$ for $\omega_t$, it is bounded for $\varpi_t$, and so is the area of the collection $s_t$ which is not bigger.

The local geometry of $(\hat{M}_t, \varpi_t)$ is controlled: indeed, on the ALE part, $(\hat{M}_t, \varpi_t)$ converges to $Y_{\zeta_1, \zeta_c}$, while on the rest of the manifold, the curvature of $\varpi_t = \frac{\omega_t}{t^p}$ goes to zero. Moreover the injectivity radius of $\varpi_t$ remains bounded below. It follows that the local regularity results in [9] apply uniformly in $t$, in particular [9, Theorem 2.8] there is a uniform Hölder bound on the $s_t$. Since $\Sigma^2 \neq 0$, the image of $s_t$ must cut $S_0$, and it follows that for $t$ small enough, the image of $s_t$ is completely included in a bounded domain of the ALE part.

Now we again claim that the compactness theorem [9, Theorem 5.8] applies in our context, because the geometry is controlled. This implies that some sequence $s_{t_j}$ for $t_j \to 0$ converges to a Lagrangian stationary, weakly conformal $W^{1,2}$ map.
s_0 : S^2 \rightarrow Y_{\hat{g},\hat{c}}$, still representing the same homotopy class. Since $S_0$ is calibrated, the family must identify to the sphere $S_0 \subset Y_{\hat{g},\hat{c}}$. Since all $s_t$ are Lagrangian stationary, by regularity \cite[Theorem 4.10]{BiquardRollin2020} the convergence is smooth. Therefore for each $t > 0$ small enough, $s_{t,1} : S^2 \rightarrow \hat{M}_t$ is an embedding converging to the standard embedding $S_0 \rightarrow Y_{\hat{g},\hat{c}}$. By the uniqueness statement in Lemma 36 it must coincide with the Hamiltonian stationary sphere that we constructed.

6. T-singularities and $\mathbb{Q}$-Gorenstein smoothings

6.1. CSCK metrics. We extend our results in the setting of $\mathbb{Q}$-Gorenstein smoothings. The singularities that can appear are rational double points on one hand, on the other hand cyclic singularities of type $\frac{1}{dnm}(1, dnm - 1)$, where $n$ and $m$ are coprime integers. The last one is actually a $\mathbb{Z}_n$ quotient of the rational double point $\frac{1}{dnm}(1, -1)$ by the action generated by $(\xi, \xi^{dnm-1})$, for $\xi = e^{2\pi i/n}$.

We now explain why the results of the previous sections extend. Roughly speaking, the deformation theory of $\mathbb{Q}$-Gorenstein smoothings is the $\mathbb{Z}_n$ invariant part of the deformation theory for $A_{dn-1}$ singularities, and the models we glue are the $\mathbb{Z}_n$ quotients of $A_{dn-1}$ gravitational instantons. These models (the tangent gravitons) are no more hyperKähler ALE spaces, but only Kähler Ricci flat ALE spaces, and are given explicitly the Gibbons-Hawking ansatz, see \cite{BiquardRollin2020}. Nevertheless everything done in sections 2–5 extends just by quotienting the local models by the action of $\mathbb{Z}_n$. This gives immediately Theorem A and Theorem B in the general case of $T$ singularities.

6.2. Hamiltonian stationary spheres. Here there are some interesting phenomena happening in the case of $T$ singularities. The starting point is the same: in the setting of Theorem D, near a singular point $x \in X \hookrightarrow \mathcal{M} \rightarrow \Delta$, we have, up to a covering of group $\mathbb{Z}_n$, a graviton $Y_{\hat{g},\hat{c}}$, where $\zeta_1 \in h^{\mathbb{Z}_n}_{\mathbb{C}}$, $\zeta_2 \in h^{\mathbb{Z}_n}_{\mathbb{C}}$ and the space $\mathcal{M}_t$ is made by gluing $Y_{\hat{g},\hat{c}}$/\mathbb{Z}_n with the orbifold $X$. In particular, given a large $\mathbb{Z}_n$ invariant region $V \subset Y_{\hat{g},\hat{c}}$, one can identify $V/\mathbb{Z}_n$ with some region in $U \subset \mathcal{M}_t$ such that the metric $\frac{\partial}{\partial t}$ converges to the restriction to $V/\mathbb{Z}_n$ of the ALE Ricci flat metric. Denote this projection $p : V \rightarrow U$.

If we have a root $\theta \in \mathfrak{g}^+\mathbb{C}$, such that $\langle \theta, \zeta \rangle = 0$ and $\theta$ is primitive for this property, and moreover $\langle \zeta_1(t), \theta \rangle = 0$ for all $t$, then in the local $\mathbb{Z}_n$-covering $V$ the root $\theta$ represents a $p^*\Omega_t$ Lagrangian class. Corollary 38 applies as well, and $\theta$ can be represented by a $p^*\omega_1$ Hamiltonian stationary sphere $S_t \subset V$, converging to a sphere $S_0$ of the graviton $Y_{\hat{g},\hat{c}}$, which is holomorphic with respect to a complex structure, orthogonal to $I_1$. Then $p(S_t)$ is a Hamiltonian stationary surface in $(\mathcal{M}_t, \omega_1)$, but $p(S_t)$ might be not embedded. This depends only on the model: $p(S_t)$ is embedded if $p(S_0)$ is, so we have to analyze the model.

Denote $\vartheta = \frac{1}{n} \sum_{g \in \mathbb{Z}_n} g \cdot \theta$. We claim that, if $\vartheta \neq 0$, then $p(S_0)$ is embedded, and we get a Hamiltonian stationary sphere in the homology class $p_\ast \vartheta$. This will end the proof of Theorem D. At the end of the section, we will also see some examples of behaviors when $\vartheta = 0$, resulting in the construction of a $\mathbb{R}P^2$ or a $S^2$ with a double point.

Fortunately the possible spheres $S_0$ are explicit in the Gibbons-Hawking ansatz, so we merely have to check the above claim. Therefore we remind briefly what we need \cite[§5]{BiquardRollin2020}.
We consider $k + 1$ distinct points $p_0, \ldots, p_k \in \mathbb{R}^3$, and the harmonic function $V(x) = \frac{1}{2} \sum_i \frac{1}{|x - p_i|}$. Then $*dV$ is a closed 2-form on $\mathbb{R}^3 \setminus \{p_i\}$, which is furthermore integral (indeed, the integral of $*dV$ on a small sphere around $p_i$ is 1). Therefore $*dV = d\eta$, where $\eta$ is the connection 1-form on the total space of a circle bundle $L \to \mathbb{R}^3 \setminus \{p_i\}$. Because of the topology of $L$ near each $p_i$, the restriction of $L$ to a small 2-sphere around $p_i$ is diffeomorphic to a 3-sphere, and one can compactify $L$ into a smooth manifold $M$, equipped with a projection $\pi : M \to \mathbb{R}^3$, by adding just one point above each $p_i$. Then it turns out that

$$g = V(dx_1^2 + dx_2^2 + dx_3^2) + V^{-1}\eta^2$$

is a smooth hyperKähler metric on $M$, whose three complex structures are given by

$$I_i dx_i = V^{-1}\eta, \quad I_i dx_j = dx_k,$$

where $(i, j, k)$ is a circular permutation of $(1, 2, 3)$. More generally, for any $\xi = (\xi_1, \xi_2, \xi_3) \in S^2$, we have a complex structure $I_\xi$ such that $I_\xi \sum \xi_i dx_i = V^{-1}\eta$ and $I_\xi$ is a rotation of angle $\frac{\pi}{3}$ in the plane $(\sum \xi_i dx_i)^\perp \subset (\mathbb{R}^3)^*$; the corresponding Kähler form is $\omega_\xi = \sum \xi_i (dx_i \wedge \eta + V dx_j \wedge dx_k)$. All the structures are invariant under the circle action.

If the segment $[p_a, p_b]$ does not contain another point $p_c$, then $\pi^{-1}[a, b]$ is a 2-sphere, which is holomorphic for the complex structure $I_\xi$, where $\xi = \frac{a - b}{|a - b|}$, and Lagrangian for the Kähler forms $\omega_\zeta$ for $\zeta \perp \xi$. It follows immediately that $\pi^{-1}[a, b]$ is Hamiltonian stationary for the Kähler metric $(M, I_\xi, \omega_\xi)$, where $\zeta \perp \xi$, and this gives our model spheres in the case of $A_k$ singularities.

It is also interesting to describe the cohomology in this model: define the 2-form

$$\chi_i = df_i \wedge \eta + *df_i, \quad f_i(x) = \frac{1}{2V(x)|x - p_i|}.$$

It is easy to check that $\chi_i$ is a smooth closed antiselfdual 2-form on $M$, and $\sum \chi_i = 0$. This is the only relation and one gets the representation of the cohomology of $M$ by harmonic forms:

$$H^2(M, \mathbb{R}) = \left\{ \sum_i c_i \chi_i, \sum_i c_i = 0 \right\}. \quad (6.1)$$

(This actually describes the $L^2$ cohomology of $M$, which turns out to be equal to the ordinary cohomology.) The form $\chi_i$ evaluated on the 2-sphere $\pi^{-1}[p_a, p_b]$ gives

$$\langle \chi_i, \pi^{-1}[p_a, p_b] \rangle = 2\pi (f_i(p_a) - f_i(p_b)) = 2\pi (\delta_{ia} - \delta_{ib}).$$

This formula justifies the equality (6.1).

In the case of $T$ singularities, we start from a $A_{dn-1}$ gravitational instanton, given from the Gibbons-Hawking ansatz with $k + 1 = dn$ points. For a careful choice of the points $p_a$, there is a free isometric action of $\mathbb{Z}_n$ which is holomorphic for one of the complex structures: denote $z = x_1 + ix_2$ (this a $I_3$ holomorphic function), we consider the action of a generator $\varpi = e^{2m\theta}$ of $\mathbb{Z}_n$ given by

$$\varpi \cdot z = \varpi z, \quad \varpi \cdot \theta = \varpi^m \theta,$$

where $\theta$ is the angular coordinate, and $n$ and $m$ are coprime. Of course this action is well defined only if the configuration of the $dn$ points is invariant under $z \mapsto \varpi z$, that is if they are organized into a collection of $d$ regular centered $n$-polygons in planes orthogonal to the vector $\partial_{x_3}$. This gives all the ALE Ricci flat
models that we need for singularities of class $T$. Incidentally, the parameters are a collection of $d$ points (one in each polygon), that is $3d$ real parameters, modulo the translation in the $\partial x_3$ direction, so finally $3d - 1$ parameters as expected ($d$ complex parameters and $d - 1$ real parameters). In particular, from (6.1), the $\mathbb{Z}_n$ invariant part of $H^2(M, \mathbb{R})$ has dimension $d - 1$.

We can now describe Hamiltonian stationary spheres: as we have seen, these are given by $\pi^{-1}[p_a, p_b]$, where $p_a - p_b \perp \partial x_3$, that is by the segments in the planes of the polygons. Here there are two cases:

- a segment $[p_a, p_b]$ between two points of two distinct polygons (which is possible only if the two polygons are in the same plane): if we change the point $p_b$ in the same polygon, we do not change the homology class in the quotient, because the sides of the polygon go to zero in the homology of the quotient; therefore we can choose $p_b$ to be the closest vertex to $p_a$, so that the images under $\mathbb{Z}_n$ of the segment $[p_a, p_b]$ are disjoint; therefore in the quotient we still obtain a 2-sphere with nonzero class in homology (indeed the pairing with $\frac{1}{n} \sum_{g \in \mathbb{Z}_n} g \cdot (\chi_a - \chi_b)$ is nonzero);
- a segment $[p_a, p_b]$ between two points of the same polygon: we consider only the following cases (the images of the other spheres have more complicated crossings):
  - $[p_a, p_b]$ is an edge of the polygon; then in the quotient, the points $p_a$ and $p_b$ represent the same point and we obtain an immersed 2-sphere with one double point;
  - $n = 2$ and $p_b = -p_a$: then the image of $\pi^{-1}[p_a, p_b]$ is an embedded $\mathbb{R}P^2$.

The other segments $[p_a, p_b]$ are more complicated since for a $g \in \mathbb{Z}_n$, the segment $g \cdot [p_a, p_b]$ might meet $[p_a, p_b]$ in an interior point, which means that one gets a double circle.

7. Applications

7.1. Del Pezzo surfaces. Our result is applied to produce extremal metrics on $\mathbb{Q}$-Gorenstein smoothings of singular extremal Del Pezzo surfaces with no nontrivial holomorphic vector field.

More precisely, let $X$ be a normal Del Pezzo surface. If $X$ admits a $\mathbb{Q}$-Gorenstein smoothing, then all the singularities of $X$ must be of class $T$. So it is natural to assume that every singularity of $X$ is of such type. Locally, we may pick a one parameter $\mathbb{Q}$-Gorenstein smoothing for each singularity of $X$. It turns out that such local smoothing can always be globalized. In other words, one can find a $\mathbb{Q}$-Gorenstein smoothing $X \hookrightarrow \mathcal{M} \rightarrow \Delta$ such that the germs of deformations of the singularities are the one we started with. This result is due to the fact that $H^2(X, TX) = 0$, hence there is no local to global obstruction to deformation theory as proved in [3, Proposition 3.1].

In particular, we can always construct in this way a one parameter $\mathbb{Q}$-Gorenstein smoothing $X \hookrightarrow \mathcal{M} \rightarrow \Delta$ satisfying the non degeneracy condition in the sense of Definition 1. Suppose that $X$ admits an extremal Kähler metric and no nontrivial holomorphic vector field (hence the metric must be CSCK) and that $\Omega_t$ is a family of Kähler classes on $\mathcal{M}_t$ that degenerates toward the orbifold Kähler class. Then, by Theorem A, the smoothing $\mathcal{M}_t$ admits a CSCK metric with Kähler class $\Omega_t$ for all $t > 0$ sufficiently small.
For instance, consider the Del Pezzo orbifold $\mathcal{X} = (\mathbb{CP}^1 \times \mathbb{CP}^1)/\mathbb{Z}_4$, where the action of $\mathbb{Z}_4$ on the product is spanned by

$$([u_1 : v_1], [u_2 : v_2]) \mapsto ([iu_1 : v_1], [iu_2 : v_2]).$$

The quotient contains exactly four singularities. Two of them are $A_3$ singularities whereas the two others are of type $T$, modelled on cyclic quotients of the form $\mathbb{C}^3(1,1,1)$.

We construct a nondegenerate family of smoothings $\mathcal{X} \hookrightarrow \mathcal{M} \to \Delta$ as explained above. Quite interestingly, a smoothing $\mathcal{M}_t$ for $t \neq 0$ is not diffeomorphic to the minimal resolution $\hat{\mathcal{X}}$ of $\mathcal{X}$. In such a situation $\mathcal{M}_t$, as a smooth manifold, is obtained by removing a neighborhood of the $-4$ exceptional spheres in $\hat{\mathcal{X}}$ and gluing back two copies of the rational homology ball $T^*S^2/\mathbb{Z}_2 = T^*\mathbb{RP}^2$. Such an operation is known under the name of rational blowdown. Thus, $\mathcal{M}_t$ is the rational blowdown of $\hat{\mathcal{X}}$ for $t \neq 0$. As $\hat{\mathcal{X}}$ is an eight-point iterated blow-up of $\mathbb{CP}^1 \times \mathbb{CP}^1$, one can show that $\mathcal{M}_t$ is a six-point blow up of $\mathbb{CP}^1 \times \mathbb{CP}^1$.

The product $\mathbb{CP}^1 \times \mathbb{CP}^1$ can be endowed with a CSCK metric by choosing a multiple of the standard Fubini-Study metric on each factor. The group $\mathbb{Z}_4$ acts isometrically on the product, thus we obtain a CSCK orbifold metric on $\mathcal{X}$.

Then we pick any family of Kähler classes $\Omega_t$ on $\mathcal{M}_t$ for $t > 0$ that degenerates toward the orbifold Kähler class. At the point, we are ready to apply Theorem A. Unfortunately, $\mathcal{X}$ does admit nontrivial holomorphic vector fields. To get around this issue, we work equivariantly, modulo an additional symmetry. There is a $\mathbb{Z}_2$ action on $\mathbb{CP}^1 \times \mathbb{CP}^1$ spanned by

$$([u_1 : v_1], [u_2 : v_2]) \mapsto ([v_1 : u_1], [v_2 : u_2]).$$

This action descends to the quotient $\mathcal{X} = (\mathbb{CP}^1 \times \mathbb{CP}^1)/\mathbb{Z}_4$. The main point is that $\mathcal{X}$ does not carry any nontrivial holomorphic vector field. Such a $\mathbb{Z}_2$-action on $\mathcal{X}$ extends as a $\mathbb{Z}_2$ fiberwise-action on the smoothing $\mathcal{M} \to \Delta$. We may restrict our attention to $\mathbb{Z}_2$-equivariant smoothing (i.e. such that $\mathbb{Z}_2$ acts trivially on $\Delta$) and $\mathbb{Z}_2$-invariant Kähler classes $\Omega_t$. The proof of Theorem A can be done in this $\mathbb{Z}_2$-equivariant context. It follows that $\mathcal{M}_t$ admits a CSCK metric with Kähler class $\Omega_t$ for all $t > 0$ sufficiently small.

In conclusion $\mathcal{M}_t$ carries a Kähler-Einstein metric for all $t$ sufficiently small. It should be pointed out that $\mathcal{M}_t$ is not diffeomorphic to the minimal resolution of $\mathcal{X}$ for $t \neq 0$. In fact $\mathcal{M}_t$ is the full rational blow-down of $\hat{\mathcal{X}}$ which is diffeomorphic to a 6-point blow-up of $\mathbb{CP}^1 \times \mathbb{CP}^1$.

Working with a Kähler-Einstein orbifold metric on $\mathcal{X}$ and $\Omega_t = c_1(\mathcal{M}_t)$ we recover Tian’s metric for certain special Fano surfaces very close to the boundary of the moduli space, diffeomorphic to $\mathbb{CP}^1 \times \mathbb{CP}^1$ blown up six times. In addition Theorem D applies in this setting. Let $E$ the homology class of an exceptional holomorphic sphere in the resolution $\hat{\mathcal{X}}$. Then $E$ can be represented by a stationary Lagrangian sphere in $\mathcal{M}_t$ for $t > 0$ sufficiently small with respect to the Kähler-Einstein metric. It is also possible to prove that $\mathcal{M}_t$ contains two stationary Lagrangian $\mathbb{R}P^2$ obtained by perturbing the zero section of the tangent graviton $T^*\mathbb{R}P^2$.

Similar examples can be constructed by considering the CSCK orbifold $\mathcal{X} = (\mathbb{CP}^1 \times \mathbb{CP}^1)/\mathbb{Z}_2$, an example considered by Spotti [10]. In this case $\mathcal{X}$ has four $A_1$ singularities and the smoothings are diffeomorphic to the minimal resolution $\hat{\mathcal{X}}$. The construction above provides a construction of CSCK metrics on certain
four-point blowups of $\mathbb{CP}^1 \times \mathbb{CP}^1$. In particular, we can apply this to the Kähler-Einstein case. Again, we prove that the $-2$ exceptional spheres can be deformed to get stationary Lagrangian spheres in the smoothing endowed with its Kähler-Einstein metric.

7.2. Geometrically ruled CSCK orbifold surfaces. A large class of geometrically ruled CSCK orbifolds can be constructed via representation theory. The idea is to consider an orbifold Riemann surface $\Sigma$ and a twisted product $X = \Sigma \times_{\rho} \mathbb{CP}^1$ where $\rho$ is a morphism $\rho: \pi_{orb}^1(\Sigma) \to SU_2/\mathbb{Z}_2$, where $\pi_{orb}^1(\Sigma)$ is the orbifold fundamental group. Here we require that if $p_i$ is a singular point of order $q_i$ in $\Sigma$ and $l_i$ is the homotopy class of a small loop around $p_i$, then $\rho(l_i)$ is of order $q_i$.

If $\Sigma$ has only orbifold points of order 2, then $X$ has isolated singularities of type $A_1$. Suppose that $\Sigma$ carries a CSCK metric (we just have to exclude the case of a teardrop with exactly one singularity of order 2). Then the local product metric provides a CSCK orbifold metric on $X$.

Under the assumption that $\pi_{orb}^1(\Sigma)$ acts transitively on $\mathbb{CP}^1$ via $\rho$ and that $\Sigma$ is not the football, the orbifold $X$ does not carry any nontrivial holomorphic vector field [8].

In the next section, we show that is is always possible to find a nondegenerate $\mathbb{Q}$-Gorenstein smoothing of $X$. In particular Theorem A and Theorem D apply and we may construct some new CSCK metrics on blownup ruled surfaces with stationary Lagrangian spheres.

7.3. Smoothing model for orbifold ruled surfaces. The example of ruled orbifold $X \to \Sigma$ given in the previous section has singularities that come by pair above each orbifold point in $\Sigma$.

More precisely, the local model is given by an orbifold surface $Y \to \mathbb{C}/\mathbb{Z}_2$ where $Y = (\mathbb{C} \times \mathbb{CP}^1)/\mathbb{Z}_2$, the action of $\mathbb{Z}_2$ is spanned by $(u, [v : w]) \mapsto (-u, [-v : w])$ and the projection map $Y \to \mathbb{C}/\mathbb{Z}_2$ is just induced by the first canonical projection.

Using the coordinates $(u, [v : w])$ on the ramified cover $\mathbb{C} \times \mathbb{CP}^1$, we see that $\mathbb{Z}_2$-invariant polynomials in the chart $w \neq 0$ are generated by

$$\begin{align*}
x_1 &= u^2 \\
y_1 &= \left(\frac{v}{w}\right)^2 \\
z_1 &= \frac{w}{u}
\end{align*}$$

(7.1)

and the equation of $Y$ in this chart is given by

$$x_1y_1 = z_1^2,$$

which is the equation of an $A_1$ singularity. Similarly, in the chart $v \neq 0$, we have the invariant polynomials

$$\begin{align*}
x_2 &= u^2 \\
y_2 &= \left(\frac{w}{v}\right)^2 \\
z_2 &= \frac{v}{u}
\end{align*}$$

(7.2)

and the equation

$$x_2y_2 = z_2^2,$$

giving a second $A_1$ singularity.

Putting together (7.1) and (7.2), we conclude that $Y$ is the subvariety of $\mathbb{C} \times \mathbb{CP}^2$ given by the equation

$$x_\alpha \beta = \gamma^2.$$
where \((x, [\alpha : \beta : \gamma]) \in \mathbb{C} \times \mathbb{CP}^2, x = x_1 = x_2, \frac{\gamma}{\alpha} = y_1 = \frac{1}{\beta}, \frac{\beta}{\alpha} = z_1\) and \(\frac{\gamma}{\beta} = z_2\).

We introduce a family of deformation \(\mathcal{Y} \hookrightarrow \mathcal{N} \to \mathbb{C}^2\) where \(\mathcal{N}\) is the subvariety with points \((x, [\alpha : \beta : \gamma], \varepsilon_1, \varepsilon_2) \in \mathbb{C} \times \mathbb{CP}^2 \times \mathbb{C}^2\) given by the equation
\[
\varepsilon_1 \alpha^2 + \varepsilon_2 \beta^2 + x \alpha \beta = \gamma^2
\]
and the map \(\mathcal{N} \to \mathbb{C}^2\) is induced by the canonical projection \((x, [\alpha : \beta : \gamma], \varepsilon_1, \varepsilon_2) \mapsto \varepsilon = (\varepsilon_1, \varepsilon_2)\). The singular locus of \(\mathcal{N}\) is contained in the hypersurface \(\varepsilon_1 \varepsilon_2 = 0\) and if neither \(\varepsilon_1\) nor \(\varepsilon_2\) vanish, then the fiber \(\mathcal{N}_\varepsilon\) is a smooth deformation of \(\mathcal{Y}\).

Using affine coordinates, one can check that the parameters \(\varepsilon_i\) correspond to the parameters of the semi-universal family of smoothings for the \(A_1\) singularity. In particular, if we choose a line in \(\mathbb{C}^2\) distinct of the lines \(\varepsilon_1 = 0\) or \(\varepsilon_2 = 0\), we obtain a nondegenerate family of smoothings of \((\mathbb{C} \times \mathbb{CP}^1)/\mathbb{Z}_2\).

We have a canonical projection \(\mathcal{N} \to \mathbb{C}\) given by the coordinate \(x\). The restriction of this map \(\mathcal{N}_\varepsilon \to \mathbb{C}\) defines a ruled surface over \(\mathbb{C}\) and it is smooth unless \(\varepsilon_1 \varepsilon_2 = 0\). One can also check that the fibers of the ruling are all \(\mathbb{CP}^1\) except when \(x^2 = 4\varepsilon_1 \varepsilon_2\) where the polynomial \(\varepsilon_1 \alpha^2 + \varepsilon_2 \beta^2 + x \alpha \beta - \gamma^2\) splits as a product of two polynomials of degree 1 in \((\alpha, \beta, \gamma)\). If \(\varepsilon_1 \varepsilon_2 \neq 0\), there are two distinct fibers that consist of a union of two \(\mathbb{CP}^1\) with normal crossing at one point. Topological considerations imply that the curves have selfintersection −1. In conclusion, assuming \(\varepsilon_1 \varepsilon_2 \neq 0\), the ruled surface \(\mathcal{N}_\varepsilon \to \mathbb{C}\) is a two point blowup of \(\mathbb{C} \times \mathbb{CP}^1\) at two distinct fibers.

Let \(\Delta^2_{1/2}\) be the ball of radius \(1/2\) in \(\mathbb{C}^2\), so that \(|\varepsilon_1 \varepsilon_2| < 1/4\) for \(\varepsilon \in \Delta^2_{1/2}\). Let \(\mathcal{N}'\) (resp. \(\mathcal{N}''\)) be the restriction of \(\mathcal{N}\) to the domain \(|x| \leq 2\) and \(\varepsilon \in \Delta^2_{1/2}\) (resp. \(x \in A = \{1 < |x| \leq 2\}\) and \(\varepsilon \in \Delta^2_{1/2}\)). Accordingly, we shall denote \(\mathcal{Y}' = \mathcal{N}'_0\) and \(\mathcal{Y}'' = \mathcal{N}''_0\).

By definition, \(\mathcal{N}''\) is equipped with a projection \(\mathcal{N}'' \to A \times \Delta^2_{1/2}\). This projection is a geometric ruling (a submersive holomorphic map with fibers \(\mathbb{CP}^1\)) for reducible curves appear only for \(x^2 = 4\varepsilon_1 \varepsilon_2\). Hence there exists a biholomorphism
\[
\phi : \mathcal{N}'' \to A \times \Delta^2_{1/2} \times \mathbb{CP}^1
\]
which commutes with the projection maps to \(A \times \Delta^2_{1/2}\).

The restriction of the map \(\phi\) induces an isomorphism \(\mathcal{Y}'' \to A \times \mathbb{CP}^1\). Taking the product with the identity, we deduce an isomorphism
\[
\psi : \Delta^2_{1/2} \times \mathcal{Y}'' \to A \times \Delta^2_{1/2} \times \mathbb{CP}^1.
\]
We shall the maps \(\phi\) and \(\psi\) to construct deformations of orbifold ruled surfaces in the next section.

7.4. Construction of deformations. Let \(\mathcal{X}\) be a compact complex orbifold surface with a holomorphic embedding
\[
j : \mathcal{Y}' \hookrightarrow \mathcal{X}
\]
where \(\mathcal{Y}' = \mathcal{N}'_0\). We shall construct a smoothing of \(\mathcal{X}\) using the smoothing \(\mathcal{N}'\) described in the previous section.

Let \(\mathcal{X}'\) be the complement in \(\mathcal{X}\) of the domain \(|x| \leq 1\) of \(\mathcal{Y}'\). In particular, we have the restriction \(j : \mathcal{Y}' \hookrightarrow \mathcal{X}'\). We introduce
\[
\mathcal{M} = (\Delta^2_{1/2} \times \mathcal{X}') \cup \mathcal{N}' / \sim
\]
The equivalence relation is given as follows: if \((\varepsilon, m) \in \Delta_{1/2}^2 \times X'\) is such that \(m = j(y)\) for some \(y \in Y''\), we identify the point \((\varepsilon, m)\) with \(z \in N'' \subset N'\) provided \(\psi(\varepsilon, m) = \phi(z)\).

The complex variety \(\mathcal{M}\) endowed with the canonical maps \(X \hookrightarrow \mathcal{M} \to \Delta_{1/2}^2\) is a flat deformation of \(X\) and it is non degenerate in the sense of Definition 1.

We deduce the following proposition by applying Theorem A and Theorem D to the family of smoothings \(X \hookrightarrow \mathcal{M} \to \Delta\).

**Proposition 39.** Let \(X = \sum \times_{\rho} \mathbb{C}P^1\) be a CSCK geometrically ruled surface with singularities of type \(A_1\) and no nontrivial holomorphic vector fields as described in §7.2. Then there exists one parameter families of nondegenerate smoothings \(X \hookrightarrow \mathcal{M} \to \Delta\). In particular, \(X\) admits CSCK smoothings with stationary Lagrangian spheres representing the vanishing Lagrangian cycles.
