Online Learning of Parameterized Uncertain Dynamical Environments with Finite-sample Guarantees

Dan Li\textsuperscript{1}, Dariush Fooladivanda\textsuperscript{2} and Sonia Mart\textsuperscript{1}nez

Abstract— We present a novel online learning algorithm for a class of unknown and uncertain dynamical environments that are fully observable. First, we obtain a novel probabilistic characterization of systems whose mean behavior is known but which are subject to additive, unknown subGaussian disturbances. This characterization relies on recent concentration of measure results and is given in terms of ambiguity sets. Second, we extend the results to environments whose mean behavior is also unknown but described by a parameterized class of possible mean behaviors. Our algorithm adapts the ambiguity set dynamically by learning the parametric dependence online, and retaining similar probabilistic guarantees with respect to the additive, unknown disturbance. We illustrate the results on a differential-drive robot subject to environmental uncertainty.

I. INTRODUCTION

The online learning of uncertain dynamical systems has broad application in various domains, including those of artificial intelligence and robotics [1]–[3]. Fundamentally, one is to exploit input-output data to identify the representation of the environment that best captures its behavior. In this way, several techniques, from first-principles system identification to, more recently, (deep) neural networks, have been successfully used in various domains. Unfortunately, safe performance usually depends upon the assimilation of vast amounts of data, which is mostly done offline and prevents its application in real-time scenarios. Motivated by this, we investigate the integration of recently-developed probabilistically-guaranteed system descriptions with online, predictor-based learning algorithms.

The system identification literature broadly encompasses linear [4], [5] and non-linear systems [6], [7], with asymptotic performance guarantees. More recently, finite-sample analysis of identification methods have been proposed for linear systems [8]–[11]. These methods leverage modern measure-of-concentration results [12], [13] for non-asymptotic guarantees of the identification error bounds. Measure-of-concentration results are also used in [14], [15]. However, the goal of [14], [15] is to learn an unknown initial distribution evolving under a known dynamical system while assimilating data via a linear observer. This characterization is given in terms of ambiguity sets, which are constructed via multiple system trajectories or realizations. In contrast, here we employ Wasserstein metrics to develop an online learning algorithm for uncertain dynamical systems with similar-in-spirit probabilistic guarantees.

Statement of Contributions: We propose an online learning algorithm that characterizes a class of unknown and uncertain dynamical environments with probabilistic guarantees using a finite amount of data. To achieve this, we first assume that the mean behavior of the stochastic system is known but the system states are subject to an additive, unknown sub-Gaussian distribution, characterized by a set of distributions or ambiguity set. Then, we extend the results to environments whose mean behavior is unknown but belongs to a parameterized class of behaviors. In this regard, we propose a time-varying parameterized ambiguity set and a learning methodology to capture the behavior of the environment. We show how the proposed online learning algorithm retains desirable probabilistic guarantees with high confidence. A differential-drive robot subject to environmental uncertainty is provided for an illustration. Basic notations and definitions can be found in the footnote.\textsuperscript{1}

II. PROBLEM STATEMENT

This section presents the description of the uncertain dynamical environment which we aim to learn, with a problem

\begin{itemize}
\item[\textsuperscript{1}]\begin{itemize}
\item Let $\mathbb{R}^m$, $\mathbb{R}_m^m$, $\mathbb{Z}_m^m$ and $\mathbb{R}^{m\times m}$ denote respectively the $m$-dimensional real space, the $m$-dimensional nonnegative real space, the $m$-dimensional nonnegative integer space, and the space of $m \times m$ matrices. Let $x \in \mathbb{R}^m$ denote a column vector of dimension $m$, while $x^\top$ represents its transpose. The shorthand notation $1_m$ denotes the column vector $(1, \ldots, 1)^\top \in \mathbb{R}^m$.
\item We use subscripts to index vectors, i.e., $x_k \in \mathbb{R}^m$ for $k \in \mathbb{Z}_0^m$, and we use $x_i$ to denote the $i$th component of $x$. We denote respectively the 2-norm and infinity norm by $\|x\|$ and $\|x\|_{\infty}$. We define the $m$-dimensional norm ball with center $x \in \mathbb{R}^m$ and radius $\epsilon \in \mathbb{R}_0^m$ as the set $B(x, \epsilon) := \{y \in \mathbb{R}^m \mid \|y - x\| \leq \epsilon\}$. We denote by $(\cdot)^\top$ an inner product in the space of interest. Consider the space $\mathbb{R}^m$, we define $(x, y) := \langle x, y \rangle := x^\top y$, $x, y \in \mathbb{R}^m$. In particular, $\|x\| := \sqrt{(x, x)}$. Consider Finsler manifold $\mathbb{R}^2 \times [-\pi, \pi] \cong \mathbb{R} \times \mathbb{S}^1$ where $\mathbb{S}^1$ stands for the unit circle. For $(x, \theta_1), (y, \theta_2) \in \mathbb{R}^2 \times [-\pi, \pi]$, we define $\langle (x, \theta_1), (y, \theta_2) \rangle := x^\top y + \cos(\min(\theta_1 - \theta_2, 2\pi - |\theta_1 - \theta_2|))$. In particular, we use $\| (x, \theta) \| := \sqrt{(x, x)} + 1$. Given an $A \in \mathbb{R}^{m \times m}$, we write its Singular Value Decomposition (SVD) as $A = U \Sigma V^\top$, where $U, V \in \mathbb{R}^{m \times m}$ are orthonormal and $\Sigma$ is diagonal with non-negative entries. These entries are called singular values of $A$, and we denote by $\sigma_{\max}(A)$ and $\sigma_{\min}(A)$ the maximal and non-zero minimal singular value of $A$, respectively. We denote by $A^\dagger := V \Sigma^\dagger U^\top$ the Moore–Penrose inverse of $A$, where $\Sigma^\dagger$ is the same as $\Sigma$ except the replacement of each positive entry by its inverse. Let $(\Omega, \mathcal{F}, P)$ be a probability space, with $\Omega$ the sample space, $\mathcal{F}$ a $\sigma$-algebra, and $P$ the associated probability distribution. Let $x : \Omega \to \mathbb{R}^m$ be an induced random vector. We denote by $\mathbb{M}$ the space of all probability distributions with finite first moment. To measure the distance in $\mathbb{M}$, we use the dual version of the $1$-Wasserstein metric $\delta_1 : \mathbb{M} \times \mathbb{M} \to \mathbb{R}_0^m$, defined as in [16]. A closed Wasserstein ball of radius $\epsilon$ centered at $x \in \mathbb{M}$ is denoted by $B_{\mathbb{M}}(x, \epsilon) := \{Q \in \mathbb{M} \mid \delta_1(P, Q) \leq \epsilon\}$. We denote the Dirac measure at $x_0 \in \Omega$ as $\delta_{x_0} : \Omega \to \{0, 1\}$. For any set $A \subseteq \mathcal{F}$, we let $\delta_{\{x_0\}}(A) = 1$, if $x_0 \in A$, otherwise 0. For an $x \in \Omega$, we denote $P \equiv P + x$, if $P$ is a translation of $Q$ by $x$.
\end{itemize}
\end{itemize}
definition. Let \( t \in \mathbb{Z}_{\geq 0} \) denote time discretization. For each \( t \), the uncertain system is characterized by a random variable \( x \in \mathbb{R}^n \) which evolves according to an unknown, discrete-time, stochastic and, potentially, time-varying system

\[
x_{t+1} = f(t, x_t, d_t) + w_t, \quad \text{with some } x_0 \sim P_0.
\]

(1)

The distribution \( P_{t+1} \) characterizing \( x_{t+1} \) is determined by the current state’s distribution, the unknown mapping \( f : \mathbb{R}_{\geq 0} \times \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^n \), and random vectors \( w_t \) that cannot be captured by \( f \). We further assume that \( d_t \) is an exogenous signal that is selected in advance or revealed online, which can play the role of an external reference or control. Let us denote by \( Q_t \) the distribution of the random vector \( w_t \in \mathbb{R}^n \).

Assumption II.1 (Independent and stationary subGaussian distributions) Consider random vectors \( w_t \in \mathbb{R}^n \), \( t \in \mathbb{Z}_{\geq 0} \). It is assumed that: (1) The random vectors \( w_t \) are component-wise and time-wise independent, i.e., \( w_{t,i} \) and \( w_{t,j} \) are independent, for all \( t \neq k \), \( i \neq j \), \( (t, k) \in \mathbb{Z}_{\geq 0}^2 \) and \( (i, j) \in \{1, \ldots, n\} \). (2) For each \( t \), \( w_t \) is a zero-mean subGaussian distribution, i.e., for any \( a \in \mathbb{R}^n \) we have \( \mathbb{E}[\exp(a^T w_t)] \leq \exp(\|a\|\sigma^2/2) \).

Example II.1 (\( \sigma \)-subGaussian distributions) A trivial example is any \( \mathcal{W} \equiv \mathcal{N}(0, \Sigma) \) with \( \sigma_{\text{max}}(\Sigma) \leq \sigma^2 \). As any random vector supported on a compact set belongs to the subGaussian class, in particular, the following are \( \sigma \)-subGaussian distributions: (1) any zero-mean uniform distribution \( w \sim \mathcal{U}(\Omega) \) supported over \( \Omega \subset B_\sigma(0) \); (2) any zero-mean discrete distribution with support \( \Omega \subset B_\sigma(0) \).

This paper aims to obtain a tractable characterization of the unknown distribution \( P_{t+1} \) of the immediate-future environment state \( x_{t+1} \) online, \( \forall t \). This is to be done by employing historical measurements, \( x_k, k \leq t \), and data \( d_k, k \leq t \).

Remark II.1 (On finite-horizon learning of \( \mathcal{P} \)) Our learning problem can be extended over finite horizons as follows. Let \( N \) be a learning horizon, then for each \( t \) the goal is to characterize the dynamical environment over the next \( N \) time slots, \( \{t+1, \ldots, t+N\} \), with the previous knowledge of \( d := (d(1), \ldots, d(N)) \). In other words, the objective is to characterize the joint distribution \( Q := P_{t+1}^{(1)} \times \cdots \times P_{t+N}^{(N)} \) of the stochastic process \( x := (x(1), \ldots, x(N)) \).

III. CHARACTERIZATION OF RANDOM DYNAMICAL ENVIRONMENTS UNDER PERFECT INFORMATION

We aim to provide a description the random dynamical system \( \mathcal{P} \) via ambiguity sets. More precisely, given knowledge \( d \), and system data \( \hat{x} \), we look for a set of distributions \( \mathcal{P}_{t+1} := \mathcal{P}_{t+1}(d, \hat{x}) \) characterizing \( P_{t+1} \) via

\[
\text{Prob}(P_{t+1} \in \mathcal{P}_{t+1}) \geq 1 - \beta,
\]

(2)

for some \( \beta \in (0, 1) \). Observe that the probability is taken wrt the historical random data outcomes. To do this, let \( T_0 \in \mathbb{Z}_{\geq 0} \) and \( T := \min\{t, T_0\} \geq 1 \), and consider the historical data, \( \hat{x}_k \) and \( d_k \), for \( k \in T := \{t-1, \ldots, t-1\} \). Assuming a perfect knowledge of \( f \), we show first how to use the data set \( I := \{x_t, \hat{x}_k, d_k, k \in T\} \) to construct \( \mathcal{P}_{t+1} \), \( \forall t \geq 0 \).

Let us denote by \( Q_{t+1} \equiv Q_{t+1}(d) \) the empirical distribution of \( x_{t+1} \) and define it as follows

\[
Q_{t+1} := \frac{1}{T} \sum_{k \in T} \delta_{\xi_k(d)},
\]

where \( \xi_k(d) := f(t, \hat{x}_k, d) + \hat{x}_{k+1} - f(k, \hat{x}_k, d_k), \forall k \in T \). The following result enables us to construct the ambiguity set \( \mathcal{P}_{t+1} \) that satisfies (2).

Lemma III.1 (Asymptotic dynamic ambiguity set) Let us assume that the system \( f \) is known at each time \( t \). Given a confidence level \( \beta \in (0, 1) \), parameter \( T_0 \in \mathbb{Z}_{\geq 0} \), and horizon \( T := \min\{t, T_0\} \), let us assume \( w_k \) is i.d. for \( k \in T \). Then, there exists a positive scalar \( \epsilon := c(T, \beta) \) such that (2) holds by selecting

\[
\mathcal{P}_{t+1} := \{ \mathbb{P} \mid d_{W}(\mathbb{P}, Q_{t+1}) \leq \epsilon \},
\]

a Wasserstein ball centered at \( Q_{t+1} \) with radius

\[
\epsilon := \sqrt{\frac{2n\sigma^2}{T} \ln\left(\frac{1}{\beta}\right)} + O(T^{-1/\max\{n, 2\}}),
\]

where \( n \) is the dimension of \( x \) and \( \sigma \) is as in Assumption II.1. Further, if \( T_0 = \infty \), then as \( t \to \infty \), \( \epsilon \to 0 \), i.e., the set \( \mathcal{P}_{t+1} \) shrinks to the singleton \( \mathbb{P}_{t+1} \) at a rate \( O(1/T^{-1/\max\{n, 2\}}) \).

In practice, \( T_0 \) and \( \beta \) need to be selected empirically, in order to efficiently address the particular problem that leverages the characterization of (1). We provide all the proofs of the lemmas and theorems in Appendix.

IV. CHARACTERIZATION OF RANDOM DYNAMICAL ENVIRONMENTS IN A PARAMETERIZED FAMILY

The construction of the empirical distribution \( Q_{t+1} \) of the previous section relies on the knowledge of \( f \). When \( f \) is unknown, one may represent \( f \) as belonging to a parameterized class of functions. Such as the approach adopted in the neural networks field and Koopman operator theory. Here, we focus on the case that \( f \) is approximated by a linear combination of a class of functions or “predictors” as follows.

Assumption IV.1 (Environment predictor class) There exists a set of predictors \( f(i) : \mathbb{R}_{\geq 0} \times \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^n \), \( (t, x, d) \mapsto f(i)(t, x, d), i \in \{1, \ldots, p\} \), such that: (1) The vector fields \( f(1), f(2), \ldots, f(p) \) are linearly independent almost everywhere. (2) There exists potentially time-varying coefficients \( \alpha^* := (\alpha_1^*, \ldots, \alpha_p^*) \in \mathbb{R}^p \) such that

\[
f(t, x, d) = \sum_{i=1}^{p} \alpha_i^* f(i)(t, x, d).
\]

As the selection of the predictors is not the subject of this study, we assume that the predictors are found in advance, and hence they are known to the learning algorithm.

The construction of an effective ambiguity set now depends on learning the dynamical environment mapping. Let us denote by \( \alpha \equiv \alpha_t \) the estimated value of the parameter \( \alpha^* \) at time \( t \). To construct \( \mathcal{P}_{t+1} \), consider \( T \) predictions of
Now, we select the empirical 
\[ \hat{\Sigma}_k^{(i)}(\alpha, d) := f^{(i)}(t, \hat{x}_t, d) + \frac{\hat{x}_{k+1} - f^{(i)}(k, \hat{x}_k, d_k)}{\alpha_1^p} \]
for each \( k \in \mathcal{T} \), \( i \in \{1, \ldots, p\} \), and given \( d := d_i \), we define
\[ \xi_k^{(i)}(\alpha, d) := f^{(i)}(t, \hat{x}_t, d) + \frac{\hat{x}_{k+1} - f^{(i)}(k, \hat{x}_k, d_k)}{\alpha_1^p} \]

Now, we select the empirical \( \hat{P}_{t+1} = \hat{P}_{\alpha}(\alpha, d) \), as follows:
\[
\hat{P}_{t+1} := \frac{1}{T} \sum_{k \in \mathcal{T}} \delta_{\alpha, \xi_k^{(i)}(\alpha, d)}.
\]  
(3)

The following result enables the construction of the ambiguity set \( \mathcal{P}_{t+1} \), relying on both \( d \) and \( \alpha \), which satisfies \( \hat{d} \).

**Theorem IV.1 (Adaptive dynamic ambiguity set)**

Assume that the data set \( \mathcal{D} \) is accessible, \( \forall t \). Further, let Assumption [IV.1] on the environment predictor class, hold for some \( \alpha^* \) at time \( t \). Then, given a confidence level \( \beta \in (0, 1) \), horizon parameter \( T_0 \), and a learning parameter \( \alpha \equiv \alpha_t \in \mathbb{R}^p \), there exists a scalar \( \hat{c} \) such that \( \hat{d} \) holds by selecting
\[
\mathcal{P}_{t+1} := \mathbb{B}_{\hat{c}}(\hat{P}_{t+1}) = \{ P | d_W(P, \hat{P}_{t+1}) \leq \hat{c} \},
\]
where \( \hat{c} = \epsilon + \| \alpha^* - \alpha \|_\infty H(t, T, d) \), with
\[
H(t, T, d) := \frac{1}{T} \sum_{i=1}^p \sum_{k \in \mathcal{T}} \| f^{(i)}(k, \hat{x}_k, d_k) - f^{(i)}(t, \hat{x}_t, d) \|,
\]
and the radius \( \hat{c} \) is selected as in Lemma [III.7].

Theorem [IV.1] indicates that, if we select \( \alpha \) wisely, i.e., \( \alpha \equiv \alpha^* \), then the adaptive dynamic ambiguity set is identical to that of \( \hat{d} \).

To estimate an unknown \( \alpha^* \) while preserving the probabilistic guarantees, we propose an online learning algorithm that attempts to bring \( \alpha \) close to \( \alpha^* \) with high probability. Intuitively, our approach is based on the comparison of new obtained data with updates given by a predictor combination.

**Theorem IV.2 (Learning of \( \alpha^* \))**

Let the data set \( \mathcal{D} \) and predictors \( \{ f^{(i)} \}_{i=1}^\mathcal{G} \) be given. For each \( k \in \mathcal{T} \) and \( i \in \{1, \ldots, p\} \), let us denote \( f^{(i)}_k := f^{(i)}(k, \hat{x}_k, d_k) \). Consider the data matrix \( A \equiv A_t \in \mathbb{R}^{p \times p} \) with
\[
A(i, j) := \frac{1}{T} \sum_{k \in \mathcal{T}} \langle f^{(i)}_k, P_k f^{(j)}_k \rangle, \quad i, j \in \{1, \ldots, p\},
\]
where \( P_k \) is an online regularization matrix at time \( k \), and let us consider the data vector \( b \equiv b_i \in \mathbb{R}^p \), with components
\[
b(i) := \frac{1}{T} \sum_{k \in \mathcal{T}} \langle \hat{x}_{k+1}, P_k f^{(i)}_k \rangle, \quad i \in \{1, \ldots, p\}.\]

Given \( \eta > 0 \), we select \( P_k \) such that \( \| P_k f^{(i)}_k \| \leq \eta \) for all \( i \in \{1, \ldots, p\} \), \( k \in \mathcal{T} \), and select \( \alpha \equiv \alpha_t \) to be
\[
\alpha = A_t^b,
\]  
(4)
where \( A_t^b \) denotes the Moore–Penrose inverse of \( A_t \). Let Assumption [II.4] and Assumption [IV.1] hold, and take
\[
\epsilon := \sigma \eta \sqrt{np} \sigma_{\min}^{-1}(A),
\]
where \( \sigma \) is that in Assumption [II.1] the constant \( \epsilon \approx 2.718 \), and \( \sigma_{\min}(A) \) is the minimal non-zero principal singular value

*Fig. 1: Online characterization of \( \mathcal{P}_{t+1} \), with (without) \( f \). The dark line is the trajectory of \( \hat{c} \) and the gray part is yet to be revealed. At \( t \), we obtain \( \mathcal{P}_{t+1} \) with its elements supported on \( T_0 = 3 \) shaded regions with high probability. Each region \( k \) has center \( \hat{x}_k \) and radius proportional to \( \epsilon \). Note the centers of these regions are related to a known (learned) point \( f(t, \hat{x}_t, d) \), they are close if the learning is effective.*

of \( A \). Then by selecting \( \gamma = nc/e \) the parameter \( \alpha \) is ensured to be close to \( \alpha^* \) with high probability in the following sense:
\[
\Prob(\|\alpha - \alpha^*\|_\infty \leq \gamma) \geq 1 - \exp\left(-\frac{(nc - \gamma)^2 T^2}{2((2T - 1)c\gamma + nc\gamma)}\right).
\]

In particular, selecting \( \gamma \leq nc/e \), we obtain a non-trivial bound with a slow confidence growth rate as follows
\[
\Prob(\|\alpha - \alpha^*\|_\infty \leq \gamma) \geq 1 - \frac{1}{\gamma} n\sigma \eta \sqrt{np} \sigma_{\min}^{-1}(A).
\]

**Theorem IV.2** provides an online computation of a real-time \( \alpha^* \) that is close to \( \alpha^* \) within a time varying distance \( \gamma \) with arbitrary high probability, where this distance \( \gamma \) depends only on the environment predictors as well as on the data sets. Note that the confidence of selecting \( \gamma \) is a bound of \( \|\alpha - \alpha^*\|_\infty \) increases exponentially as we increase the length \( T \) of the data sets. This motivates us to propose a computable dynamic ambiguity set, described as in Theorem [IV.1] by selecting its dynamic radius as
\[
\hat{c} = \epsilon + \gamma H(t, T, d),
\]  
(5)
where \( \epsilon, \gamma > nc \) and \( H \) are chosen as in Lemma [III.7], Theorem [IV.2] and Theorem [IV.1] respectively. Such selection results in modified guarantees of (2) as follows
\[
\Prob(\mathcal{P}_{t+1} \in \mathcal{P}_{\alpha}) \geq \left(1 - \beta\right) \left(1 - \exp\left(-\frac{(nc - \gamma)^2 T^2}{2((2T - 1)c\gamma + nc\gamma)}\right)\right),
\]  
(6)
when as time \( t \) increases with a selection of \( T_0 = \infty \) (or \( T = t \)), the confidence value on the right hand side increases to \( 1 - \beta \) exponentially fast. Fig. 1 compares the adaptation of the ambiguity set with and without knowing \( f \).

**Remark IV.1 (Data-driven selection of the radius)**

The radius of the adaptive ambiguity set (5) depends on the unknown, noise-related parameter \( \sigma \), the regularization constant \( \eta \), and on the online parameters \( \sigma_{\min}(A) \). In many engineering problems, an upper bound \( \sigma \) of the noise-related parameter can be determined a-priori or empirically. The parameter \( \eta \), together with the regularization matrices \( P \), is introduced to ensure that (5) is well posed. In particular, \( P \) can be a diagonal matrix with each diagonal term scaling its corresponding components. At each \( t \), the computation (4) needs an additional online regularization matrix, denoted by \( P_t \). For example, \( P_{t-1} \) can be a diagonal matrix with the \( j \)th diagonal term equal to \( 1/(\sqrt{p} \max_{i \in \{1, \ldots, p\}} |f^{(i)}_{t-1}(j)|) \), ...
where $f_{i-1}^{(j)}$ is the $j^\text{th}$ component of $f_{i-1}$, which results in $\eta = 1$. Finally, $\sigma_{\text{min}}(A)$ relies on the selection of the model set $\{f^{(i)}\}$, as well as the other two parameters $\eta$ and $\sigma$. In practice, all the zero singular values of $A$ is perturbed by the noise with a factor of $\sigma$. One could select the minimal non-zero principal singular value to be $\sigma_{\text{min}}(A) = \min_i \{\sigma_i(A) \mid \sigma_i(A) > 0, i \in \{1, \ldots, p\}\}$.

**Online Procedure:** To summarize, our online learning methodology is given in Algorithm table. Our approach leverages the adaptation of a dynamic ambiguity set, together with $a$-priori knowledge of $d$, and learns model parameter $\alpha$, and characterizes the unknown $f$ online via $P$.

**P-Learning 1 Learn($I, d$)**

**Require:** $\{f^{(i)}\}$, $T_0$, $\eta$, $\theta$ and $t = 1$;

**Ensure:** Online $\alpha$, $\hat{P}$, $\hat{e}$

1: repeat
2: Update data set $I := I_t$ and knowledge $d := d_t$;
3: Compute $\alpha := \alpha_t$ as in (4);
4: Select $\hat{P}_{t+1}$ as in (5) and $\hat{e} := \hat{e}_t$ as in (6);
5: Leverage $(\hat{P}_{t+1}, \hat{e})$ as characterization of $f$;
6: $t \leftarrow t + 1$;
7: until time $t$ stops.

**V. SIMULATIONS**

In this section, we illustrate the previous results on a simple vehicle example. Consider a vehicle driving under various road conditions, where its control signal is derived in advance, according to a path-planner in an ideal environment.

Our goal is to learn the real-time environment and estimate the system states via our adaptive $P$-Learning algorithm. Our vehicle is modeled as a differential-drive robot subject to uncertainty, see [17]:

$$
\begin{align*}
    x_1^+ &= x_1 + h \cos(x_3)u_1 + hw_1, \\
    x_2^+ &= x_2 + h \sin(x_3)u_1 + hw_2, \\
    x_3^+ &= x_3 - hu_2 + hw_3,
\end{align*}
$$

$$
\begin{align*}
    u_1 &= \frac{r}{2} (v_1 + v_r + e_1), \\
    u_2 &= \frac{r}{2R} (v_1 - v_r + e_2),
\end{align*}
$$

where $x := (x_1, x_2, x_3) \in \mathbb{R}^2 \times [-\pi, \pi] \cong \mathbb{R} \times \mathbb{S}^1$ stands for vehicle position and orientation on the 2-D plane. We denote by $x^+$ the state at the next time step and $u := (u_1, u_2, u_3)$ a zero-mean, mixture of Gaussian and Uniform distributions, which are subGaussian uncertainties with $\sigma = 0.5$. We assume $x_0 = (0, 0, 0)$ and $h = 10^{-3}$. The velocity $u := (u_1, u_2)$ is determined by a wheel radius $r = 0.15$ m, the distance between wheels $R = 0.4$ m, the given wheel speed $d := (v_1, v_2)$ and an unknown parameter $e := (e_1, e_2)$, which depends on the wheel and road conditions. For simulation purposes, we assume that the vehicle may move over three road zones, a slippery zone with $e^{(1)} = (4, 0)$, a sandy zone with $e^{(2)} = (-6, 0)$, and a smooth, regular zone with

Note that Assumption [V.I] holds with $\alpha^* := (0.6, 0.4, 0)$ in the slippery zone, $\alpha^* := (1.6, -0.6, 0)$ in the sandy zone and $\alpha^* := (1, 0, 0)$ in the smooth zone. We select $T_0 = 300$, and, at each time $t$, we have access to model sets $\{f^{(i)}\}$, as well as the real-time data set $I_t$ and $d$. Note that the notions of inner product and norm are those defined on the vector space $T(\mathbb{R}^2 \times \mathbb{S}) \equiv \mathbb{R}^3$. Recall that $h = 10^{-3}$, so a $T_0 = 300$ corresponds to a time window of order 0.3sec. We select online diagonal regularization matrices $P$ with diagonal $1/(\sqrt{3} \max_{i=1,2,3} |f^{(i)}|)$ for $j = 1, 2$ and for $j = 3$, resulting in $\eta = \max_{i,k} \langle P_k f^{(i)} \rangle$.

Fig. 3 demonstrates the real-time parameter learning of $\alpha_1$ and $\alpha_2$. It can be seen that these unknown parameters are effectively learned and tracked over time. Fig. 4 shows the quality of the learned parameter $\alpha$ and its effect on the determination of the radius of the adaptive ambiguity set. We note that, for a particular noise realization sequence, the estimated value $\sigma = n \sigma_{\text{min}}(A) + \theta$, with $\theta = 0.01$, upper bounds $\|f - \alpha\|_{\infty}$ in high probability. The large spikes in the figure are due to the change of zone, resulting in a large error. This is expected, as the true $\alpha^*$ changed
discontinuously. Meanwhile, the estimated radius $\hat{\epsilon}$ of the adaptive ambiguity set, calculated as in (5), is a conservative estimate of the unknown a-priori $\epsilon$ as in Theorem [V.I]. The true $\hat{\epsilon}$ captures exactly the ambiguity set over the time sequence $T$, for a $\beta = 0.05$. Over time, we empirically see the difference between the approximated $\hat{\epsilon}$ via $\gamma$ and the true one become close. In practice, the radius $\hat{\epsilon}$ can be selected in a data-driven fashion, e.g., as in Remark [V.I] to serve as a way for less conservative estimation of the radius in probability. We show in Fig. 5, the online guarantee (6) of this particular case study, and various samples of (6), obtained by taking different time horizon $T_0$.

VI. CONCLUSIONS

In this paper, we proposed an approach for online learning of unknown and uncertain dynamical environments in a parameterized class. The proposed method allows us to learn the environment, while providing an online characterization of the approximation via online-quantifiable probabilistic guarantees. The approach opens a way for the robust integration of the online learning with control design. A robotic example was used to demonstrate the efficacy of the method.

APPENDIX

We adapt these two subGaussian properties for proofs.

Lemma 1 (\textit{∞-norm of subGaussian vectors have subGaussian tails} [13]) If Assumption II.1 holds, then for each $k = 0, 1, 2, \ldots$ and any $\eta \geq 0$, we have

$$\Pr (\|w_k\|_\infty \geq \eta) \leq 2n \exp \left( -\frac{\eta^2}{2\sigma^2} \right).$$

Proof: Lemma 1 Let $w_{k,i}$ denote the $i$th component of $w_k$ where $i \in \{1, \ldots, n\}$. We apply the definition of $\infty$-norm as the following

$$\Pr (\|w_k\|_\infty \geq \eta) = \Pr \left( \max_{i \in \{1, \ldots, n\}} |w_{k,i}| \geq \eta \right),$$

$$= 1 - \Pr (|w_{k,i}| \leq \eta, \forall i \in \{1, \ldots, n\}).$$

By the independence of $w_{k,i}$ as in Assumption II.1, we have

$$\Pr (|w_{k,i}| \leq \eta, \forall i \in \{1, \ldots, n\}) = \Pr (|w_{k,1}| \leq \eta) \cdots \Pr (|w_{k,n}| \leq \eta).$$

Then for each $i \in \{1, \ldots, n\}$, we have

$$\Pr (|w_{k,i}| \leq \eta) = 1 - \Pr (|w_{k,i}| \geq \eta),$$

$$\geq 1 - 2 \exp \left( -\frac{\eta^2}{2\sigma^2} \right),$$

which results in

$$\Pr (|w_{k,i}| \leq \eta, \forall i \in \{1, \ldots, n\}) \geq \left[ 1 - 2 \exp \left( -\frac{\eta^2}{2\sigma^2} \right) \right]^n.$$ Finally, we have

$$\Pr (\|w_k\|_\infty \geq \eta) \leq 1 - \left[ 1 - 2 \exp \left( -\frac{\eta^2}{2\sigma^2} \right) \right]^n,$$

$$\leq 2n \exp \left( -\frac{\eta^2}{2\sigma^2} \right).$$

Lemma 2 (Bounded moments of normed-subGaussian vectors [13]) If Assumption II.1 holds,

$$\E [\|w_k\|_\infty] \leq n\sigma l \frac{t^{1+1}}{l}, \quad \forall l \in \mathbb{Z}_{>0}.$$

Proof: Lemma 2 The moments can be equivalently computed by

$$\E [\|w_k\|_\infty] = \int_0^\infty \Pr (\|w_k\|_\infty \geq \eta) l\eta^{l-1} d\eta.$$

Applying the result of Lemma 1, we have

$$\E [\|w_k\|_\infty] \leq 2nl \int_0^\infty \exp \left( -\frac{\eta^2}{2\sigma^2} \right) l\eta^{l-1} d\eta.$$

By the variable substitute $\bar{\eta} := \frac{\eta}{\sqrt{2\sigma^2}}$, the above bound becomes

$$\E [\|w_k\|_\infty] \leq nl(2\sigma^2)^{\frac{1}{2}} \int_0^\infty \exp (-\bar{\eta}) \bar{\eta}^{\frac{1}{2}-1} d\bar{\eta}.$$

By the definition of $\Gamma$ function and its property, we have

$$\E [\|w_k\|_\infty] \leq n\sigma l \frac{t^{1+1}}{l}.$$
**Proof of Lemma [III.1]** We prove this in two steps. First, we exploit the properties of \( w_t \). Then, we show the probabilistic guarantees of the dynamic ambiguity set.

**Step 1 (subGaussian Wasserstein distances):** Given Assumption [I.1] on the subGaussian \( \mathcal{W}_t \), the following holds:

(a) Following [18, Lemma 1], the distribution \( \mathcal{W}_t \) satisfies

\[
d_W(\mathcal{W}_{t_1}, \mathcal{W}_{t_2}) \leq \sqrt{2n\sigma^2}D(\mathcal{W}_{t_1}, \mathcal{W}_{t_2}), \quad \forall \mathcal{W}_t \in \mathcal{M}(\mathbb{R}^n),
\]

where \( d_W \) and \( D \) denote the 1-Wasserstein metric and the KL divergence of two distributions \( \mathcal{W}_t \) and \( \mathcal{W}_r \), respectively; and the set \( \mathcal{M}(\mathbb{R}^n) \) is the space of all probability distributions supported on \( \mathbb{R}^n \) with a finite first moment.

(b) Let us denote \( \mathcal{W}_{t_k} := \frac{1}{T} \sum_{k \in T} \delta_{\mathbf{x}_k} \). Note that, by the assumption that \( w_k \) is i.i.d. for \( k \in T \), \( \mathcal{W}_t \) is the empirical distribution of \( w_t \). Then, following [18, Theorem 6], we claim that the equation (8) holds if and only if the random variable \( d_W(\mathcal{W}_t, \mathcal{W}_r) \) is \( \sqrt{n\sigma}/\sqrt{T} \)-subGaussian for all \( t \). Equivalently, for all \( t \) and all \( \alpha \in \mathbb{R} \), we have

\[
E \left[ \exp \left( \alpha \cdot d_W(\mathcal{W}_t, \mathcal{W}_r) - E[d_W(\mathcal{W}_t, \mathcal{W}_r)] \right) \right] \leq \exp \left( \frac{\alpha^2 n \sigma^2}{2T} \right).
\]

(c) At each \( t \), let us consider \( C_t := E[d_W(\mathcal{W}_t, \mathcal{W}_t)] \). Following [12, Theorem 1] and [19, Theorem 3.1], we claim that, for \( n \neq 2 \), there exists a constant \( c \), depending on Assumption [I.1] such that

\[
C_t \leq c \cdot T^{-1/\max\{n, 2\}}.
\]

In particular, we have \( c = 3^{3.5} \cdot 2^{10} \cdot \sigma^3 \) when \( n = 1 \). When \( n > 3 \), the parameter \( c \) is calculated by:

\[
c := (1 + \sqrt{2})(1 + \sqrt{3}) \cdot 3^{3.5-1/n} \cdot 2^7 \cdot \sigma^3 \cdot n^{1.5}.
\]

**Step 2 (Probabilistically-guaranteed dynamic ambiguity sets):** Knowing that the distributions \( \mathbb{P}_{t+1} \) and \( \mathcal{W}_t \) obey the environment dynamics (1), in other words, \( \mathbb{P}_{t+1} = f(t, \mathbf{x}_t, d_t) + \mathcal{W}_t \), holds for any deterministic \( f \). Similarly, we have \( \mathcal{Q}_{t+1} \equiv f(t, \mathbf{x}_t, d_t) + \mathcal{W}_t \). Therefore, by the definition of the Wasserstein metric, we claim that

\[
d_W(\mathcal{Q}_{t+1}, \mathbb{P}_{t+1}) = d_W(\mathcal{W}_{t+1}, \mathcal{W}_t), \quad \forall d, \forall t,
\]

where the empirical distribution \( \mathcal{Q}_{t+1} \) is described as in the statement of the lemma. Then by the Markov inequality, for any \( \gamma \geq 0 \) and \( \lambda \geq 0 \), we have

\[
\text{Prob}(d_W(\mathcal{Q}_{t+1}, \mathbb{P}_{t+1}) \geq \gamma) = \text{Prob}(d_W(\mathcal{W}_{t+1}, \mathcal{W}_t) \geq \gamma)
\]

\[
= \text{Prob}(\exp(\lambda \cdot d_W(\mathcal{W}_{t+1}, \mathcal{W}_t)) \geq \exp(\gamma \lambda)),
\]

\[
\leq \exp(-\gamma \lambda) E \left[ \exp(\lambda \cdot d_W(\mathcal{W}_{t+1}, \mathcal{W}_t)) \right].
\]

Then by the property (9), we have

\[
\text{Prob}(d_W(\mathcal{Q}_{t+1}, \mathbb{P}_{t+1}) \geq \gamma) \leq \exp \left( - (\gamma - C_t) \lambda + \frac{n \lambda^2 \sigma^2}{2T} \right),
\]

where \( C_t := E[d_W(\mathcal{W}_{t+1}, \mathcal{W}_t)] \). The optimal \( \lambda \in \mathbb{R}_{\geq 0} \) that results in the tightest bound is taken to be

\[
\lambda := \begin{cases} (\gamma - C_t) T, & \text{if } \gamma > C_t, \\ 0, & \text{if } \gamma \leq C_t, \end{cases}
\]

resulting in, when \( \gamma > C_t \)

\[
\text{Prob}(d_W(\mathcal{Q}_{t+1}, \mathbb{P}_{t+1}) \geq \gamma) \leq \exp \left( - (\gamma - C_t) \frac{T}{2n \sigma^2} \right).
\]

Finally, let \( \gamma > C_t \) be

\[
\gamma = \epsilon := \epsilon(T, \beta) = \sqrt{2n \sigma^2} \ln \left( \frac{1}{\beta} \right) + c \cdot T^{-1/\max\{n, 2\}},
\]

where \( c \) is determined as in step 1. This results in

\[
\text{Prob}(d_W(\mathcal{Q}_{t+1}, \mathbb{P}_{t+1}) \geq \epsilon) \leq \beta,
\]

and further, we have

\[
\text{Prob}(d_W(\mathcal{Q}_{t+1}, \mathbb{P}_{t+1}) \leq \epsilon) \geq 1 - \beta.
\]

Equivalently, we have (2) by selecting \( \mathbb{P}_{t+1} := \mathbb{B}_c(\mathcal{Q}_{t+1}) \).

If we take \( T_0 = \infty \), we have \( T = t \) with \( t \to \infty \). Then, it obviously follows that \( \mathbb{P}_{t+1} \) shrinks to \( \mathbb{P}_{t+1} \) as \( t \to \infty \). ■

**Proof of Theorem [IV.1]** From the triangular inequality,

\[
d_W(\mathbb{P}_{t+1}, \hat{\mathbb{P}}_{t+1}) \leq d_W(\mathbb{P}_{t+1}, \mathcal{Q}_{t+1}) + d_W(\mathcal{Q}_{t+1}, \hat{\mathbb{P}}_{t+1}),
\]

where by Lemma [III.1] we have

\[
\text{Prob}(d_W(\mathbb{P}_{t+1}, \mathcal{Q}_{t+1}) \leq \epsilon) \geq 1 - \beta.
\]

To evaluate the second term above, we apply the definition of Wasserstein metric, given as

\[
d_W(\mathcal{Q}_{t+1}, \hat{\mathbb{P}}_{t+1}) = \sup_{h \in L} \int_Z h(\xi) Q_{t+1}(d\xi) - \int_Z h(\xi) \hat{P}_{t+1}(d\xi),
\]

where the set \( Z \) is the support of the random variable \( \mathbf{x}_{t+1} \) and the set \( L \) is the space of all Lipschitz functions defined on \( Z \) with Lipschitz constant 1. Then, we equivalently write

\[
d_W(\mathcal{Q}_{t+1}, \hat{\mathbb{P}}_{t+1}) = \sup_{h \in L} \left\{ \frac{1}{T} \sum_{k \in T} \left( h(\xi_k) - h \left( \sum_{i=1}^{p} \alpha_i \xi_k^{(i)} \right) \right) \right\},
\]

\[
\leq \sup_{h \in L} \left\{ \frac{1}{T} \sum_{k \in T} \left| h(\xi_k) - h \left( \sum_{i=1}^{p} \alpha_i \xi_k^{(i)} \right) \right| \right\}
\]

\[
\leq \frac{1}{T} \sum_{k \in T} \left\| \xi_k - \sum_{i=1}^{p} \alpha_i \xi_k^{(i)} \right\|
\]

\[
= \frac{1}{T} \sum_{k \in T} \left\| \sum_{i=1}^{p} (\alpha_i - \alpha_i^*) (f^{(i)}(k, \hat{\mathbf{x}}_k, \mathbf{d}_k) - f^{(i)}(t, \hat{\mathbf{x}}_t, \mathbf{d}_t)) \right\|
\]

\[
\leq \sum_{i=1}^{p} |\alpha_i^* - \alpha_i| \left\| f^{(i)}(k, \hat{\mathbf{x}}_k, \mathbf{d}_k) - f^{(i)}(t, \hat{\mathbf{x}}_t, \mathbf{d}_t) \right\|
\]

\[
\leq \left\| \alpha^* - \alpha \right\|_{\infty} \mathcal{H}_T(t, \mathbf{d}),
\]

where the first line comes from the Wasserstein distance between discrete distributions \( \mathcal{Q}_{t+1} \) and \( \hat{\mathbb{P}}_{t+1} \); the second line is followed by adding absolute operation and applying triangular inequality; the third line comes from the definition of the set \( \mathcal{L} \); the fourth line is from the definition of the
environment predictions and Assumption [IV.1] on the representation of unknown environment \( f \); the fifth one applies triangular inequality, and the last line uses the Hölder’s inequality. Note that the derived bound of \( d_w(Q_{t+1}, \hat{P}_{t+1}) \) holds true with probability one. Then, by summing the probability bounds of the two terms, we obtain
\[
\Pr\left( d_w(P_{t+1}, \hat{P}_{t+1}) \leq \epsilon \right) \geq 1 - \beta,
\]
which can be written as [2] with \( P_{t+1} := \mathbb{E}_t(\hat{P}_{t+1}) \).

**Proof of Theorem [IV.2]** To see this, first, we will bound \( \|\alpha - \alpha^*\|_\infty \) by samples of \( \hat{w}_k \), \( k \in T \), then we apply concentration results for probabilistic bounds on \( \|\alpha - \alpha^*\|_\infty \).

**Step 1 (Bound on \( \|\alpha - \alpha^*\|_\infty \):** At each \( k \in T \), let us denote by \( \hat{w}_k \) a sample of \( w_k \) represented by
\[
\hat{w}_k := \hat{x}_{k+1} - \sum_{j=1}^{p} \alpha^*_j f_k^{(j)}.
\]
Then, we project the data \( \hat{x}_{k+1} \) on the direction of each regularized predictor \( i \in \{1, \ldots, p\} \),
\[
(\hat{x}_{k+1}, P_k f_k^{(i)}) = \left( \sum_{j=1}^{p} \alpha_j^* f_k^{(j)} + \hat{w}_k, P_k f_k^{(i)} \right),
\]
where, given a scalar \( \eta > 0 \), the time-dependent regularization matrix is selected so that \( \|P_k f_k^{(i)}\| \leq \eta \), for all \( i \in \{1, \ldots, p\} \). Averaging the above equalities over \( k \in T \), we have for each component \( i \):
\[
b(i) = \frac{1}{T} \sum_{k \in T} \langle \hat{x}_{k+1}, P_k f_k^{(i)} \rangle,
\]
where
\[
b(i) := \frac{1}{T} \sum_{k \in T} \langle \hat{w}_k, P_k f_k^{(i)} \rangle,
\]
\[
A(i,j) := \frac{1}{T} \sum_{k \in T} \langle f_k^{(j)}, P_k f_k^{(i)} \rangle,
\]
By selecting \( \alpha \) as in (4), the relation \( b(i) = \sum_{j=1}^{p} \alpha_j A(i,j) \) holds, for each \( i \). By subtracting the above equation from the one related to \( \alpha^* \), we have
\[
\sum_{j=1}^{p} (\alpha_j - \alpha^*_j) A(i,j) = \frac{1}{T} \sum_{k \in T} \langle \hat{w}_k, P_k f_k^{(i)} \rangle.
\]
By taking the Moore–Penrose inverse of \( A \), we obtain
\[
\alpha - \alpha^* = A^\dagger c,
\]
where the vector \( c \) is
\[
\frac{1}{T} \sum_{k \in T} \left( \langle \hat{w}_k, P_k f_k^{(1)} \rangle, \ldots, \langle \hat{w}_k, P_k f_k^{(p)} \rangle \right)^\top.
\]
Take the \( \infty \)-norm operation on both sides, we have
\[
\|\alpha - \alpha^*\|_\infty \leq \|A^\dagger\|_\infty \|c\|_\infty,
\]
where we can write \( \|c\|_\infty \) as the following
\[
\|c\|_\infty := \frac{1}{T} \max_{i \in \{1, \ldots, p\}} \left\{ \left\| \sum_{k \in T} \langle \hat{w}_k, P_k f_k^{(i)} \rangle \right\| \right\},
\]
\[
\leq \frac{1}{T} \max_{i \in \{1, \ldots, p\}} \left\{ \sum_{k \in T} \left\| \langle \hat{w}_k, P_k f_k^{(i)} \rangle \right\| \right\},
\]
\[
\leq \frac{1}{T} \max_{i \in \{1, \ldots, p\}} \left\{ \sum_{k \in T} \|\hat{w}_k\| \cdot \|P_k f_k^{(i)}\| \right\},
\]
\[
\leq \frac{\sqrt{\eta}}{T} \sum_{k \in T} \|\hat{w}_k\|_\infty,
\]
where we achieve the first inequality by moving the absolute operation into the sum operation; the second inequality uses Hölder’s inequality; the third inequality is achieved by moving max operation into sum operation; the forth one is achieved by the norm equivalence and the fact that \( \|P_k f_k^{(i)}\| \leq \eta \) for all \( i \in \{1, \ldots, p\} \). Then, we achieve the following bound
\[
\|\alpha - \alpha^*\|_\infty \leq \eta \sqrt{n} \|A^\dagger\|_\infty \left[ \frac{1}{T} \sum_{k \in T} (\|\hat{w}_k\|_\infty) \right]. \tag{10}
\]
Note that, by the equivalence of the matrix norm, we have
\[
\|A^\dagger\|_\infty \leq \sqrt{p} \|A^\dagger\|_2 = \sqrt{p} \sigma_{\max}(A) = \sqrt{p} \sigma_{\max}^{-1}(A),
\]
where \( \sigma_{\max}(A) \) and \( \sigma_{\min}(A) \) denote the maximal singular value of \( A^\dagger \) and the minimal principal non-zero singular value of \( A \), respectively.

**Step 2 (Measure concentration on \( \|\alpha - \alpha^*\|_\infty \):** In this step, we find the probabilistic bound of \( \|\alpha - \alpha^*\|_\infty \) by developing that of \( \|\hat{w}_k\|_\infty \). Equivalently, given any \( \gamma > 0 \), we compute the following term
\[
\Pr\left( \frac{1}{T} \sum_{k \in T} (\|\hat{w}_k\|_\infty) \geq \gamma \right). \tag{11}
\]
There are two options to obtain the bound.

(1) **A naive bound via Markov inequality:** By the Markov inequality, we obtain a bound (11) as
\[
\Pr\left( \frac{1}{T} \sum_{k \in T} (\|\hat{w}_k\|_\infty) \geq \gamma \right) \leq \frac{1}{\gamma^2} \sum_{k \in T} \mathbb{E}[\|\hat{w}_k\|_\infty].
\]
By Lemma [2] we have \( \mathbb{E}[\|\hat{w}_k\|_\infty] \leq n \sigma \), resulting in
\[
\Pr\left( \|\alpha - \alpha^*\|_\infty \leq \gamma \right) \geq 1 - \frac{1}{\gamma^2} n \sigma \sqrt{np} \sigma_{\min}^{-1}(A),
\]
with non-trivial bound if we take \( \gamma > n \sigma \sqrt{np} \sigma_{\min}^{-1}(A) \).

(2) **A bound with exponential decay over \( T \):** For any \( \lambda \geq 0 \), the probability (11) is equivalent to
\[
\Pr\left( \exp\left( \frac{1}{T} \sum_{k \in T} \left( \lambda \|\hat{w}_k\|_\infty \right) \right) \geq \exp(\gamma \lambda) \right).
\]
By the Markov inequality to the above probability, we have

\[ \text{Prob}\left( \frac{1}{T} \sum_{k \in T} \|w_k\|_\infty \geq \gamma \right) \leq \exp(-\gamma \lambda) E\left[ \prod_{k \in T} \exp\left( \frac{\lambda}{T} \|w_k\|_\infty \right) \right]. \]

By Assumption II.1 on independence of \( w_k \), we have

\[ E\left[ \prod_{k \in T} \exp\left( \frac{\lambda}{T} \|w_k\|_\infty \right) \right] = \prod_{k \in T} E\left[ \exp\left( \frac{\lambda}{T} \|w_k\|_\infty \right) \right]. \]

For each \( k \in T \), we write each exp operation in its power series form as the following

\[ E\left[ \exp\left( \frac{\lambda}{T} \|w_k\|_\infty \right) \right] = E\left[ 1 + \sum_{l=1}^{\infty} \left( \frac{\lambda}{T} \right)^l \frac{\|w_k\|_\infty^l}{l!} \right], \]

\[ = 1 + \sum_{l=1}^{\infty} \left( \frac{\lambda}{T} \right)^l E\left[ \|w_k\|_\infty^l \right] \frac{1}{l!} \]

By Lemma 2 we have

\[ E\left[ \|w_k\|_\infty^l \right] \leq n\sigma l^{\frac{l}{2}+1}, \forall l = 1, 2, \ldots. \]

This gives

\[ E\left[ \exp\left( \frac{\lambda}{T} \|w_k\|_\infty \right) \right] \leq 1 + n \sum_{l=1}^{\infty} \left( \frac{\lambda \sigma e}{T} \right)^l. \]

To tighten the previous upper bound, consider any \( \lambda \) such that \( \lambda \in (0, \frac{T}{\sigma e}) \). Then the following bound holds

\[ E\left[ \exp\left( \frac{\lambda}{T} \|w_k\|_\infty \right) \right] \leq 1 + \frac{\lambda \sigma e}{T - \lambda \sigma e} \leq \exp\left( \frac{\lambda \sigma e}{T - \lambda \sigma e} \right). \]

Finally, we achieve

\[ \text{Prob}\left( \frac{1}{T} \sum_{k \in T} \|w_k\|_\infty \geq \gamma \right) \leq \exp(-\gamma \lambda + \sum_{k \in T} \frac{\lambda \sigma e}{T - \lambda \sigma e}). \]

Finding an optimal bound is hard, and therefore we find a sub-optimal bound by selecting \( \lambda \) to be

\[ \lambda = \begin{cases} \frac{T}{\sigma e} - \frac{nT}{2^2}, & \text{if } \gamma \geq \sigma ne, \\ 0, & \text{if } \gamma < \sigma ne. \end{cases} \]

Then, we have the following

\[ \text{Prob}\left( \frac{1}{T} \sum_{k \in T} \|w_k\|_\infty \geq \gamma \right) \leq \begin{cases} \exp\left( -\frac{(\sigma \epsilon - \gamma)^2 T^2}{4(2T - 1) \gamma \sigma e + n(\sigma e)^2} \right), & \text{if } \gamma \geq \sigma ne, \\ 1, & \text{if } \gamma < \sigma ne. \end{cases} \]

In words, the probability bounds on the quality of \( \alpha \) is

\[ \text{Prob}\left( \|\alpha - \alpha^*\|_\infty \leq \gamma \right) \geq 1 - \exp\left( -\frac{(nc - \gamma)^2 T^2}{2(2T - 1) \gamma \sigma e + nc^2} \right), \]

with any \( \gamma \geq nc \), where \( c := \sigma e \sqrt{nD} \sigma_{\min}^{-1}(A). \)

---

6We use two facts: 1) \( l^l \geq (l/e)^l \) and 2) \( l^{l-1} \leq 1 \), for all \( l \in \mathbb{Z}_{\geq 0} \), where the constant \( e = 2.71828\ldots \).

7We use the fact: \( 1 + x \leq \exp(x) \) for \( x \in \mathbb{R} \).

---
