ABSTRACT

We investigate the extinction, together with the radial velocity (RV) dispersion and distribution of red clump stars in the anticenter direction using spectra obtained with Hectospec on the MMT. We find that extinction peaks at Galactocentric radii of about 9.5 and 12.5 kpc, right in front of the locations of the Perseus and Outer arms and in line with the relative position of dust and stars in external spiral galaxies. The RV dispersion peaks around 10 kpc, which coincides with the location of the Perseus arm, yields an estimated arm–interarm density contrast of 1.3–1.5, and is in agreement with previous studies. Finally, we discover that the RV distribution bifurcates around 10–11 kpc into two peaks at +27 km s−1 and −4 km s−1. This seems to be naturally explained by the presence of the outer Lindblad resonance of the Galactic bar, but further observations will be needed to understand if the corotation resonance of the spirals arms also plays a role.

Key words: galaxies: individual (Milky Way) – Galaxy: disk – Galaxy: kinematics and dynamics – Galaxy: structure – stars: kinematics and dynamics

1. INTRODUCTION

Non-axisymmetric rotating substructures, such as a bar and spiral arms in the Milky Way, induce a corotation resonance (CR) as well as inner Lindblad resonance and outer Lindblad resonance (OLR) around certain Galactocentric radii (e.g., Weinberg 1994; Fux 2000; Quillen et al. 2011; Antoja et al. 2011). These resonances seem to be able to explain the moving groups in the velocity distribution in the solar neighborhood discovered from Hipparcos data and the Geneva–Copenhagen Survey (e.g., Dehnen 2000; De Simone et al. 2004; Quillen & Minchev 2005; Sellwood 2009). However, resonances from multiple patterns may exist and overlap, and moreover the Sun may not be located right on any of the resonance radii. Hence, it is difficult to distinguish the effects of resonances in the solar neighborhood. Observations of the velocity distribution outside the solar radius are needed to constrain the resonances.

We report in this Letter a resonance feature at a Galactocentric radius of 10–11 kpc in the radial stellar velocity distribution derived from MMT/Hectospec observations of 698 red clump stars in the anticenter direction. In Section 2 we briefly describe the observations, data reduction, and analysis. In Section 3, we identify the location of the Perseus arm and discuss possible reasons for the bifurcation seen in the radial velocity (RV) distribution. Finally, we summarize our findings in Section 4.

2. DATA REDUCTION AND ANALYSIS

We used MMT/Hectospec to obtain spectra with resolution R = 2500 of stars in four one-degree-diameter fields between l = 178°–182° at b = 0°. Red clump stars are selected as targets from the Two Micron All Sky Survey (2MASS) catalog by a single-color cut J − K > 0.65 mag. Close-by dwarf stars can overlap in intrinsic color with the red clump stars, but as the latter get reddened by extinction in the mid-plane the dwarf stars can be easily removed. The single-color selection of red clump stars is thus expected to be very efficient with only little contamination by other giant stars and remaining dwarf stars.

In total we obtained 993 spectra with mean S/N ≈ 17. The reduced spectra, of which three examples are shown in the top panel of Figure 1, show that later-type K/M giant stars and dwarf stars contain stronger MgH and TiO absorption features within 5000–5300 Å and 6000–6500 Å than red clump stars. After computing the equivalent width (EW) of the absorption features in each spectrum, we arrive at the distribution in the bottom panel of Figure 1 with a Gaussian peak of most, if not all, red clump stars plus a tail of higher EW caused by the MgH and TiO bands in the contaminating giant and dwarf stars. After conservatively selecting the stars with EW not larger than one standard deviation above the mean, we are left with 747 red clump stars. This implies a completeness of at least 85%, hence confirming the high effectiveness of the color selection. To enable the derivation of a smooth radial distribution in extinction and velocity below, we exclude another 46 stars with excessive local extinction as well as 3 stars that are 3σ outliers in velocity, leaving a final sample of 698 red clump stars. Three independent methods—H$_{\alpha}$ line fitting, synthetic template matching, and UλySS (Wu et al. 2011)—are used to extract a mean RV value and corresponding error from each spectrum.

Next, we use the Hipparcos (Perryman et al. 1997) and 2MASS (Skrutskie et al. 2006) catalog to infer, after taking into account photometric and parallax errors, the intrinsic J − K color index, and absolute K-band magnitude of the red clump stars: (J − K)$_{0}$ = 0.654±0.058 mag and $M_{K} = -1.547±0.311$ mag. The latter is in agreement with both Groenewegen (2008) and López-Corredoira et al. (2002), and since metallicity is at most weakly correlated with $M_{K}$ (Zhao et al. 2001), and likely less so for $M_{K}$, we can obtain accurate distance estimates to the red clump stars in the following way.

For each red clump star, the probability density function (PDF) of extinction given its observed color index,
the Bayesian theorem as

\[ p(A_K|J - K) \]

is computed, assuming it is a Gaussian distribution with dispersion given by the previously derived intrinsic \( J - K \) dispersion plus the \( J - K \) photometric error added in quadrature. Similarly, the likelihood of apparent \( K \)-band magnitude \( K \) given the distance modulus \( DM \) and \( A_K \), \( p(K|DM, A_K) \), is assumed to follow a Gaussian distribution with dispersion given by the previously derived intrinsic \( M_K \) dispersion together with the photometric uncertainty in \( K \). The PDF of the distance modulus given the observed \( J - K \) color and \( K \) then follows from the Bayesian theorem as

\[
p(DM|K, J - K) = \int p(K|DM, A_K)p(A_K|J - K) \times p(A_K)p(DM)dA_K, \tag{1}
\]

with adopted uniform priors \( P(A_K) \) and \( P(DM) \). Adopting as solar radius \( R_\odot = 8 \) kpc, the distance modulus \( DM \) is converted to Galactocentric radius \( R_{GC} \).

Figure 2 shows the distributions of \( K \)-band extinction \( A_K \), radial velocity dispersions \( \sigma_{RV} \), and \( RV \) versus \( R_{GC} \) distribution. Given a distance, the distribution in \( A_K \) follows by summing up \( p(A_K|J - K)p(DM|K, J - K) \) for all stars. The line in the top panel in Figure 2 shows the \( A_K \) with maximum probability. The shadow shows the 68% confidence region. There are two significant jumps, and hence dense dust regions around 9.5 kpc and 12.5 kpc are found in the distribution in \( A_K \).

The radial profile of \( \sigma_{RV} \) in the middle panel is obtained from the weighted variance of \( RV \), which equals to \( \sigma_{RV}^2 \) plus the squared measurement error of \( RV \), \( \epsilon_{RV}^2 \). The weight is given by \( p(DM|K, J - K) \) for each star with normalization. During the calculation, we assume that the probability of the measured \( RV \) is a Gaussian with sigma \( \epsilon_{RV}^2 \). The uncertainty of \( \sigma_{RV} \) is given from a bootstrap resampling process. It reveals that there is a clear bump at 10 kpc.

Finally, the bottom panel shows the \( RV \) versus \( R_{GC} \) distribution from combining the PDFs in \( RV \) and distance for each star. The uncertainties in \( RV \) are about 3.2 km s\(^{-1}\) and in \( R_{GC} \) are about 14.6% and smooth the total distribution. Even so, the velocity distribution shows two significant peaks around 10–11 kpc at RVs of about +27 km s\(^{-1}\) and −4 km s\(^{-1}\).

### 3. DISCUSSION

#### 3.1. Dusty Arms

The jump in extinction around 9.5 kpc in the top panel of Figure 2 indicates a broad and dense dust region in the path of the line of sight. Its location is just short of the Perseus arm at 9.9 kpc (Reid et al. 2009), implying that it is the dust lane of the spiral structure. Indeed, taking into account the Galactic rotation direction, the dust lane is in front of the stellar arm. Similarly, the jump in extinction around 12.5 kpc is in front of the Outer arm located at 13.1 kpc (Reid et al. 2009).

#### 3.2. Arm–Interarm Contrast

In the anticenter direction the measured radial velocity \( RV \) is approximately equal to the Galactic space or Cartesian velocity...
been found in the arm, following Antoja et al. (2011).

Here \( K \approx 1.3 \). Alternatively, if \( \sigma_R \) is proportional to \( \Sigma^{1/3} \) (Dehnen 1999), we obtain \( K \approx 1.5 \). The resulting contrast of \( K \approx 1.3 \) is in agreement with previous studies (Drimmel & Spergel 2001; Benjamin et al. 2005; Grosbøl et al. 2004).

3.3. Bifurcation Due to a Resonance?

The bifurcation in RV around 10–11 kpc could have different causes: (1) local dynamics of the spiral structure, (2) resonance of the spiral structure, or (3) resonance of the bar potential.

Quillen et al. (2011) argued that, within a density wave, the orientations of the orbits of the stars on the spiral arm are correlated with the orbits of the stars in the U – V velocity distribution. Since what we see is only the marginalization distribution over \( V \), an arc would be difficult to show. Even if the arc is elongated along \( V \) and thus shows a sharp peak in \( U \), it is hard to explain the \( \sim 30 \text{ km s}^{-1} \) gap between the two peaks. Moreover, the bifurcation is at a larger radius than the location of the Perseus arm. Therefore, it seems that the local orbital distribution in the spiral arm cannot be the main reason of the bifurcation.

If 10–11 kpc corresponds to the corotation radius of the spiral structure then its pattern speed is \( 20–22 \text{ km s}^{-1} \text{ kpc}^{-1} \), in agreement with Gerhard (2011). However, Antoja et al. (2011) show that spiral structure alone results typically in too little substructure in the velocity distribution.

The bifurcation can be the result of resonance with the Galactic bar. The pattern speed of the Galactic bar has been reported in the range from 30 to 65 km s\(^{-1}\) kpc\(^{-1}\) depending on different data and methods (Gerhard 2011). If we adopt 40 km s\(^{-1}\) kpc\(^{-1}\) and a flat rotation curve of \( v_r = 220 \text{ km s}^{-1} \) (Rodríguez-Fernandez & Combes 2008), the OLR radius is right around 10–11 kpc. It is then expected that stars group into inward and outward streams under the OLR radius, naturally explaining the bifurcation in RV. Meanwhile, the CR radius corresponding to this pattern speed is located around 5–6 kpc, which can explain the Hercules stream in the solar neighborhood. As even the bar pattern speed itself is not yet well determined, further investigation in both observations and theory are needed to verify the resonant origin of the bifurcation.

\( U \), but with opposite sign. The bump in \( \sigma_{RV} \) around 10 kpc indicates the mass center of the Perseus arm. Since the velocity dispersion in an equilibrium system is related to the mass density, the arm–interarm density contrast can be estimated. The peak value of \( \sigma_{RV} \) is 29.4 km s\(^{-1}\) at 10 kpc, while it decreases to 27.8 km s\(^{-1}\) at the interarm radius of around 11 kpc. Assuming an isothermal density distribution for the stars and a constant vertical-to-radial-velocity dispersion ratio \( \sigma_z/\sigma_R \) is proportional to \( \Sigma^{1/2} \), where \( \Sigma \) is the surface density. The arm–interarm contrast is then \( K \approx 1.3 \).

\( 2. \) a Perseus arm–interarm contrast between 1.3 and 1.5, in line with previous studies; and

\( 3. \) a strong bifurcation in the RV distribution around 10–11 kpc, likely related to the outer Lindblad resonance of the Galactic bar, although additional observations are needed to constrain a possible spiral CR.

\( \delta \Sigma \) is the incremental surface density in the arm, following Antoja et al. (2011).

4. SUMMARY

In this Letter, we use 698 red clump stars in the mid-plane of the Milky Way to derive the radial profile of extinction and RV dispersion, as well as the velocity–distance distribution in the anticenter direction. We find

1. dust lanes in front of the Perseus and Outer arms, consistent with external spiral galaxies;

2. a Perseus arm–interarm contrast between 1.3 and 1.5, in line with previous studies; and

3. a strong bifurcation in the RV distribution around 10–11 kpc, likely related to the outer Lindblad resonance of the Galactic bar, although additional observations are needed to constrain a possible spiral CR.
