Abstract

We present calculation of optical conductivity in a simple model of electronic spectrum of two-dimensional system with “hot patches” on the Fermi surface, leading to non-Fermi-liquid renormalization of the spectral density (pseudogap) on these patches. It is shown that this model qualitatively reproduces basic anomalies of optical experiments in the pseudogap state of copper oxides.
Among the number of anomalies of the normal phase of high-temperature superconductors especially interesting is the observation of the pseudogap in the electronic spectrum of underdoped copper oxides [1,2]. Most striking evidence for this unusual state was obtained in the ARPES experiments [3,4], which demonstrated the anisotropic evolution of electron spectral density. In particular, in these experiments the maximal value of the pseudogap was observed in the vicinity of \((\pi, 0)\) point in the Brillouin zone, while in the direction of diagonals of the zone the pseudogap was absent. Accordingly, around \((\pi, 0)\) the Fermi surface is completely destroyed, while around diagonals it is conserved. In this sense it is usually said that the symmetry of the pseudogap is of “d-wave” type and coincides with the symmetry of the superconducting gap in these compounds. These anomalies are observed up to the temperatures \(T \simeq T^*\), which are significantly higher than the temperature of superconducting transition \(T_c\).

Pseudogap effects are also observed as certain anomalies of the optical conductivity of the number of high-temperature superconductors [5–9]. These anomalies are manifested mainly in the existence of anomalously narrow Drude–like peak (the drop in effective scattering rate) in the region of small frequencies and rather weak absorption through pseudogap at higher frequencies.

There is a number of theoretical approaches, trying to explain pseudogap anomalies. In this paper we assume that these anomalies are mainly due to fluctuations of antiferromagnetic short-range order, as in the “hot-spots” model [10,11]. In this model it is possible to obtain “nearly” exact solution for the electronic spectrum, based upon complete summation of all the relevant Feynman diagrams, describing electron interaction with antiferromagnetic fluctuations [10,12], generalizing to two dimensions the earlier solution of a similar one-dimensional problem [13–17].

Calculations in “hot spots” model are complicated by the use of “realistic” spectrum of current carriers, so that in this work we shall consider much simplified “hot patches” model of the pseudogap state proposed in Ref. [18], which is physically quite close to “hot spots” model. Following Ref. [18] we assume that the Fermi surface of two-dimensional electronic system is like shown in Fig.1. Analogous model of the Fermi surface was considered in Ref. [19], where it was stressed, that it is quite close to that observed in a number of high-temperature superconductors. Fluctuations of short-range order are assumed to be static and Gaussian with correlation function of the form [12][18]:

\[
S(q) = \frac{1}{\pi^2} \frac{\xi^{-1}}{(q_x - Q_x)^2 + \xi^{-2}} + \frac{\xi^{-1}}{(q_y - Q_y)^2 + \xi^{-2}}
\]

(1)

where either \(Q_x = \pm 2p_F\), \(Q_y = 0\) or \(Q_y = \pm 2p_F\), \(Q_x = 0\). We shall assume that these fluctuations interact only with electrons from the “hot” (flat) patches of the Fermi surface shown in Fig.1. Effective interaction of these electrons with fluctuations we shall model as \((2\pi)^2\Delta^2S(q)\), where \(\Delta\) is of dimensions of energy and defines the characteristic width of the pseudogap [1]. Thus, in fact we assume that scattering by fluctuations is of essentially

\[\Delta_p = \Delta[\theta(p_x^0 - p_x)\theta(p_x^0 + p_x) + \theta(p_y^0 - p_y)\theta(p_y^0 + p_x)].\]

\[1\] More formally we may say that we introduce an effective interaction “constant” of electrons with fluctuations as: \(\Delta_p = \Delta[\theta(p_x^0 - p_x)\theta(p_x^0 + p_x) + \theta(p_y^0 - p_y)\theta(p_y^0 + p_x)].\)
one-dimensional nature. The choice of scattering vector $Q = (±2p_F, 0)$ or $Q = (0, ±2p_F)$ corresponds to the picture of incommensurate fluctuations. Commensurate case with $Q = (\frac{\pi}{a}, \frac{\pi}{a})$ (where $a$ is lattice constant) can also be analyzed.

On “cold” patches we shall assume the existence of some weak static scattering of rather arbitrary nature with appropriate scattering rate described by phenomenological parameter $\gamma$, with $\gamma \ll \Delta$ in most cases, so that on “hot” patches it can be just neglected. Accordingly on these “cold” patches the electronic spectrum is described by the usual Green’s function for the system with weak scattering (Fermi–liquid).

In the limit of $\xi \to \infty$ this model can be solved exactly by method used in Refs. [13–14], while for finite $\xi$ it can be “nearly” exactly solved (cf. [10–12]) by the method of Refs. [15–17].

At first we shall consider maximally simplified case of $\xi \to \infty$, when an effective interaction with fluctuations (1) takes the simplest form:

$$\langle 2\pi \rangle^2 \Delta^2 \left\{ \delta(q_x ± 2p_F)\delta(q_y) + \delta(q_y ± 2p_F)\delta(q_x) \right\}$$

(2)

In this case we can easily sum all perturbation series for an electron scattered by these fluctuations using the method of Refs. [13,14], both for one-electron and two-electron Green’s functions. For the case of incommensurate fluctuations of short-range order the one-electron Green’s function becomes:

$$G(\epsilon, p) = \int_0^\infty d\zeta e^{\zeta} \frac{\epsilon + \xi_p}{\epsilon^2 - \xi_p^2 - \zeta^2}$$

(3)

where $\xi_p = v_F(|p| - p_F)$ ($v_F$—Fermi velocity) and $\Delta(\phi)$ is defined for $0 \leq \phi \leq \frac{\pi}{2}$ as:

$$\Delta(\phi) = \begin{cases} \Delta, & 0 \leq \phi \leq \alpha, \frac{\pi}{2} - \alpha \leq \phi \leq \frac{\pi}{2} \\ 0, & \alpha \leq \phi \leq \frac{\pi}{2} - \alpha \end{cases}$$

(4)

where $\alpha = \arctg\left(\frac{p_y}{p_F} \right)$, $\phi$ - is polar angle, defining the direction of the vector $p$ in $(p_x, p_y)$ plane. For the other values of $\phi$ parameter $\Delta(\phi)$ is defined by the obvious symmetry considerations similarly to (4). It is easily seen that changing $\alpha$ in the interval of $0 \leq \alpha \leq \frac{\pi}{4}$, we in fact change the size of “hot” patches on the Fermi surface, where “nesting” condition $\xi_p + Q = -\xi_p$ is satisfied. In particular, $\alpha = \pi/4$ corresponds to a square Fermi surface, where the “nesting” condition is satisfied everywhere. Below we always rather arbitrarily assume $\alpha = \pi/6$. Qualitative dependencies of a number of physical properties of the model on $\alpha$ are given in Ref. [18]. Outside “hot” patches (second inequality in (4)) Green’s function (3) just coincides with a free one (in fact here we must only take into account the above mentioned weak scattering $\gamma$).

Spectral density and density of states, defined by Green’s function (3) were given in Ref. [18] and demonstrate non Fermi-liquid (pseudogap) behavior on “hot” patches of the Fermi surface. Two-particle Green’s function (density-density response function) on “hot” patches can be calculated also by complete summation of appropriate diagrams as it was done before in one-dimensional case [13–14].

Conductivity in this model is determined by additive contributions from “hot” and “cold” patches. For its real part we obtain:
\[ \text{Re}\sigma(\omega) = \frac{4\alpha}{\pi} \text{Re}\sigma_\Delta(\omega) + (1 - \frac{4\alpha}{\pi}) \text{Re}\sigma_D(\omega) \]  

(5)

where with the account of results of Ref. [13,14] we have:

\[ \text{Re}\sigma_\Delta(\omega) = \frac{\omega_p^2}{4} \frac{\Delta^2}{\omega^2} \int_0^\infty d\zeta \exp(-\zeta) \frac{\zeta}{\sqrt{\omega^2/4\Delta^2 - \zeta}} \]  

(6)

where \( \omega_p \)-plasma frequency and

\[ \text{Re}\sigma_D(\omega) = \frac{\omega_p^2}{4\pi} \frac{\gamma}{\omega^2 + \gamma^2} \]  

(7)

–is the usual Drude–like conductivity from “cold” patches.

In Fig.2 we present the frequency dependence of the real part of conductivity, calculated from (5), (6), (7) for different values of \( \gamma \). Even in this simplest approximation these dependencies are very similar to those observed in the experiments of Refs. [5–9]. As the scattering rate \( \gamma \) on “cold” patches grows, the Drude–like peak at small frequencies is dumped.

More realistic case of finite correlation length of “antiferromagnetic” short-range order fluctuations \( \xi \) in (1) can be analyzed by the method of Refs. [15–17], which allows to find “nearly exact” [12] solution of the problem. For one-electron Green’s function on “hot” patches we obtain the following recurrence relation (continuous fraction representation) [15]:

\[ G^{-1}(\epsilon, \xi_p) = G_0^{-1}(\epsilon, \xi_p) - \Sigma_1(\epsilon, \xi_p) \]  

(8)

where

\[ \Sigma_k(\epsilon, \xi_p) = \frac{\Delta^2}{\epsilon - (-1)^k \xi_p + ikv_Fk - \Sigma_{k+1}(\epsilon, \xi_p)} \]  

(9)

Combinatorial factor (determining the number of diagrams):

\[ v(k) = \begin{cases} 
\frac{k+1}{2} & \text{for odd } k \\
\frac{k}{2} & \text{for even } k 
\end{cases} \]  

(10)

for the case of incommensurate fluctuations of short-range order. For commensurate case:

\[ v(k) = k \]  

(11)

In spin-fermion model [10,11]:

\[ v(k) = \begin{cases} 
\frac{k+2}{3} & \text{for odd } k \\
\frac{k}{3} & \text{for even } k 
\end{cases} \]  

(12)

For the vertex-part, determining density-density response function (two-particle Green’s function) on “hot” patches, we have the following recurrence relation (details can be found in [16,17] and in [11]):
\[ J_{k-1}^{RA}(\epsilon, \xi_p; \epsilon + \omega, \xi_{p+q}) = \]
\[ = e + \Delta^2 v(k)G_k^A(\epsilon, \xi_p)G_k^R(\epsilon + \omega, \xi_{p+q})J_{k-1}^{RA}(\epsilon, \xi_p; \epsilon + \omega, \xi_{p+q}) \]
\[ \times \left\{ 1 + \frac{2iv_F\kappa k}{\omega - (-1)^k v_F q + v(k + 1)\Delta^2}[G_{k+1}^A(\epsilon, \xi_p) - G_{k+1}^R(\epsilon + \omega, \xi_{p+q})] \right\} \]

where e—electronic charge, \( R(A) \) denote retarded (advanced) Green’s function. Appropriate contribution of “hot” patches to conductivity \( Re\sigma(\omega) \) in (4) can be calculated as in Ref. [16,17], while \( Re\sigma_D(\omega) \) is again given by(7). Typical results of these calculations are presented in Figs.3-6. It is seen that difference between the results for incommensurate and spin-fermion combinatorics are rather small. The general qualitative picture is also conserved in the case commensurate combinatorics. Real part of conductivity is characterized by rather narrow Drude-like peak for small frequencies \( \omega < \gamma \) due to “cold” patches on the Fermi surface and relatively flat maximum for frequencies \( \omega \sim 2\Delta \), corresponding to the absorption through the pseudogap which opens on “hot” patches. Drude-like peak is dumped with the growth of \( \gamma \), while the maximum at small frequencies, which can be seen in Fig.2 and Fig.3, can be attributed to the “remains” of one-dimensional localization [16,17]. The dependence of conductivity on correlation length of fluctuations \( \xi = \kappa^{-1} \) is rather weak for all (most interesting) values of parameters analyzed here. The qualitative picture obtained is very similar to experimental data obtained for the number of high-temperature superconducting copper oxides studied in Refs. [3,4]. Apparently there will be no problem with quantitative fitting of experimental data using the known values of \( \omega_p \sim 1.5 - 2.5 eV \) and \( 2\Delta \sim 0.1 eV \), as well as the values of \( \gamma \), which can be determined from the width of the observed Drude-like peak, and varying “free” parameters \( \alpha \) (the size of “hot” patches) and \( \xi \) (for this we also can use the estimates from other experiments [11]).

The author is grateful to Dr. E.Z. Kuchinskii for useful discussions.
