Stability analysis of Models 1-4

In this section, we present the stability analysis of Models 1-4, which is similar to the analysis of DNF systems described in our previous study \cite{1}. The majority of presented formulas can be applied to all models and we do explicitly distinguish them, unless necessary.

We linearised Models 1-4 about their respective equilibrium \((C_s, R_s)\):

\[
\begin{pmatrix}
\frac{dC}{dt} \\
\frac{dR}{dt}
\end{pmatrix} = \begin{pmatrix}
-x & -y \\
0 & -\beta
\end{pmatrix}\begin{pmatrix}
C \\
R
\end{pmatrix} + \begin{pmatrix}
0 & 0 \\
1 & 0
\end{pmatrix}\begin{pmatrix}
C(t - \tau) \\
R(t - \tau)
\end{pmatrix},
\] (1)

where elements \(x, y\) are represented in equations (7)-(10) of the main manuscript for Models 1-4, respectively.

Further, we formulated a characteristic transcendental equation of the system (1):

\[
P(\lambda, \tau) = (\lambda + x)(\lambda + \beta) + ye^{-\lambda\tau} = 0, \text{ where } x, y > 0.
\] (2)

According to the lemma from \cite{2}, as \(\tau\) varies, the sum of the multiplicities of zeros of (2) in the open right half-plane \(M(\tau)\) can change only if a zero appears on or crosses the imaginary axis. Thus, the only way that \(M(\tau) \neq M(\tau')\) for \(\tau < \tau'\) is, if there exists a marginal value \(\tau_m\) between \(\tau\) and \(\tau'\), such that \(P(\lambda_m, \tau_m) = 0\) and \(\text{Re}(\lambda_m) = 0\) \cite{3}.

Consequently, we presented a root of (2) in the form \(\lambda_m = i \omega_m\), where \(\omega_m > 0\):

\[
P(i \omega_m, \tau_m) = x \beta - \omega_m^2 + i (x + \beta) \omega_m + ye^{-i \omega_m \tau_m} = 0.
\]

Applying Euler’s formula \(e^{-i \omega_m \tau_m} = \cos(\omega_m \tau_m) - i \sin(\omega_m \tau_m)\) we obtain:

\[
x \beta - \omega_m^2 + i (x + \beta) \omega_m + y (\cos(\omega_m \tau_m) - i \sin(\omega_m \tau_m)) = 0.
\] (3)
Satisfying (3) real and imaginary parts should both be equal to zero:

\[ x\beta - \omega_m^2 + y\cos(\omega_m\tau_m) = 0, \tag{4} \]
\[ (x + \beta)\omega_m - y\sin(\omega_m\tau_m) = 0, \tag{5} \]

which is equivalent to:

\[ (x\beta - \omega_m^2)^2 = (-y\cos(\omega_m\tau_m))^2, \]
\[ (x + \beta)^2 \omega_m^2 = (y\sin(\omega_m\tau_m))^2. \]

We summed up above equations and applied Pythagorean trigonometric identity:

\[ \omega_m^4 + (x^2 + \beta^2)\omega_m^2 + x^2 \beta^2 - y^2 = 0. \tag{6} \]

Equation (6) has real non-zero roots if and only if \( x^2 \beta^2 - y^2 < 0 \), which is equivalent to \( x\beta < y \). Otherwise, \( \tau_m \) does not exist and the equilibrium \((C_s, R_s)\) of Models 1-4 is absolutely stable. We assumed that \( x\beta < y \) holds and defined the discriminant \( D \) of (6) by

\[ D = (x^2 + \beta^2)^2 - 4(x^2 \beta^2 - y^2). \tag{7} \]

Then, we defined roots of (6):

\[ \omega_m^2 = \frac{1}{2} \left( -x^2 - \beta^2 \pm \sqrt{D} \right). \]

Using the fact that \( \omega_m^2 \) should be positive, we get:

\[ \omega_m^2 = \frac{1}{2} \left( -x^2 - \beta^2 + \sqrt{D} \right), \quad \omega_m = \sqrt{\frac{1}{2} \left( -x^2 - \beta^2 + \sqrt{D} \right)}. \]

Further, we substituted the obtained expression for \( \omega_m \) into (4) and (5):

\[ \cos(\omega_m\tau_m) = \frac{1}{2y} \left( -(x + \beta)^2 + \sqrt{D} \right), \tag{8} \]
\[ \sin(\omega_m\tau_m) = \frac{x + \beta}{y} \omega_m > 0. \tag{9} \]

Using (8) and (9) we expressed the value of \( \tau_m \) in the following form:

\[ \tau_m(n) = \frac{1}{\omega_m} \left[ \arccos \left( \frac{1}{2y} \left( -(x + \beta)^2 + \sqrt{D} \right) \right) + 2\pi n \right], \quad n = 0, 1, 2, \ldots \]

Since \( \sin(\omega_m\tau_m) > 0 \) holds, we concluded that if \( -(x + \beta)^2 + \sqrt{D} > 0 \), then

\[ \arccos \left( \frac{1}{2y} \left( -(x + \beta)^2 + \sqrt{D} \right) \right) \in (0, \frac{\pi}{2}), \quad \text{otherwise} \ \arccos \left( \frac{1}{2y} \left( -(x + \beta)^2 + \sqrt{D} \right) \right) \in (\frac{\pi}{2}, \pi). \]

In both cases, the smallest time delay, which causes a purely imaginary pair of roots \( \lambda_{1,2} = \pm i\omega_m \), is

\[ \tau_m = \frac{1}{\omega_m} \arccos \left( \frac{1}{2y} \left( -(x + \beta)^2 + \sqrt{D} \right) \right). \tag{10} \]
Further, we proved the stability of the equilibrium \((C_s, R_s)\) for any \(\tau \in [0, \tau_m]\). Indeed, roots of \(P(\lambda, 0)\) are either real negative or have negative real part (see above).

Then, according to Lemma from [2], \(M(\tau) = 0\) for any \(\tau \in [0, \tau_m]\). Hence, for any \(\tau \in [0, \tau_m]\) the equilibrium \((C_s, R_s)\) is asymptotically stable.

Now, we prove that a Hopf bifurcation occurs at \(\tau = \tau_m\). For this we differentiated the characteristic polynomial (2) with respect to \(\tau\) and equated it to zero:

\[
2\lambda \frac{d\lambda}{d\tau} + (x + \beta) \frac{d\lambda}{d\tau} = ye^{-\lambda \tau} \left( \frac{d\lambda}{d\tau} + \lambda \right).
\]

Then, we obtained the expression for \(\frac{d\lambda}{d\tau}\):

\[
\frac{d\lambda}{d\tau} = \frac{y}{e^{\lambda \tau} (x + \beta + 2\lambda) - y \tau}.
\]

We substituted \(\lambda = i\omega_m\) into the expression for \(\frac{d\lambda}{d\tau}\) and applied Euler’s formula:

\[
\frac{d\lambda}{d\tau}(\tau) = \frac{i \omega_m y \cos(\omega_m \tau) + \omega_m y \sin(\omega_m \tau)}{x + \beta - y \tau \cos(\omega_m \tau) + i (2\omega_m + \tau y \sin(\omega_m \tau))}.
\]

We substituted the expression for \(\tau_m\) (10), used (8) and (9), multiplied the top and the bottom by the conjugate of the denominator, took real part and obtained:

\[
\frac{dRe(\lambda)}{d\tau}(\tau_m) = \frac{\sqrt{D} \omega_m^2}{(x + \beta - y \tau_m \cos(\omega_m \tau_m))^2 + (2 \omega_m + \tau_m y \sin(\omega_m \tau_m))^2} > 0. \tag{11}
\]

The positivity of (11) guarantees that the hypotheses of the implicit function theorem hold. Hence, we may conclude that for \(\tau \approx \tau_m\) the root of the characteristic polynomial (2) \(\lambda_m = i\omega_m\) crosses the imaginary axis from left to the right.

According to Proposition 6.5 from [3], for \(\tau \geq \tau_m\) the equilibrium \((C_s, R_s)\) is unstable.

**Auto-inhibition increases \(\tau_m\)**

We represented \(\tau_m\) (10) as a function of \(x, y\) and \(\beta\):

\[
\tau_m(x, y, \beta) = f(x, y, \beta) g(x, y, \beta), \tag{12}
\]

where

\[
f(x, y, \beta) = \frac{\sqrt{2}}{\sqrt{-x^2 - \beta^2 + \sqrt{(x^2 + \beta^2)^2 + 4(y^2 - x^2\beta^2)}}} > 0,
\]

\[
g(x, y, \beta) = \arccos \frac{-(x + \beta)^2 + \sqrt{(x^2 + \beta^2)^2 + 4(y^2 - x^2\beta^2)}}{2y} > 0.
\]
Assuming \( x \beta < y \) and using \( D \) from (7), we obtained derivatives of functions \( f \) and \( g \) with respect to \( x \) and \( y \):

\[
\frac{\partial f}{\partial x}(x, y, \beta) = \frac{\sqrt{2}x \left( \sqrt{D} - (x^2 - \beta^2) \right)}{\sqrt{D} \left( \sqrt{D} - x^2 - \beta^2 \right)} > 0,
\]

\[
\frac{\partial g}{\partial x}(x, y, \beta) = \frac{2(x + \beta) \left( \sqrt{D} - x^2 + x\beta \right)}{\sqrt{D} \sqrt{4y^2 - (x + \beta)^2 - \sqrt{D}}} > 0,
\]

\[
\frac{\partial f}{\partial y}(x, y, \beta) = -\frac{2\sqrt{2}y}{\sqrt{D} \left( \sqrt{D} - x^2 - \beta^2 \right)^{3/2}} < 0,
\]

\[
\frac{\partial g}{\partial y}(x, y, \beta) = -\frac{(x + \beta)^2 \left( -x^2 - \beta^2 + 2x\beta + \sqrt{D} \right)}{\sqrt{D}y \sqrt{4y^2 - (x + \beta)^2 - \sqrt{D}}} < 0.
\]

(13)

Thus, we conclude that \( f(x, y, \beta) \) and \( g(x, y, \beta) \) are both positive functions, which increase with \( x \) and decrease with \( y \). Consequently, \( \tau_m(x, y, \beta) \) follows the same pattern. Using the relation between equilibria of models with and without auto-inhibitory feedback and properties of feedback functions \( F, S_1, S_2 \) described in the main manuscript, we calculated lower and upper bounds of \( x \) and \( y \). Further, we showed how these bounds can be increased or decreased leading to changing in the value of \( \tau_m \).

Firstly, we defined the relation between equilibrium components \( R_s \) and \( C_s \) for Models 1-4. For this we equated the right hand side of the differential equation \( \frac{dR_s}{dt} \) to 0:

\[
R_s = \frac{1}{\beta} C_s.
\]

(14)

Further, for each Model 1-4 we equated the right hand side of the differential equation \( \frac{dC_s}{dt} \) to 0 and substituted the expression for \( R_s \) (14):

\[
I S_1 \left( \frac{1}{\beta} C_s \right) \cdot F(C_s) = \alpha C_s \text{ for Model 1, }
\]

\[
I S_1 \left( \frac{1}{\beta} C_s \right) (1 - C_s) \cdot F(C_s) = \alpha C_s \text{ for Model 2, }
\]

\[
I C_s = \alpha C_s + \delta C_s S_2 \left( \frac{1}{\beta} C_s \right) \text{ for Model 3, }
\]

(15) (16) (17)
\[
I (1 - C_s) \cdot F(C_s) = \alpha C_s + \delta C_s S_2 \left( \frac{1}{\beta} C_s \right)
\]
for Model 4. 

(18)

Thus, for each model we got the equation defining the equilibrium component \( C_s \) in the form:

\[
\theta_1 \cdot F(C_s) = \theta_2.
\]

(19)

According to (19), we find the equilibrium component \( C_s \) as the intersection of functions \( \theta_1 \circ F \) and \( \theta_2 \) (see Fig. S1). Since \( \theta_1 \) is either constant or decreasing function with respect to \( C \) and \( \theta_2 \) is increasing function with respect to \( C \), the equilibrium component \( C_s \) always exists and is unique.

In case the auto-inhibitory feedback is not present in the system \( (F(C) \equiv 1) \), the equilibrium component \( \hat{C}_s \) of the model without auto-inhibition is always greater than the equilibrium component \( C_s \) of the model with auto-inhibition (see Fig. S1). According to (19), the same conclusion holds for equilibrium components \( R_s \) and \( \hat{R}_s \) of models with and without auto-inhibition, respectively.

**Figure S1** Schematic intersection of functions \( \theta_1, \theta_1 \circ F \) and \( \theta_2 \). Functions \( \theta_1 \) and \( \theta_2 \) were introduced to find equilibrium components of Models 1-4. a How to find equilibrium components \( C_s, \hat{C}_s \) for Model 3. b How to find equilibrium components \( C_s, \hat{C}_s \) for Models 1, 2, 4.

Taking into account obtained relations \( C_s \leq \hat{C}_s \) and \( R_s \leq \hat{R}_s \) and properties of feedback functions \( F, S_1, S_2 \) described in the main manuscript we obtained following estimations of \( x \) and \( y \):

\[
0 < \varepsilon_{lb}(|F'(C_s)|) < x < \varepsilon_{ub}(|F'(C_s)|),
\]

\[
0 \leq \sigma_{lb} < y < \sigma_{ub}.
\]

(20)

Refer to Table S2 for values of \( \varepsilon_{lb}, \varepsilon_{ub}, \sigma_{lb}, \sigma_{ub} \) for each Model 1-4.

Both the lower and upper bound of \( x \), i.e., \( \varepsilon_{lb} \) and \( \varepsilon_{ub} \), are increasing with \( |F'(C_s)| \) for Models 1-4. Therefore, we can always increase a given \( x \) by choosing an appropriate value for \( |F'(C_s)| \). The lower and upper bound of \( y \), i.e., \( \sigma_{lb} \) and \( \sigma_{ub} \), have non-negative constant values. Consequently, according to (13), we can always increase \( \tau_m \) by increasing \( |F'(C_s)| \).

Taken together, we show how auto-inhibitory feedback allows to modify the range of the interval \([0, \tau_m]\).
Numerical evidence of increasing $\tau_m$ by auto-inhibition

The theoretical analysis presented in the section above shows that increasing the slope of the auto-inhibitory function at the equilibrium $|F'(C_s)|$ leads to increasing the marginal time delay $\tau_m$. Here, we suggest an algorithm how to increase $|F'(C_s)|$ and, consequently, $\tau_m$ for the p53 model.

As auto-inhibitory feedback function we used a reverse Hill function $F_H(C)$ (Fig. S2a):

$$F_H(C) = \frac{1}{1 + (\kappa C)^\nu}, \nu > 1, \kappa \geq 0. \text{ (21)}$$

![Figure S2](image)

**Figure S2** Reverse Hill function. a Plot of the reverse Hill function $F_H(C)$ (21). b Absolute value of the derivative of the reverse Hill function with the fixed $\kappa$ and different values of $\nu$.

For the reverse Hill-function, an obvious choice to increase the slope is increasing the Hill-coefficient $\nu$. Therefore, we made $\nu$ a free positive parameter, which value we choose. For simplicity we considered only integer values of $\nu$, however the algorithm can be extended to real values of $\nu$. Then we adjusted values of $\kappa$ and equilibrium $(C_s, R_s)$ and maximized $|F'_H(C_s)|$, which is equivalent to solving $F''_H(C_s) = 0$. Thus, for the fixed value of $\nu$ we solved the following system of equations with respect to $(C_s, R_s, \kappa)$ using fitted parameter values $(\alpha, \beta, \delta, K_m, n)$ from Table S1:

$$F''_H(C_s) = \frac{\nu(\kappa C_s)^\nu ((\nu + 1)(\kappa C_s)^\nu - \nu + 1)}{C_s^2 ((\kappa C_s)^\nu + 1)^3} = 0,$$

$$0 = I F_H(C_s) - \alpha C_s - \delta C_s S_2(R_s),$$

$$0 = C_s - \beta R_s. \text{ (22)}$$

Then, we quantified $\tau_m$ using (12). If it is necessary, we increase $\nu$, solve the system (22) with respect to $(C_s, R_s, \kappa)$ and quantify $\tau_m$ again.

Fig. S3 demonstrates results of application of the algorithm to the p53 model. In Fig. S3a we illustrated the graph of the slope $|F'_H(C)|$ for several values of $\nu$ and adjusted values of $\kappa$. One can see that $|F'_H(C_s)|$ is increasing, when we increase $\nu$, whereas the value of $C_s$ is only slightly decreasing (indicated by black dots in Fig. S3a). Consequently, $\tau_m$ is also increasing with respect to the Hill coefficient $\nu$ (Fig. S3b). For $\nu \geq 3$ the equilibrium is asymptotically stable. For $\nu > 8$
the equilibrium is absolutely stable. Thus, the relation between $\nu$, $|F'_H(C)|$ and $\tau_m$ demonstrated in Fig. S3 corresponds well to the theoretical analysis made above.

In Fig. S4 we depicted simulations of the p53 model with fitted parameters from Table S1 and synthetically activated auto-inhibitory feedback $F_H(C)$ (21) with $\nu = 3$, $\kappa = 1.73$. One can see that the model with auto-inhibitory feedback produces damped instead of sustained oscillations.

![Figure S3](image)

**Figure S3** Influence of the synthetically activated auto-inhibitory feedback $F_H(C)$ on the stability of the p53 model. **a** Absolute value of the derivative of $F_H(C)$ for $\nu = 2$, $3$, $4$, $5$ and adjusted values of $\kappa$. Dots – absolute values of the derivative at the equilibrium point $C_s$. **b** Dependency between $\tau_m$ and Hill coefficient $\nu$. The dashed line designates the value of the fitted time delay $\tau$.

![Figure S4](image)

**Figure S4** Simulation of the p53 model with synthetically activated auto-inhibitory feedback. Simulation of the p53 model with fitted parameters from Table S1 and synthetically activated auto-inhibitory feedback $F_H(C)$ (21) with $\nu = 3$, $\kappa = 1.73$.

Further, we investigated the stability of the p53 model with and without synthetically activated feedback with respect to several parameters. In Fig. S5a-c we show that increasing the Hill coefficient $\nu$ and adjusting $\kappa$ leads to a decreasing parameter region, where oscillations occur. Fig. S5d demonstrates that $\tau_m$ increases with respect to $\kappa$ for both $\nu = 2$ (dark gray) and $\nu = 3$ (light grey). Thus, these results correspond well to our previous research [4], where we proved for the model with delayed negative feedback that nested negative feedbacks lead to increasing resistance of the
system. In addition, in Fig. S5a we illustrate that $\tau_m$ increases with respect to $\alpha$ that indicates the stabilizing property of $\alpha$ and may explain such a small fitted parameter value. On the other hand, $\tau_m$ decreases with respect to $I$ (Fig. S5c).

Figure S5 Dependencies between parameters of the p53 model. The p53 model is considered without (black) and with synthetically activated ($\nu = 2$, $\kappa = 1.23$ dark grey, $\nu = 3$, $\kappa = 1.73$ light grey) auto-inhibitory feedback. a $\tau_m$ and $\alpha$. b $\tau_m$ and $\beta$. c $\tau_m$ and $I$. d $\tau_m$ and $\kappa$.

Designations: dots – the fitted value of the parameter used in the p53 model, dashed line – the fitted value of $\tau$ (Table S1).

Robustness of optimal solution of p53 model

We analysed the robustness of the optimal solutions for the p53 model with respect to noise. To this end, we randomly sampled parameter values within $\pm 10\%$ of their respective fitted values using a uniform distribution for 100 times. Then we simulated p53 model with perturbed parameters and calculated 0.05 and 0.95 quantiles of obtained simulations (grey regions in Fig. S6). Fig. S6 shows that the model solution with fitted parameters is located between 0.05 and 0.95 quantiles for all considered time points.

Further, for each perturbed parameter set we calculated the relative variation of the integral of
the first transient response after the stimulation:

\[ \text{var}_i = \left| \frac{\int_0^{t_{\text{Int}}} C(t) dt - \int_0^{t_{\text{Int}}} C^i_p(t) dt}{\int_0^{t_{\text{Int}}} C(t) dt} \right| \cdot 100\%, \]

where \( C(t) \) corresponds to the model solution with fitted parameters, \( C^i_p(t) \) corresponds to the model solution with \( i \)th perturbed parameter set \( (i = 1, 2, 3, ..., 100) \), \( t_{\text{Int}} \) corresponds to the time of the first minimum after initial stimulation (Fig. S6).

This way, the robustness of both initial activation amplitude and timing of the first transient response, two characteristic measures of system dynamics, can be estimated concomitantly.

As the measure of robustness we calculated the mean value \( < \text{var} > \) and standard deviation \( sd \) of obtained relative variations \( \text{var}_i \):

\[ < \text{var} > \pm sd = 8.7 \pm 6.4\%. \]

One may see that for the considered model values of \( < \text{var} > \) and \( sd \) do not exceed 9%. Thus, the fitted solution turned out to be very robust with respect to noise in the parameters, also indicating that the fitted solution is in a well-defined local minimum.

![Figure S6 Robustness of the optimal solution of the p53 model. Fitted parameter values of the p53 model were perturbed 100 times and used for model simulations. Dashed areas correspond to integral values \( \int_0^{t_{\text{Int}}} C(t) dt \) used for calculating relative variations \( \text{var}_i \).](image)

**Modelling the switch from oscillatory to adaptive response of the p53 system**

For modelling the transition from oscillatory to adaptive response of the p53 system we extended the p53 model (3) by including an additional component \( ATM \). The resulting wiring scheme is depicted in Fig. S7.
We translated the wiring scheme from Fig. S7 into the following system of DDEs:

\[
\begin{align*}
\frac{dATM}{dt} &= I - \gamma ATM, \\
\frac{dp53}{dt} &= ATM - \alpha p53 - \delta p53 \frac{Mdm2^n}{Mdm2^n + Km^n}, \\
\frac{dMdm2}{dt} &= \frac{p53(t - \tau)}{1 + ATM^{n2}} - \beta R.
\end{align*}
\] (23)

The extended p53 model (23) was further simulated with parameters from Table S1, \(\gamma = 0.05\) and \(n_2 = 2\) (see Fig. S8a) and with parameters from Table S1, \(I = 1, \gamma = 0.05\) and \(n_2 = 2\) (see Fig. S8b). As a result, the extended p53 model demonstrates sustained oscillations for low DNA damage (\(I = 0.23\)) and monotone adaptive response for high DNA damage (\(I = 1\)).

**Figure S8** Simulation of the extended p53 model (23). a Simulation with parameters from Table S1, \(\gamma = 0.05\) and \(n_2 = 2\). b Simulation with parameters from Table S1, \(I=1, \gamma = 0.05\) and \(n_2 = 2\).
Calculating the duration of “On” and “Off” states of p53 pulses

For calculating the duration of “On” and “Off” states of p53 pulses we simulated p53 model (3) with parameters from Table S1 for later time points \( (t > 400 \text{ h}) \), when the system reached its steady state (see Fig. S9). Then we quantified the mean value between maxima and minima of the simulation curve (see black dashed line in Fig. S9). As a result the simulation curve was split on upper and lower parts with respect to the mean value. We designated the upper part as “On” state and the lower part as “Off” state.

![Figure S9 Defining “On” and “Off” states for the p53 response. Black dashed line designates the mean value between maxima and minima of the simulation curve.](image)

Then we checked how different model parameters control the duration of “On” and “Off” states (see Fig. S10). For this we varied parameter values \( I, \tau, K_m, n, \alpha, \delta, \beta, \kappa \) and \( \nu \) one at a time in the range, where p53 model (3) produces sustained oscillations. Then for each varied parameter value we calculated the duration of “On” and “Off” states of the p53 response as described above.

### Table S1

| Parameters | p53 model |
|------------|-----------|
| \( I \)    | 0.23 [a.u.] |
| \( \tau \) | 1.37 h    |
| \( \alpha \) | \( 5.9 \times 10^{-13} \text{ h}^{-1} \) |
| \( \beta \) | 0.94 h\(^{-1}\) |
| \( \delta \) | 176 h\(^{-1}\) |
| \( K_m \)  | 2 \( \mu \text{M} \) |
| \( n \)    | 5         |
| \( C'(0) \) | 0 [a.u.] |
| \( R(0) \) | 0 [a.u.] |
| \( SSR \)  | 2.16      |

\( SSR \) - the sum of squared residuals
### Table S2 Lower and upper bounds of $x$ and $y$ for Models 1-4.

| Model 1 |  |  |
|---------|---|---|
| $\varepsilon_{lb} = I \, S_1(\hat{R}_s)|F'(C_s)| + \alpha,$ |  |  |
| $\varepsilon_{ub} = I \, S_1(0)|F'(C_s)| + \alpha,$ |  |  |
| $\sigma_{lb} = 0,$ |  |  |
| $\sigma_{ub} = I \, \max_{R \in [0, \hat{R}_s]} |S'_1(R)|.$ |  |  |

| Model 2 |  |  |
|---------|---|---|
| $\varepsilon_{lb} = I \, S_1(\hat{R}_s) (1 - \hat{C}_s)|F'(C_s)| + \alpha,$ |  |  |
| $\varepsilon_{ub} = I \, S_1(0) [1 + |F'(C_s)|] + \alpha,$ |  |  |
| $\sigma_{lb} = 0,$ |  |  |
| $\sigma_{ub} = I \, \max_{R \in [0, \hat{R}_s]} |S'_1(R)|.$ |  |  |

| Model 3 |  |  |
|---------|---|---|
| $\varepsilon_{lb} = I \, |F'(C_s)| + \alpha + \delta S_2(0),$ |  |  |
| $\varepsilon_{ub} = I \, |F'(C_s)| + \alpha + \delta S_2(\hat{R}_s),$ |  |  |
| $\sigma_{lb} = 0,$ |  |  |
| $\sigma_{ub} = \delta \hat{C}_s \, \max_{R \in [0, \hat{R}_s]} |S'_2(R)|.$ |  |  |

|---------|---|---|
| $\varepsilon_{lb} = I \, (1 - \hat{C}_s)|F'(C_s)| + \alpha + \delta S_2(0),$ |  |  |
| $\varepsilon_{ub} = I \, [1 + |F'(C_s)|] + \alpha + \delta S_2(\hat{R}_s),$ |  |  |
| $\sigma_{lb} = 0,$ |  |  |
| $\sigma_{ub} = \delta \hat{C}_s \, \max_{R \in [0, \hat{R}_s]} |S'_2(R)|.$ |  |  |
Figure S10 Dependency between parameter values of the p53 model (3) and duration of “On” and “Off” states. a $I, \kappa = 0$. b $\tau, \kappa = 0$. c $K_m, \kappa = 0$. d $n, \kappa = 0$. e $\delta, \kappa = 0$. f $\beta, \kappa = 0$. g $\kappa, \nu = 3$. h $\nu, \kappa = 1.73$. 
Figure S11 Dependency between parameter values of Models 1-4 and $\tau_m$ applied to the parameter set $I = 0.87$, $\alpha = 0.11$, $\beta = 0.17$, $\delta = 58.2$, $n = 12.77$, $K_m = 0.23$. a For Model 1. b For Model 2. c For Model 3. d For Model 4. e Dependency between the parameter $K_m$ and $\tau_m$ for Models 1-4. With $\text{par}_{\text{var}}$ and $\text{par}$ we designated varied and initial chosen parameter values, respectively. For Figs. a-d we varied the value of each parameter in the range from 0.1 to 10 times of its respective chosen value leaving the rest parameter values fixed. For Fig. e we varied the parameter $K_m$ in the range from 0.1 to 100 times of its respective chosen value.
Figure S12 Results of Monte-Carlo analysis of Models 1-4 applied to the second parameter set $I = 0.48, \alpha = 0.14, \beta = 0.44, \delta = 83.71, n = 10, K_m = 0.9, \tau = 10$ without auto-inhibition ($\kappa = 0$). a Simulation of Models 1-4. b Stability analysis of Monte-Carlo simulations of Models 1-4. Model parameters were randomly sampled 10000 times in the certain range. The range was defined according to assumptions about model characteristics: strength of DNF (strong or weak) and presence of auto-inhibition. The percentage of parameter sets, which induced absolute stability, was quantified.
