Abstract

Introduction: Chronic renal failure is associated with atherosclerosis and increased incidence of cardiovascular morbidity and mortality.

The aim of this work was to compare between children with ESRD under regular HD and healthy controls as regard serum levels of lipids as early predictors of premature atherosclerosis proven by common carotid intima-media thickness (CCA-IMT).

Methods: The present study was carried out on 45 children with ESRD on regular hemodialysis in an University hospital and 30 healthy age and sex matched children were serving as controls. All subjects were subjected to thorough history taking, clinical examination including anthropometric measurement and blood pressure measurements, routine laboratory assessments measuring complete blood picture, C-reactive protein, blood urea and serum Creatinine, lipid profile including serum levels of total cholesterol, triglycerides (TG), low density lipoprotein (LDL) and high density lipoprotein (HDL) and radiological assessment using B-mode Doppler ultrasonography to measure common carotid artery intima media thickness (CCA-IMT) to detect presence and extent of atherosclerosis.

Results: There was significant increase in serum levels of triglyceride, cholesterol and LDL and a significant decrease in HDL in dialysis children when compared to healthy controls. There was also a highly significant increase in CCA-IMT of the patients group when compared to the controls (P < 0.001) with significant positive correlation with duration of dialysis and serum TG and a significant negative correlation with serum HDL.

Conclusions: Increased serum levels of TG, cholesterol, LDL and decreased serum level of HDL are early predictors for premature atherosclerosis in children with ESRD.

Keywords: Atherosclerosis, Children, Haemodialysis, Chronic Renal.

Introduction

Background: Cardiovascular disease accounts for one quarter of deaths in children and adults younger than 30 years old who started treatment of end stage renal disease (ESRD) at their childhood period (1, 2). Dyslipidemia became frequent in long term survivors undergoing maintenance hemodialysis due to improvement of dialysis adequacy (3, 4, 5).

The aim of this work was to compare between children with ESRD under regular HD and healthy controls as regard serum levels of lipids as early predictors of premature atherosclerosis proven by common carotid intima-media thickness (CCA-IMT).
Subjects and Methods

Sample Size, Design of the Study and Setting: The present study was carried out after approval from research ethical committee centre of Tanta University Hospital (TUH) and obtaining informed written consents from parents of included children, in Paediatric Nephrology Unit of Paediatric Department, Tanta University Hospital from August 2016 to August 2017 on 45 children with ESRD on regular haemodialysis (HD). Their ages ranged from 4 to 19 years with their mean 13.87±3.83. They were 27 males and 18 females. All patients were undergoing regular HD, three times per week, with each dialysis session lasting for three to four hours. Thirty healthy children matched in age and sex distribution were serving as control group. Their ages ranged from 4 to 19 years with their mean 13.8±3.8. They were 15 males and 15 females. Patients were dialyzed on Fresenius 4008- B dialysis machine (Germany) at blood flow rate = 2.5 x weight (kg) + 100ml/min., using polysulphane hollow fiber dialyzers suitable for the surface area of the patients (Fresenius F3 = 0.4 m², F4 = 0.7 m², F5 = 1.0 m² and F6 = 1.2 m²). Bicarbonate dialysis solutions were used. All patients were receiving supportive therapy in the form of subcutaneous erythropoietin in a dose of 50 IU/Kg/session, IV iron dextran 100 mg/Kg/week, oral folic acid 1 mg/day, oral calcium 1000 mg/day, oral vitamin D (one alpha) in a dose of 0.01-0.05 µg/Kg/ day and oral antihypertensive medications for hypertensive patients.

Inclusion Criteria: All children with ESRD and treated by regular maintenance haemodialysis.

Exclusion Criteria: Familial hypertriglyceridemia, Diabetes Mellitus, Congeital Heart Disease and obesity.

All patients and controls were subjected to the following History taking including duration of dialysis, Clinical examination including anthropometric measurements in the dialysis free day and blood pressure measurements,

Anthropometric measurements (weight, height and midarm circumference (MAC) by CDC growth charts developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Pretension and Health.

Promotion (6) They were expressed as percent of ideal for age. Ideal measurement is defined as the 50th percentile for age.

Arterial blood pressure was measured by the auscultatory method using a mercury sphygmomanometer with the patient in the semi setting position after 10 minutes of rest, in the non-fistula arm using an appropriate sized cuff. Arterial blood pressure was taken as the mean value of 3 successive readings in 3 different days. The mean arterial blood pressure was measured using the following equation:

Mean arterial BP=Diastolic BP + 1/3 Pulse pressure

While, the pulse pressure equals systolic BP – diastolic BP (7)

The laboratory investigations done just predialysis and sent directly to the laboratory including haemoglobin level and serum creatinine, serum albumin, C reactive protein (CRP), Serum cholesterol, triglyceride, high density lipoprotein (HDL) and low density lipoprotein (LDL)(6, 7, 8).

The radiological assessments included measurement of Common Carotid Artery Intima-Media thickness (CCA-IMT).

Validity of CCA-IMT Measurement

CCA-IMT measured by well trained diagnostic radiologist in department of Diagnostic Radiology of TUH by Doppler high resolution B-mode ultrasonography (US), using (Siemens Sono–Line G60F, Germany)
transducer frequency 5-10 MHz linear probe for carotid arteries). CCA-IMT indicated the structural changes in arterial tree. CCA-IMT was measured on the far wall at 4 cm segment preceding the carotid bifurcation. The median Measurements of a CCA-IMT were always performed in plaque-free arterial segments in CCA.

Arteries were scanned longitudinally and transversely to determine the presence of plaques. A localized echostructure encroaching into the vessel lumen was considered to be plaque when the arterial wall was > 50% thicker than the neighbouring sites. Highly echogenic plaques producing bright white echoes with shadowing were considered to be calcifications[9 & 10]. Arterial calcifications in each arterial region were quantified qualitatively as absent (0) or present (1). The final overall score was obtained by the addition of calcifications from all studied zones. The final score ranged from 0 (absence of calcium deposits), to 3 (calcifications present in all arterial segments examined) (11). Assessment of arterial stiffness index by measurement of CCA diameter and CCA intima-media thickness(IMT): measured by high resolution B-mode ultrasonography (Siemens Sono-Line G60F, Germany, using 5-10 MHz transducer) enabling assessment of arterial wall displacement during the cardiac cycle which was measured on the far wall at the same level as the diameter measurements and were always performed in plaque-free arterial segments in CCA (11).

Statistical Analysis

Statistical analysis was performed with Statistical Package for Social Science (SPSS version 17). For quantitative data, the mean and the standard deviation were calculated, Chi-square was done for qualitative data, comparison between the studied groups was performed with student t-test, with P<0.05 were considered statistically significant. Correlation between variables was evaluated using Pearson's correlation coefficient (12).

The Results

Table (1) summarize demographic data of the studied patients and controls. The decline in anthropometric measures of studied patients that there was significant growth retardation in children with ESRD as compared to controls (mean value of weight 30.1±10.1 kg versus 52.03±14.3 kg)(P<0.001) and mean value of height 131±15.01 cm versus 153.1±16.14 cm)(p<0.001) and mean value of MAC 17.46±3.71 CM versus 22.73±3.55 cm)(p<0.001). There was a significant increase in both systolic and diastolic blood pressure values in patients group compared to the controls (mean value of systolic blood pressure 139±10.04 mmHg versus 114±7.59 mmHg)(p<0.001) and mean value of diastolic blood pressure 95.5±7.42 mmHg versus 74±5.98 mmHg)(p<0.001). Table (2) summarize routine laboratory data of the studied patients and controls. There was a highly significant decrease in serum albumin and haemoglobin level in patients as compared to the controls (mean value of albumin 3.94±0.27 gm/dl versus 5.11±0.59 gm/l)(p<0.001) and mean value of HB 8.11±1.99g/dl versus 12.2±0.65 g/dl)(P<0.001)(P=0.001). There was a highly significant increase in CRP in patients as compared to the controls (mean value 37.5±7.52 mg/l versus 0.7±0.08 mg/l)(p<0.001)(P=0.001). There was a highly significant increase in serum TG and highly significant decrease in the serum HDL of the patients group when compared to the controls (mean value of serum TG 156.93±14.49 mg/dl versus 77.44±13.15 mg/dl)(p<0.001) while mean value of HDL 29.32±3.78 mg/dl versus 45.25±2.79 mg/dl)(p<0.001)(P < 0.001).

There was also statistically significant increase in serum levels of cholesterol and LDL in dialysis children (mean values were 222.06±32.26 and 150.06±22.63 mg/dl respectively) when compared to healthy controls (mean values were 159.62±29.83 and 90.39±8.8 respectively)(p<0.001).
Regarding CCA-IMT results in our study, there was a highly significant increase in CCA-IMT of the patients group when compared to the controls (mean value 579.6±162.01 um versus 336±52.8 um) (P < 0.001). Table (4) and figures (1-4) shows correlations between different studied parameters in patient group. Regarding CCA-IMT correlations with different studied parameters, there is significant positive correlation between the mean CCA-IMT and the dialysis duration (r= 0.291)(p=0.047). There is also significant positive correlation between CCA IMT and serum level of triglycerides (r= -0.455)(p=0.019). In contrary, there is a significant negative correlation between CCA IMT and serum level of albumin (r= -0.229 )(p=0.049) and serum level of HDL (r=-0.411)(p=0.019). In our studied patients, there is a significant negative correlation between serum level of HDL and duration of dialysis. (r= -0.339)(P=0.021). While there is a significant positive correlation between and HDL and serum level of albumin (r= 0.399)(P=0.028). And there is a significant positive correlation between serum level of triglycerides and duration of dialysis (r= 0.021)(P=0.038). While a significant negative correlation between serum level of triglycerides and serum levels of albumin (r= -0.400)(P=0.031).

Discussion

Although CKD patients are commonly burdened with multiple cardiovascular risk factors, Dyslipidemia is a known, frequent, highly prevalent and potentially modifiable risk factor for atherosclerosis in both adults and children with CKD. (13, 14, 15). In the present study, children with ESRD on regular HD were investigated for dyslipidemia and its relation to dialysis duration, serum albumin and CCA-IMT as a predictor of atherosclerosis.

Our patients had a characteristic dyslipidemia in form of hypertriglyceridemia and reduced serum levels of HDL, whereas serum levels of LDL and total cholesterol levels remain in normal range as in controls. These findings are consistent with many previously done studies in both children (1) and adults (16) on regular HD. In contrary to our results, other studies reported that total serum cholesterol levels were elevated in children on regular HD (17), post-transplantation (18) and in children on chronic peritoneal dialysis (19, 20, 21). The discrepancy in results may be explained by different epidemiological factors and variable nutritional status in patients compared to the patients in our study. Low serum cholesterol levels in the sitting of ESRD regularly on HD was reported by Kopple, 2005 and was associated with higher mortality which may be due to the high rates of malnutrition and inflammation among these patients (22).

Most studies that tried to elucidate the pathogenesis of lipid abnormalities in HD patients found reduced lipoprotein lipase, and markedly elevated concentrations of apolipoprotien C-III (23). However the pathophysiologic mechanisms leading to dyslipidemia in CRF are still an active area of research. They may be due to insulin resistance, non nephrotic range proteinuria, malnutrition, intrinsic or genetic differences in individual metabolism (24 & 25 & 26).

In addition, decreased antioxidant activity and loss of carnitine which plays an important role in facilitating the transport of fatty acids across the inner mitochondrial membrane prior to beta oxidation, is common in HD patients. In the present study, malnutrition was evident in the patients as shown by the significant decrease in anthropometric measurements and hypo albuminemia when compared to the controls. Although serum albumin levels may be influenced by many factors, they are considered a marker for nutritional status. The significant negative correlation between serum albumin and serum TG levels, while significant positive correlation between serum albumin and HDL levels suggests that nutritional status is an important factor in the development of uremic dyslipidemia. (25).

The positive CRP in patients of the present study indicates that uremic children have a state of chronic inflammation resulting from various factors: elevated cytokine production, reduced renal clearance, un detected persistent infections, and dialysis related factors. CRP is an excellent marker of systemic inflammation that may impair endothelial function. Endothelia dysfunction may result in decreased endothelial cell delipidation of very low density lipoprotein (VLDL) predisposing to dyslipidemia in addition to the cardiovascular risk. However, a report in children did not observe a relationship between endothelial dysfunction and CRP levels and raised a debate whether CRP is a pathogenic mechanism or epiphenomenon (25).

Studies in adults on chronic HD place malnutrition-inflammation complex at the center of a debate about the role of traditional and non traditional risk factors for poor CV outcome (26). The studies have shown that in adults on chronic HD low blood pressure, low body mass index (BMI), low serum cholesterol and low serum homocysteine are often correlated with unfavorable clinical outcome, malnutrition-inflammation complex causes a low BMI, hypocholesterolemia and low homocysteine levels. The introduction of high resolution ultrasoundography (US) has provided a reliable, reproducible and non invasive method to detect and monitor the progression of subclinical atherosclerosis. It is well known that in the general population subclinical atherosclerosis begins in childhood and it is very likely that this process is accelerated in children with CKD (27).
Early Prediction of Premature Atherosclerosis in Children with End Stage Renal Disease (ESRD) on Regular Haemodialysis, A Single Centre Experience

The present study was conducted on children with ESRD, previously published Egyptian researches studied CCA-IMT in children with chronic kidney disease (CKD) and concluded that CCA-IMT was statistically higher in children with ESRD under regular HD than children with chronic renal failure under conservative treatment and added both groups had a higher CCA-IMT than their control children (28). The present study found a significant increase in CCA-IMT in the patients compared to controls (mean value 579.6±162.01 um versus 336±52.8 um) (P < 0.001). These values were near results of Abu Zeid A et al (795 ± 251 um versus 383 ± 50) (28). And El-Gamasy MA et al (612.3 ± 153.78 um versus 336 ± 52) (29) This findings were higher than results reported in some studies both in children (30 & 31 & 32) and adults (33, 34) on regular HD. We can explain this by many factors including increased levels of CCA-IMT with increased age (28, 30, 31), different ages, races, ethnicity and associated hypertension and hyperlipidemia in different studies.

In contrary to our results, Groothoff et al., 2002 found that there is no difference in CCA-IMT in patients with ESRD on HD and controls. This difference may be explained by the shorter duration on dialysis, the difference in nutritional status and pattern of dyslipidemia compared to our patients (20)

The pattern of dyslipidemia in our patient is atherogenic as indicated by the positive correlation found between CCA-IMT and TG levels while the correlation was negative with HDL. There is strong epidemiological evidence that HDL exerts a protective effect against atherosclerosis independent of the effect of LDL (35).

Damjanovic and Dimkovic, evaluated CCA-IMT in 45 children on regular dialysis and found higher mean of CCA-IMT in HD patients compared to controls. He showed positive correlation between CCA-IMT with risk factors for atherosclerosis (Age, duration on dialysis and lipid profile). (27)

Dyslipidemia is associated with increased risk of vascular disease in adult with ESRD (36). A small autopsy series of children with ESRD or post-kidney transplantation showed pathologic changes in the intima of the coronary arteries and a cross sectional study evaluating coronary artery calcification by electron beam computed tomography also supported accelerated coronary artery disease. (37) Thus ESRD are considered major risk factors for CV disease among clinicians evaluating patients with dyslipidemia.

The correlation between CCA-IMT and pulse pressure in our study indicates that arteriosclerosis leads to arterial stiffness and increased peripheral resistance and these factors oppose left ventricle (LV) ejection and leads to increased LV workload and concentric LV hypertrophy.

Litwin et al., (2005), as a part of the ESCAPE trial, investigated vascular structure and function in children with CRF The author demonstrated vascular abnormalities in all patient groups with the most marked changes in the dialysis patients with hyperphosphatemia, hyperparathyroidism and the treatment with Ca containing phosphate binders were the determinants of arterial abnormalities. Another important observation in this study was a significantly lower CCA-IMT in children post-transplants, suggesting that the vascular abnormalities partially regress. (32)

The correlation between dialysis duration and lipid abnormalities from one side and IMT from the other side indicates the role of uremic milieu in the pathogenesis of dyslipidemia predisposed to vascular changes. This may emphasis the important of renal transplantation in eliminating many uremia related risks and reducing the risk of cardiac death by approximately 80 percent (38).

One of limitations of our study was small sized sample that limited our conclusions.

Conclusions

From the present study we conclude that children with ESRD on regular haemodialysis are vulnerable to develop dyslipidemia, which is characterized by hypertriglyceridemia, hypercholesterolemia, increased serum LDL and reduced serum HDL levels. The malnutritional status and chronic inflammation are important factors...
Early Prediction of Premature Atherosclerosis in Children with End Stage Renal Disease (ESRD) on Regular Haemodialysis, A Single Centre Experience

in development of uremic dyslipidemia. The longer the duration of dialysis, the more frequent the occurrence of dyslipidemia, the more increase in CCA-IMT in patients. Dyslipidemia was associated with increased risk of atherosclerosis in ESRD patients, which is predicted by increase in CCA-IMT.

RECOMMENDATIONS

Regular follow-up of children with ESRD by cardiovascular examination by blood pressure monitoring, assessment of lipid profile and echocardiographic assessment for regular measurement of CCA-IMT as easy accurate and non invasive method to build strategies to control these risk factors. The availability of program for cadaveric renal transplantation may decrease time on dialysis and improve patient outcome. Correction of malnutrition and decrease factors lead to the occurrence of inflammation in patients with ESRD on regular haemodialysis may be helpful to improve dyslipidemia in children under HD.
