Cryogenic resonator design for trapped ion experiments in Paul traps

Matthias F. Brandl¹, Philipp Schindler¹, Thomas Monz¹, and Rainer Blatt¹,²

January 26, 2016

Trapping ions in Paul traps requires high radio-frequency voltages, which are generated using resonators. When operating traps in a cryogenic environment, an in-vacuum resonator showing low loss is crucial to limit the thermal load to the cryostat. In this study, we present a guide for the design and production of compact, shielded cryogenic resonators. We produced and characterized three different types of resonators and furthermore demonstrate efficient impedance matching of these resonators at cryogenic temperatures.

1 Introduction

Over the last two decades, the application of ion traps has expanded from mass spectrometry ¹ and frequency standards ²,³ towards engineering of quantum systems which can be used for quantum computation ⁴,⁵,⁶ and quantum simulation ⁷,⁸. It is commonly accepted that large-scale trapped ion quantum information processors require micrometer-scale ion traps ⁵. Such traps usually suffer from excessive electric field noise close to metallic surfaces at room temperature, but at cryogenic temperatures this noise is strongly reduced ⁹,¹⁰. Thus, it seems natural to move towards cryogenic experimental setups which have the additional advantage that the ambient pressure is usually a few orders of magnitude lower than at room temperature. This enables trapping of longer ion strings due to fewer collisions with
background gas. Furthermore, no bake-out procedure of the vacuum vessel is required, allowing for rapid trap cycle times.

The operation of Paul traps requires high radio-frequency (RF) voltages, which are usually generated with the aid of the voltage gain present in RF resonators. For this purpose, helical resonators are typically used in the frequency regime up to 50MHz, whereas for experiments requiring higher drive frequencies coaxial resonators have been used as well \[11 \, 12 \, 13\]. In cryogenic experiments, the resonator needs to fulfill different criteria than in room temperature experiments where the resonator can be placed outside the vacuum vessel. In particular, the connections in a cryostat need to have low thermal conductivity to limit the thermal load. Following the Wiedemann-Franz law, this results in a low electrical conductivity between room-temperature and the cryogenic parts of the experiment. Thus, the resonators have to be operated at the cold-stage. Moreover, space constraints are stricter in cryogenic systems which makes helical resonators undesirable as they are generally bulky\[1\]. To minimize the volume of the resonator, an RLC-series-resonator can be used \[15\].

In Section 2, we focus on the choice of the trap drive frequency, the required voltage gain, and voltage monitoring. Section 3 covers coil design for three types of coils, and in the following Section 4, we discuss impedance matching of the resonator and present an efficient way to match cryogenic resonators. Section 5 focuses on the design of RF shielding, and finally, we present the results in Section 6.

2 General considerations

In trapped ion experiments, RF-voltages of several hundreds of volts are commonly applied to the trap, which has a simple capacitor as its electrical circuit equivalent. Thus, we need to design a resonator that maximizes the RF-voltage at this capacitor for a given input power. In this section, we discuss general considerations in resonator design which are not limited to a specific resonator type.

2.1 Choosing the trap drive frequency

At first, we consider the losses in an RLC-resonator and its scaling with frequency. From the solution of the equation of motion of a trapped ion in a Paul trap (Mathieu equation), one obtains the trap voltages with the stability parameter \( q \) \[16\], which scales as

\[
q = \frac{2eV}{Mr\Omega^2} \propto \frac{V}{\Omega^2}
\]

where \( V \) is the amplitude of the RF-voltage at the trap and \( \Omega \) is the trap drive (angular) frequency. Hence, for constant \( q \) the loss power scales as

\[
P \propto V^2 \propto \Omega^4.
\]

A low trap drive frequency will reduce the losses. On the other hand, high secular motion frequencies of the ion in the trap are desirable for operation. Higher secular frequencies require a higher \( \Omega \), and thus the desired secular frequencies set a lower limit for \( \Omega \). In this study, we aim for a \( q \) around 0.25, an axial secular frequency of 1MHz, and both radial frequencies to be 3.7MHz. This will require a trap drive frequency of \( \Omega = 2\pi \, 42.6MHz \). Simulations of our trap show that we need a drive voltage of about 170Vrms to reach the desired trap frequencies. In order to limit the thermal load onto the cryostat from dissipated power in the resonator, this voltage should be reached with less than 100mW of RF input power. This power corresponds to a consumption of about 1/7l of liquid helium per hour when operating a wet cryostat at 4.2K \[17\].

2.2 Voltage gain of an RLC-resonator

Fig. 1 shows an RLC-series-resonator driven through a matching network. In the following, we will assume perfect impedance matching with a loss-less matching network. Thus, we can set the input power equal to the loss power in the resonator \( P_{\text{input}} = P_{\text{loss resonator}} \), where \( P_{\text{input}} = \frac{V_{\text{in}}^2}{R_{\text{wave}}} \) with \( V_{\text{in}} \) being the input voltage supplied to the circuit and \( R_{\text{wave}} \) the wave impedance of the connecting cable, commonly 50\( \Omega \). We can further write

\[
P_{\text{loss resonator}} = |I|^2 \cdot R_{\text{eff}} = \left| \frac{V_c}{\pi C} \right|^2 \cdot R_{\text{eff}},
\]

\[1\]Helical resonators have been used in cryogenic systems \[14\].
where $I$ is the current in the resonator, $R_{\text{eff}}$ its effective loss resistance, $\Omega$ its frequency, $V_c$ the voltage at the capacitor, and $C$ the capacitor representing the trap. Thus, we obtain

$$\frac{V_{\text{in}}^2}{R_{\text{wave}}} = |\Omega CV_{\text{in}} G_V|^2 \cdot R_{\text{eff}}$$

(4)

where $G_V$ is the voltage gain of the circuit, defined as $G_V = \frac{V_c}{V_{\text{in}}}$. The quality factor $Q$ of a resonator is defined as the resonance frequency $f_0$ divided by the bandwidth $\Delta f$

$$Q = \frac{f_0}{\Delta f}$$

(5)

In trapped ion experiments, we are usually not interested in a small bandwidth around $\Omega$ but rather in a large voltage gain at the trap drive frequency. It should be noted that the voltage gain and bandwidth are qualitatively but not necessarily quantitatively the same for different types of resonators. The quantity that is of direct interest for our application is the voltage gain, which can be derived from (4) as

$$G_V = \frac{1}{\Omega \cdot C} \cdot \frac{1}{\sqrt{R_{\text{wave}} \cdot R_{\text{eff}}}} = \sqrt{\frac{Q}{R_{\text{wave}} \cdot \Omega \cdot C}}$$

(6)

with the quality factor of an ideal RLC resonator $Q = \frac{1}{R_{\text{eff}} \Omega C}$. This indicates that both, the capacitive load, and the effective resistance of the resonator should be minimized.

### 2.3 Pick-up

Voltage pick-ups are not required for the operation of the trap, but are useful to measure the voltage on the trap and are required to actively stabilize the RF voltage on the trap. In this section, we discuss inductive and capacitive pick-up, as shown in Fig. 2.

A capacitive pick-up consists of a voltage divider parallel to the trap, where $C_{\text{pickup2}} \gg C_{\text{pickup1}}$, which leads to the pick-up voltage

$$V_{\text{pickup},C} = \frac{C_{\text{pickup1}}}{C_{\text{pickup1}} + C_{\text{pickup2}}} \cdot V_c$$

(7)

$C_{\text{pickup1}}$ has to be small compared to the trap capacitance $C$, or the capacitive load of the RLC-resonator.
will increase significantly, reducing $G_V$ as shown in (6). Typical values for $C_{\text{pickup2}}$ are several hundred times the value of $C_{\text{pickup1}}$.

In an ideal RLC-series-resonator, the voltage on the coil is the same as the voltage at the capacitor but with a $180^\circ$ phase shift. We can monitor the voltage at the coil as a signal proportional to the voltage at the trap since we are only interested in the amplitude of the trap voltage. Here, $L$ and $L_{\text{pickup}}$ are coupled, and the pick-up voltage can be estimated with the derivations from ref. [13].

In order to maintain low losses, the pick-up should not add significant losses in the resonator. If one uses a coaxial cable with a wave impedance $R_{\text{wave}}$ to monitor the pick-up signal, a resistor $R_{\text{wave}}$ is used as a termination to avoid reflections. The losses are then $V_{\text{pickup}}^2/R_{\text{wave}}$ which need to be small compared to the losses in the resonator $P$.

In general, we recommend using an inductive pick-up, because it does not increase the capacitive load, which would reduce the voltage gain. However for experiments, which frequently test different traps, a capacitive pick-up may be preferable since the more accurate ratio between pick-up and applied voltage facilitates estimating trapping parameters.

3 Coil design

Surface traps for cryogenic environments typically use a high-quality dielectric carrier material and thus the losses in the resonator are usually dominated by the coil. In this study, we demonstrate the design and production of compact and low-loss coils that should allow us to drive our resonator under the conditions stated in Section 2.1. Coils produced with machines are desirable because the production process is reproducible. Furthermore, we prefer toroid coils as they guide the magnetic field in their center, making them less sensitive to their environment. In our application, ferromagnetic core materials are undesirable, because they would induce spatial inhomogeneities of the magnetic field near the trap. We estimate the load capacitance of our resonator to be 10pF, which at a given resonance frequency of 42.6MHz yields a required inductance of 1.4$\mu$H.

3.1 PCB Coils

Kamby and coworkers [15] demonstrated the integration of toroidal RF-inductors into printed circuit boards (PCB). These coils can be fully produced by machines and in this study we will refer to these inductors as PCB coils. Ref. [15] provides specific formulas for the inductance $L$, the resistance of one segment $R_{\text{seg}}$, and the resistance of one via $R_{\text{via}}$ of PCB coils. In order to minimize the losses of the coil we want to minimize the resistance of one winding while maintaining a constant cross-section to keep the inductance constant.

The resistance of one winding is defined by

$$2R_{\text{seg}} + 2R_{\text{via}} = 2 \frac{R_{\text{seg}}}{r_o - r_i} (r_o - r_i) + 2 \frac{R_{\text{via}}}{h} h = 2R'_{\text{seg}} (r_o - r_i) + 2R'_{\text{via}} h,$$

(8)

where $r_o$ and $r_i$ are the outer and the inner radius of the PCB coil, $h$ is the thickness of the PCB, and $R'_{\text{seg}}$ and $R'_{\text{via}}$ are the average length-dependent resistances of a segment and a via. $R'_{\text{seg}}$ and $R'_{\text{via}}$ depend on the exact geometry, but usually vias have similar cross-sections as the segments making their length-dependent resistances approximately equal. That means, in order to minimize (8) and to keep the cross section of the coil constant, $(r_o - r_i)$ and $h$ should be similar in size.

We chose Rogers 4350B as the substrate material, because it has a small loss tangent, a similar thermal expansion coefficient as copper, and is ultra-high vacuum compatible. The thickest available Rogers 4350B had 3.1mm thickness, which is unfortunately too thin to minimize the resistance for a given cross-section.

We produced this type of coil in-house and during multiple iterations, we varied the size and the number of vias. The lowest losses for our production process could be achieved with the design depicted in Fig. 3. The PCB coil has an outer diameter of 35mm and an inner diameter 20.4mm with a substrate thickness of 3.1mm. Its 64 windings result in an inductance of 1.4$\mu$H. We added one winding which is galvanically isolated from the rest of the coil. This winding acts as an inductive pick-up and should thus be as reproducible as the entire coil.
Figure 3: PCB coil produced in copper with a diameter of 35mm and 64 windings. Additionally, there is a pick-up coil included in the design with just one winding.

3.2 Wire Coils

For the second type of coils, wire coils, we wound a single wire around a rigid structure leading to a similar geometry as the PCB coils. Such a coil is less reproducible than a PCB coil since the wire length will vary for each coil. Hence, its inductance and its resistance will vary as well. A coil with the same geometry as for the PCB coils above, made out of silver-plated copper on a Rogers 4350B substrate, is shown in Fig. 4.

In wire coils, the cross-section of the core of a wire coil is bigger than that of a PCB coil, because the wire bends are less sharp. Hence, we expect the inductance of a wire coil to be higher than the one of a PCB coil with the same nominal geometry. The 0.4mm thick silver-plated copper wire, which we used for the wire coil, had a cross-section similar to the average cross-section of a PCB coil. Therefore, we expect similar losses in both types of coils with the same geometries. These considerations allow us to characterize the production processes of the PCB coils by comparing the two types of coils. Higher losses
in the PCB coils are an indication that the production of the PCB coils can be improved. Since we do not need traces on the substrate, it is possible use any machinable material with a low loss tangent. We also produced wire coils with a Teflon core since it has a lower loss tangent and a lower dielectric constant than Rogers 4350B. Thus, the losses will be less affected by the core material and the self-resonance frequency of the coil will be higher. Another option to minimize the losses in the coil can be to use a superconducting wire to reduce the ohmic losses of the resonator.

3.3 Spiral Coil

The quality factor of the presented coils are limited by the ohmic resistance of the conductor. Thus, a coil based on a superconductor is expected to result in lower losses in the resonator. Furthermore, it could be necessary to operate the experiment at temperatures above 15K to reduce the liquid helium consumption in wet cryostats. At these temperatures, a superconductor with a high critical temperature such as a high temperature superconductor (HTS) is required. However, a coil made from a readily available HTS material needs to be a two-dimensional (2D) structure due to manufacturing constraints, and we choose to use a spiral coil as shown in Fig. 5.

Since such coils require only 2D structuring, they can be manufactured in a very accurate and reproducible way. For the demonstrated spiral coil, a high-temperature superconductor (HTS) was produced by Ceraco Ceramic Coating. Our coils were made out of an yttrium barium copper oxide (YBCO) film of 330nm thickness on a sapphire wafer. To facilitate soldered connections, a 200nm film of gold was placed on top of the superconductor. The critical temperature of this YBCO film is above 87K, and its critical current density is higher than $2 \times 10^6$ A/cm² at 77K. We can derive the peak current in the coil from Section 2 to be 0.64A. Hence, traces with a width of more than 100µm are required to stay below the critical current density.

For our square spiral coils, we chose a trace width of 300µm, a trace gap of 150µm, and 10 windings. We designed 9 different coils varying the outer diameter between 14 and 20mm. Equation 4.1 of reference [19] gives an estimate for the inductance, which results in target inductances between 1.2µH and 1.6µH for our coils. This design should allow for coils with very high quality factors already at temperatures accessible with liquid nitrogen instead of liquid helium.

It should be noted here that superconductors are perfect diamagnets, which are spatial inhomogeneities for magnetic fields. One can align the 2D plane of the spiral coil with the spatially homogeneous magnetic field of the experiment to minimize this effect, but one should always keep this in mind.

Figure 5: An yttrium barium copper oxide (YBCO) coil with a 200nm protection layer of gold on a 25mm x 25mm piece of sapphire.

4 Impedance Matching

The resonator is connected to the source through a cable with a given wave resistance $R_{\text{wave}}$, typically 50Ω. The complex voltage reflection coefficient $\mathcal{r}_v$ at the transition from the cable to the resonator \cite{20} is then

$$\mathcal{r}_v = \frac{V_{\text{reflection}}}{V_{\text{input}}} = \frac{Z_{\text{res}} - R_{\text{wave}}}{Z_{\text{res}} + R_{\text{wave}}} ,$$  \hspace{1cm} (9)

where $V_{\text{reflection}}$ is the complex reflected voltage, $V_{\text{input}}$ is the complex incoming voltage, and $Z_{\text{res}}$ is the complex impedance of the resonator\footnote{The underline denotes a complex quantity.}. The reflected power coefficient $R_p$ is then just $R_p = |\mathcal{r}_v|^2$.

Since RLC-series resonators have a very low impedance on resonance, $Z_{\text{res}} = R_{\text{eff}}$, the transition from a 50Ω-cable to the resonator on resonance will reflect almost all the inserted power. In order to minimize the reflection, a properly designed impedance matching network is required. The most commonly used matching network is the $L$-network as it is the simplest, consisting only of two circuit elements.

Fig. 6 shows the two possible $L$-networks where the reactance parallel to the resonator transforms the real part of the impedance to be $R_{\text{wave}}$. The resulting imaginary term is small compared to $R_{\text{wave}}$ (for low loss resonators) and can be compensated with the series reactance.

The resonator’s quality factor from \cite{5} can be written as

$$Q_{\text{coil}} = \frac{\Omega L}{R_{\text{eff}}}$$  \hspace{1cm} (10)

for an RLC-series resonator. Fig. 7 shows the required values for the matching capacitor $C_M$ and inductance $L_M$ as a function of the quality factor of the coil with inductance of 1.4µH. For quality factors around 1000, the required inductance $L_M$ is in the range of 10nH. Thin traces on a PCB have approximately a length-dependent inductance of 1nH/mm. Therefore, small deviations in the trace length will lead to inefficient matching. The strong dependence of the matching on the reactance parallel to the resonator makes the matching network from Fig. 6(b) more favorable, because capacitances of several hundred pF can be adjusted with much more precision than inductances of about 10nH. One can incorporate the inductance $L_M$ into the trace on the PCB from the coaxial connector to the matching capacitance, by setting this distance between 1 and 2cm. Hence, we expect a power reflection of 1% or less even without adding an additional inductor.

RF transformers or baluns on the RF input side are commonly used to avoid ground loops between the RF source and the experiment. When using the circuit from Fig. 6(b) in combination with a transformer, the DC potential of the trap electrodes is not defined. We mitigate this by adding an RF-choke parallel to the matching capacitor, where $\Omega L_{\text{choke}} \gg \frac{1}{R_{\text{choke}}}$, as depicted in Fig. 8.

In a cryostat, it is impractical to adjust the matching capacitance $C_M$ during or after a cool down.

---

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{fig6.png}
\caption{Two possible matching networks. In a) the matching capacitor $C_M$ is in series and the matching coil $L_M$ parallel to the RLC-series resonator. In b) the matching coil $L_M$ is in series and the matching capacitor $C_M$ parallel to the RLC-series resonator.}
\end{figure}
Figure 7: Calculated values of the matching capacitor $C_M$ and matching coil $L_M$ for the matching networks of Fig. 6 over a varying quality factor of the coil. The matching is calculated for a 50Ω-cable, an inductor of 1.4µH, and a capacitor of 10pF.

Hence, we have to find an efficient way of choosing the best value for $C_M$ with a minimum number of temperature cycles. For this, we simulated our matching circuit for varying and also for a constant value of $C_M$. Fig. 9 shows results of simulations where the fixed capacitor value was chosen for a match at $Q_{coil} = 1200$. Fig. 9a) depicts an increase of the optimum $C_M$ with increasing $Q_{coil}$. Fig. 9b) illustrates the dependence of the matched resonance frequency on $Q_{coil}$. In Fig. 9c), the simulations confirm the dependence of the voltage gain on $Q_{coil}$, following from (6). If the physical value for $Q_{coil}$ is smaller than the expected value, used to chose the fixed matching capacitor, the voltage gain is about the same than for an ideal match. But if the actual quality factor $Q_{coil}$ is higher than the expected value, the voltage gain will be lower than with an ideal match. Hence underestimating the quality factor of the coil should be avoided since it would result in a significantly lower voltage gain.

Fig. 9d) shows the reflection coefficient as a function of $Q_{coil}$. The effect of $L_M$ is small and thus it was omitted for these simulations. We can see that even without $L_M$, but with an ideally matched $C_M$, a low reflection coefficient can be achieved. If one chooses a constant value for $C_M$ at a match for $Q_{coil} = 1200$, the reflected power will stay below 5% even if $Q_{coil}$ varies between 800 and 2000.

The parameters for exact impedance matching can be estimated with one additional cooling cycle. For the first cycle, one has to guess the value for $Q_{coil}$ and adjust $C_M$ according to simulations following the approach of Fig. 9a). When the resonator is cold, the reflection coefficient is measured and compared with the simulations in Fig. 9d). The measured reflection coefficient can then only correspond to two values for $Q_{coil}$. If the reflection coefficient passed a minimum during cool-down, one should choose the higher value, if not, the lower value of $Q_{coil}$. With this new value for $Q_{coil}$, one can calculate the correct matching capacitor value $C_M$. Our experience shows that this method will yield a power reflection coefficient of less than 2% for the second cool down.
Figure 9: The matching of these plots is calculated for a 50Ω-cable, an inductor of 1.4µH, and a capacitor of 10pF, thus a resonance frequency of 42.6MHz. The red lines show the values for a fixed capacitance $C_M$ chosen for an ideal matching of $Q_{coil} = 1200$. In a), one can see the required matching capacitor as a function of the quality factor of the coil $Q_{coil}$. b) shows the change in resonance frequency of an ideal match. In c), the voltage gain is plotted over $Q_{coil}$. d) shows the reflection coefficient of the matching network.

5 RF Shield

RF resonators emit electromagnetic radiation, which needs to be shielded to minimize unwanted RF interference in other parts of the experiment. The RF shield needs to be grounded, and thereby generates a capacitance between the resonator and ground. This capacitance has to be minimized as suggested in [6]. In order to keep the resonator compact, we have to find a trade-off between the size of the shield and the capacitance added by it.

First, we need to find a model for the shield capacitance $C_S$. Fig. 10 depicts a model where we divide the coil in $2N$ half windings. Each has an ohmic resistance of $R_{HW}$, an inductance $L_{HW} = L/2N$, and a capacitance to the shield $C_{S,HW}$. We can estimate $C_{S,HW}$ with the standard formula for a parallel-plate capacitor if we assume that the grounded shield is parallel to the coil. From the calculations of the impedance of the entire circuit, we can extract the effective capacitance $C_S$ that occurs due to the presence of the shield.

The results of these simulations for our PCB coils with an outer radius of 17.5mm and an inner radius of 10.2mm are shown in Fig. 11. It can be seen that a distance of about 2mm is sufficient to keep the additional capacitive load below 1pF. Adapted simulations for the wire coils yield results similar to the ones for the PCB coils. Hence, we can use the same shield for both types of coils.

We expect that the capacitance caused by the shield for the spiral coils is even smaller, because its surface is smaller. Additionally, if we place the spiral coil in the center of the same shield, the distance to the shield will be 1.55mm bigger than for the other coils. Hence, the capacitance to ground will decrease further. Moreover, the shield has an influence on the magnetic field lines of the spiral coil in this configuration and thereby also on the inductance and the losses of the coil.

At room temperature, the penetration depth due to skin effect in copper at frequencies around 40MHz is about 10µm. Thus, any mechanically stable shield, of a couple of 1/10mm thickness, should yield a suitable attenuation. Fig. 12 shows a resonator encased in a silver-plated copper shield. The dimensions
of this resonator are 57mm x 40mm x 10.2mm. On the left side of the resonator, one can see a PCB with the matching network at the top and the SMT-connector for the inductive pick-up at the bottom. On the right side is the PCB coil, and the two PCBs are connected together by soldered joints.

6 Results

In our measurement setup, we used a capacitive pick-up to measure the voltage at the trap. With the known ratio of this capacitive voltage divider, we could directly measure the voltage at the trap and calibrate the inductive pick-up of the coil.

Table 1 shows our measurement results. The PCB coils had an inductance very close to the desired value. Unfortunately, we could not achieve the expected quality factor. We had designed the wire coils to have losses similar to the PCB coils, but the PCB coils showed much higher losses than the wire coils. We think this is due to an imperfect production process that we could not improve further with our in-house techniques.
Figure 12: The RLC-resonator built with a PCB coil (right) and the matching network (left) in a silver-plated copper shield. The dimensions of the shielded resonator are 57mm x 40mm x 10.2mm.

Table 1: Measured resonance frequencies, voltage gains, and quality factors of the tested coils.

| Name     | T    | $f_{res}$ | $G_V$ | $Q_{coil}$ |
|----------|------|-----------|-------|------------|
| PCB coil | 295K | 42.4MHz   | 19.4  | 60         |
| PCB coil | ∼80K | 42.8MHz   | 27.1  | 115        |
| PCB coil | ∼10K | 42.9MHz   | 41.5  | 208        |
| Wire Coil| 295K | 36.8MHz   | 25.2  | 89         |
| Wire Coil| ∼80K | 37.2MHz   | 36.5  | 184        |
| Wire Coil| ∼10K | 37.9MHz   | 58.9  | 624        |
| HTS Coil | <88K | 44.3MHz   | 92.1  | 1172       |

Additionally to the PCB coils in copper, we produced them in silver as well. The inductances were similar, but the losses in the silver coils were even higher. This was unexpected as silver is a better conductor than copper. But the silver coils needed to be reworked after fabrication to remove shorts between the segments. During this process, the silver coating might have been scratched, resulting in higher losses. We expect that silver plating after structuring should reduce the losses compared to a copper coil, but we were unable to do so with our in-house fabrication process.

The voltage gain of about 60 of the wire coil would require 160mW RF input power to get to the desired 170V$_{\text{rms}}$ at the trap. If we adjust the voltage to keep the stability parameter $q = 0.25$, only 100mW RF input power are required at the modified resonance frequency.

We expect that one can improve the quality factor of the wire coil by using a thicker wire. We also tested a resonator with a lead-plated wire, which did not show an increased voltage gain. We either could not reach the critical temperature of lead in our test setup, or the lead was not pure enough to become superconducting.

The spiral coil showed the highest voltage gain, although the shield influences the magnetic field generated by the coil. We observed a change of the resonance frequency of a couple of percent when cooling down from liquid nitrogen temperatures to liquid helium temperatures, which we attribute to the shield surrounding the coil. With a voltage gain of 92, one would need about 70mW of RF input power to get 170V$_{\text{rms}}$. With a stability parameter $q = 0.25$ at the higher resonance frequency, it would be 82mW.
7 Conclusion

We have demonstrated three designs of RF resonators for trapped ion experiments with Paul traps. The PCB coils have favorable mechanical properties but still need an improved production process, such as e.g. thermal annealing. The wire coils fulfill our criteria and can be further improved by using a thicker or superconducting wire. The HTS spiral coil showed the highest voltage gain, which was already accessible at temperatures reached with liquid nitrogen cooling.

Efficient matching is usually difficult in a cryogenic environment because normally one cannot tune the matching parameters when the cryostat is cold. We have shown a recipe to efficiently match RLC-resonators without precise knowledge of their quality factors. During this empirical study we regularly achieved matching with a power reflection of less than 2% on the second cool-down. Additionally, we designed and implemented a shield for resonators to minimize RF pick-up in other parts of the experiment.
