Case Report

Sudden Cardiac Arrest as the First Manifestation of Takayasu Arteritis

ARTICLE INFO

Management of out-of-hospital cardiac arrest (OHCA) remains challenging, particularly in young patients. Takayasu arteritis is a rare large-vessel vasculitis relatively. Coronary involvement has been previously described; we provided the first intracoronary images by OCT. We report the first case of OHCA with shockable rhythm revealing chronic total occlusion of the left main in a 41-year-old lady. The coronary anomaly made it possible to diagnose the vasculitis and to treat it by corticosteroid and immunosuppressive treatment. Vasculitis should be evoked in atypical coronary syndrome in young patients. A collaborative multidisciplinary approach permits optimal care for this complex patient.

ABSTRACT

The journey in the intensive care unit was uneventful, with an adapted awakening and she was transferred to the coronary care unit on day 3. The analysis confirmed the absence of acute ischaemic etiology with a slight increase in troponin level (peak, 0.7 mg/L; normal, < 0.05 mg/L) and the cardiac magnetic resonance imaging showed diffuse edema only. The inflammatory markers were also normal.

In this context of panarteritis, a comprehensive assessment of aortitis has been completed. All markers were negative. The diagnostic of Takayasu arteritis was retained. A treatment with corticosteroid was given. Installation of a defibrillator and surgical revascularization were decided. The patient refused both despite repeated clear and relevant information about the risks involved. The medical treatment was completed with pulses of corticosteroids followed by tapering corticosteroids associated with anti-interleukin 6 therapy (tocilizumab, 8mg/kg/4 weeks). On 6 months of control, CT scan was unchanged with evidence of a sub-occlusion of the common trunk with collateral flow

Rentrop 3 (Figure 3). The patient wore the Life Vest® for 6 months without any recorded rhythmic event. After 10 months of follow-up, the patient was asymptomatic and fine, still refusing surgery and defibrillator.

**Figure 1:** Coronary angiogram (right view) showing chronic total occlusion of the ostium of the left main stem (arrow) with an ectasic proximal circumflex with a Rentrop 3 collateralization by the right coronary artery.

**Figure 2:** Initial CT scan showing circumferential thickening of the aorta.

**Figure 3:** 6 months follow-up CT scan showing the sub-occlusion of the left main stem.

**Discussion**

Takayasu arteritis is a chronic inflammatory disease of unknown etiology that usually affects young Asian women, involving the aortic arch and the proximal portion of its major branches as well as the coronary and pulmonary arteries [1]. The diagnostic has to be evoked for young patients in front of a typical vascular involvement on imaging, without any other cause of arteritis [2, 3]. If revascularization is needed, it is recommended outside the active inflammatory phase of the disease [4]. Medical treatment is essential and may allow partial regression of vascular lesions [5]. This observation suggests the importance of considering vasculitis as a potential etiology of coronary disease in young patients, in particular young women. A multidisciplinary approach is the key to the care of these complex patients.
