We propose that the fermionic part of the action in the framework of the noncommutative description of the Standard Model is spectral, in an analogous way to the bosonic part of the action that is customary considered as being spectral. We then discuss the terms that appear in the asymptotic expansion of the fermionic spectral action.

1. Introduction

Current experimental data have confirmed neutrino oscillations, implying that at least two of the neutrinos have small albeit nonzero masses [1]. Several models have been consequently proposed to explain the origin of such nonzero neutrino masses, considering neutrinos as being either Dirac fermions or Majorana particles [2].

In the geometric interpretation of the Standard Model of particle physics, proposed within the framework of noncommutative geometry, neutrinos were originally massless Majorana particles [3]. Yet the experimental confirmation that, beyond any doubt, neutrinos of different flavor oscillate, has enforced the introduction of the neutrino masses into the model. Most of the Standard Model phenomenology obtained through the noncommutative spectral geometry approach is based on considering either Dirac or Majorana massive neutrinos and employing the see-saw mechanism [4].

In this note we propose a consistent treatment of both the fermionic and the bosonic parts of the action [5], an approach which implies nontrivial corrections leading to nonminimal fermion couplings. The idea behind the fermionic spectral action we propose, follows the customary bosonic spectral action approach. For the bosonic spectral action, one assumes the existence of some energy cut-off \( \Lambda \), and thus obtains an effective action that depends on the spectrum of the Dirac operator truncated at \( \Lambda \). One then computes the asymptotic expansion of the leading term in \( \Lambda \). We propose a similar approach for the fermionic action, usually expressed as the expectation value of the Dirac operator for a fermionic field \( \Psi \), which depends only on the truncated Dirac operator (namely one considers only the terms with eigenvalues smaller than the cutoff \( \Lambda \)).

The purpose of this paper is to investigate the qualitative consequences of the spectral fermionic action we propose, leaving the details of the model (including the Lorentzian formulation [6], fermion doubling [7,8], various forms of the fermionic action for different KO-dimensions etc.) for a future study. Though usually, it is argued that the bosonic spectral action offers a window into very high energies [9] and implies a natural framework for an early universe cosmology [10], we believe that correction terms to the fermionic spectral action can be even currently observed. A previously proposed toy model [11] suggested that the fermionic spectral action might be responsible for additional mass terms; in the following we discuss in detail the possible nonminimal interaction terms.

2. The fermionic action

The fermionic action for the spectral triple, which gives the dynamics and interactions between fermions and the bosonic field, is usually formulated as the expectation value of the Dirac operator \( D_A \) that takes the inner fluctuations into account, in the state given by a fermionic field \( \Psi \):

\[
S_F = \langle \Psi | D_A | \Psi \rangle.
\]  

(2.1)

For the almost commutative geometries, with a specific KO dimension 2 \((\text{mod } 8)\), which is used in the description of the Standard Model, one could consider another version of the action (on the total Hilbert space), in terms of the antisymmetric bilinear form:
\[ S_{f,f} = \langle J | \Psi | D_A \Psi \rangle, \]  

(2.2)

where \( J \) the real structure on the spectral triple defined by the choice of an algebra, a Hilbert space and a self-adjoint Dirac operator. This form may be restricted to the subspace of right-handed fermions, reducing the unnecessary doubling of the space of fermions [7].

In the noncommutative geometry approach there exists, however, a remarkable and quite unnatural difference between the two parts of the action. While the bosonic part depends only on the reduced spectrum of the Dirac operator, the fermionic one considers explicitly the full spectrum. This has been first observed in [12], where it was postulated that also the fermionic action should have a similar form, yet the problem was not discussed until the analysis of [11].

3. The spectral fermionic action

We propose to write the fermionic action functional, using similar cut-off regularization as is customary done for the bosonic case. Let us note that a \( \zeta \)-function regularization for the bosonic spectral action has been proposed in [13] in order to address the issues of renormalizability and spectral dimensions. Certainly, using the spectral action generalization leads to issues with the interpretation of the Euclidean formulation of spinors and the reduction of the model due to the so-called fermion doubling (or, more correctly, double doubling).

We shall work solely in the Euclidean setup, leaving aside potential problems and looking only for terms that could lead to new physics. Our approach follows the one used for the bosonic spectral action, where the leading terms introduce one by one the geometry, the interactions, and the coupling between them. The fermionic term, by definition gives only the minimal coupling between fermions, gauge fields and the Higgs. In what follows we will investigate the type and form of nonminimal couplings, motivated by the geometric structure of the interactions as described by noncommutative geometry.

Let us propose (for the simplest Euclidean model) the cutoff fermionic action

\[ S_{f,\Lambda} = \langle \Psi | g_\Lambda (D_{\Lambda}) \Psi \rangle, \]  

(3.1)

for a suitable function \( g \) and taking \( g_\Lambda(x) = g(x/\Lambda) \). Observe, that we take a function of \( D_{\Lambda} \) and not \( D_{\Lambda}^2 \) on purpose, as the spectrum of \( D_{\Lambda} \) is not necessarily invariant with respect to change \( D_{\Lambda} \to -D_{\Lambda} \). Since any function can be splitted into the sum of an even and an odd function, and an even function can be taken as a function of \( D_{\Lambda}^2 \), and using

\[ g(x) = f(x^2) + xh(x^2), \]  

(3.2)

one realizes that Eq. (3.1) includes two choices:

\[ S_{f,\Lambda} = \langle \Psi | J \Lambda (D_{\Lambda}^2) \Psi \rangle, \quad S_{0,\Lambda} = \frac{1}{\Lambda} \langle \Psi | D_{\Lambda} h_\Lambda (D_{\Lambda}^2) \Psi \rangle, \]  

(3.3)

where in principle, \( f, h \) are two arbitrary functions of the cut-off type. Using the fact that \( D_{\Lambda} \) commutes with \( h_\Lambda (D_{\Lambda}^2) \) we can rewrite the latter expression as:

\[ S_{0,\Lambda} = \frac{1}{\Lambda} \langle \Psi | h_\Lambda (D_{\Lambda}^2) D_{\Lambda} \Psi \rangle, \]  

(3.4)

which would enable us to use the tools of heat trace expansion [14,15] for commutative and almost commutative geometries.

3.1. Commutative geometries

Let \( M \) be a Riemannian spin manifold and \( L^2(S) \) its spinor bundle and \( \Psi \) a spinor field. Define by \( P_\Psi \) an endomorphism of the bundle of spinors that locally, at each point \( x \in M \), projects on the spinor \( \Psi(x), \Phi(x) \to \langle \Psi(x) | \Phi(x) \rangle \sigma \), or equivalently, using physics notation \( P_\Psi = \langle \Psi(x) | \Phi(x) \rangle \).

Let \( D \) be a Dirac operator that lifts the torsion-free Levi-Civita connection to the spinor bundle. Although one can consider Dirac operators that arise from connections with torsions, we concentrate on the usually assumed case of vanishing torsion. We shall interpret the above fermionic action terms as arising from the heat kernel expansion of the type:

\[ S_{e,\Lambda} = \text{Tr} \left( P_\Psi g_{\Lambda} (D^2) \right), \]  

(3.5)

noting that \( P_\Psi \) is a local operator (endomorphism of the bundle on which \( D \) acts). Following the same approach as for the bosonic spectral action, we use the heat trace expansion:

\[ \text{Tr} \left( e^{-t D^2} \right) = \sum_{n=0}^\infty t^n (n-4) \int_M a_n(x, T), \]  

(3.6)

where

\[ a_0(T, x) = (4\pi)^{-2} \text{tr} T, \quad a_1(T, x) = (4\pi)^{-2} \text{tr} \left( T \left( -\frac{R}{6} + E \right) \right). \]  

(3.7)

For the fermionic spectral action, the coefficients of this expansion are the moments of the functions \( f \) and \( h \) [15] (see Eq. (3.2)). Here \( \text{tr} \) denotes the local trace operation in the endomorphisms of the spinor bundle taken at point \( x \). Note that \( \text{tr} P_\Psi = \langle \Psi(x) | \Phi(x) \rangle \) and therefore, for a 4-dimensional manifold we shall have the following leading terms, which arise from the fact that for the Dirac operator \( E = R/4 \), with \( R \) the scalar Ricci curvature:

\[ \Lambda^4 \int_M \sqrt{\text{g}} \left( \text{tr} P_\Psi \right) = \Lambda^4 \int_M \sqrt{\text{g}} \langle \Psi(x) | \Phi(x) \rangle, \]  

(3.8)

\[ \Lambda^2 \int_M \sqrt{\text{g}} \text{tr} \left( P_\Psi \frac{R}{12} \right) = \Lambda^2 \int_M \sqrt{\text{g}} \frac{R}{12} \langle \Psi(x) | \Phi(x) \rangle. \]

The leading term (in \( \Lambda^4 \)), which resembles the cosmological constant term, corresponds to the bare fermion mass term whereas the second term (in \( \Lambda^2 \)) comes from every part of the spectral action and describes the non-minimal coupling of fermions to gravity through the scalar curvature [18,19].

As for the odd part of the fermionic spectral action, we propose to write it using similar arguments as:

\[ S_{0,\Lambda} = \frac{1}{\Lambda} \text{Tr} \left( P_\Psi D_\Psi h_{\Lambda} (D^2) \right), \]  

(3.9)

where the local operator \( P_\Psi D_\Psi \) is and endomorphism of the spinor bundle of the form:

\[ \Phi(x) \to D \Phi(x) \langle \Psi(x) | \Phi(x) \rangle. \]  

(3.10)

In a similar way as for the even case, observe that \( \text{tr} P_\Psi D_\Psi = \langle \Psi(x) | D \Psi(x) \rangle \) with (.) the local scalar product on the sections of the spinor bundle, with values in \( C^\infty(M) \).

The odd component of the fermionic spectral action introduces at leading order (in \( \Lambda^3 \)) the fermion dynamics:

\[ \Lambda^3 \int_M \sqrt{\text{g}} \langle \Psi(x) | D \Phi(x) \rangle, \]  

(3.11)
while the next order terms would contribute (in the case of pure gravity) further coupling to scalar curvature $R$:

$$\Lambda \int \frac{\sqrt{g}}{M} R \langle \Psi(x) | D \Phi(x) \rangle. \quad (3.12)$$

3.2. The Einstein-Yang-Mills system

The above discussed case extends to the situation of a simple noncommutative modification of geometry [5] where one considers the algebra of $M_2(\mathbb{C})$ valued functions on the spin manifold $M$ and uses the family of Dirac operators constructed by gauge fluctuation of the Dirac operator $D$. Such family, which is obtained through the so-called internal fluctuations of the metric, is of the form:

$$D_A = D \otimes \text{id} + A, \quad (3.13)$$

where $A$ is a gauge potential $(A = \sum_i a_i [D, b_i])$ for $a_i, b_i \in C^\infty(M) \otimes M_2(\mathbb{C})$. This includes, in particular, the case of Dirac operators twisted by a connection on a vector bundle.

If the spectral triple is real and satisfies the one-condition [20] one should modify the above family by correcting $A$ through (with a sign determined by $JD = \pm D J$ $JAJ^{-1}$). Since the square of the Dirac operator contains the gauge curvature $F$, the formulae for the heat trace expansion are modified, $E = (R/12) + F$, and consequently the first three leading fermionic action terms are modified as follows:

$$\Lambda^4 \int \sqrt{g} \langle \Psi(x) | D \Psi(x) \rangle, \quad \Lambda^3 \int \sqrt{g} \langle \Psi(x) | D_A \Psi(x) \rangle, \quad \Lambda^2 \int \sqrt{g} \langle \Psi(x) | \left( \frac{R}{12} + F \right) \Psi(x) \rangle. \quad (3.14)$$

The only difference from the previous case is – apart from the multiplicity of fermionic fields that comes from the representation of the algebra $M_2(\mathbb{C})$ – the minimal coupling of fermions with gauge fields that appears in the second term (in $\Lambda^3$) as well as the Pauli interaction Lagrangian that appears in the third term (in $\Lambda^2$), that locally looks like

$$\int \sqrt{g} \langle \Psi(x) | F \Psi(x) \rangle = \int \sqrt{g} \Psi(x)^T (\gamma^\mu \gamma^\nu F_{\mu\nu}(x)) \Psi(x), \quad (3.15)$$

and which can be nontrivial even in the case of electrodynamics, which in the case when $J$ is present corresponds to the algebra $\mathbb{C} \otimes \mathbb{C}$.

3.3. The almost commutative geometries

Let us now consider the simplest noncommutative geometry, made from the product of a smooth four-dimensional manifold $M$ (with a fixed spin structure), by a discrete finite-dimensional noncommutative internal space $F$, defined in the language of finite spectral triples. Since effectively the Dirac operator of this product geometry is of the same type as for an Einstein-Yang-Mills system, one does not expect any significant qualitative differences from the corresponding studies of commutative geometries.

Let us recall the basic notions. We take as the underlying algebra of the model $\mathcal{A} = C^\infty(M) \otimes \mathcal{A}_F$, which is represented on the Hilbert space $L^2(S) \otimes \mathcal{H}_F$, and the Dirac operator is $D = D_M \otimes \text{id} + \gamma_5 \otimes D_F$, where again $D$ denotes the standard Dirac operator on the spin manifold $M$ and $D_F$ is the Dirac operator of the finite spectral triple $(\mathcal{A}, \mathcal{H}, D_F)$. We refer for the details of construction of product geometries and related issues to [3].

The family of Dirac operators $D_A$ arises similarly as discussed in the previous section, as fluctuations of the Dirac operator. They include both the classical gauge fields, with the unitary group of inner automorphisms of the algebra $\mathcal{A}_F$ as well as the gauge fields related to discrete geometry, which are interpreted as the Higgs field. More precisely,

$$D_A = D \otimes \text{id} + A + (\gamma_5 \otimes 1) D_F (H), \quad (3.16)$$

where $A$ are the inner fluctuations of the Dirac operator $D$ (containing, if we assume the reality of the spectral triple, also the real part of fluctuation) and $D_F (H)$ are inner fluctuations of the product geometry with respect to the discrete Dirac operator $D_F$. Note that both $A$ and $D_F (H)$ are, from the technical point of view, just matrix-valued functions on the manifold $M$, which are represented on $L^2(S) \otimes \mathcal{H}_F$.

To obtain the leading terms in the spectral action we use the heat trace asymptotic expansion for the square of the Dirac operator,

$$D_A^2 = \nabla^* \nabla - E, \quad (3.17)$$

where $\nabla$ is a connection on the spinor bundle tensored with $\mathcal{H}_F$ and $E$ is the endomorphism of the latter bundle.

In local coordinates over the manifold, with $\gamma^\mu$ being the usual gamma matrices, we have:

$$E = -(D_F (\Phi))^2 - \sum_\mu \langle \gamma^\mu \gamma^\nu F_{\mu\nu} (\Phi) + i \gamma_5 \gamma^\mu M (\mu (H)), \quad (3.18)$$

where $F_{\mu\nu}$ is the curvature tensor of the gauge connections, $(D_F (\Phi))^2$ is the potential term for the fields $H$ and the last term $M (\Phi (H))$ is the endomorphism of the bundle that depends on the covariant derivative of fields $H$.

We shall analyze these terms in the next section, in the particular case of the almost commutative geometry underlying the Standard Model.

4. The application to the Standard Model

Let us briefly recall the basics of the Standard Model description within the framework of almost commutative geometry. To obtain the Standard Model the minimal choice of the algebra in the spectral triple defining the discrete internal space $F$ is $\mathcal{A}_F = \mathbb{C} \oplus \mathbb{H} \oplus M_2(\mathbb{C})$. This algebra is represented on a 16-dimensional Hilbert space that includes all fermions (assuming Dirac neutrinos) or 15-dimensional if we work with Majorana neutrinos only. For the details of the action in a convenient basis see [20] or [16,17] for a most recent formulation and principles of constructing the Dirac operator both for the quark and leptonic sector.

The discrete Dirac operator written in the basis of fermions, taken in the order (for leptons) $\nu_R, e_R, \nu_L, e_L$ (not that as a rule each fermion is denoted cumulatively for $N$ generations) is

$$D_F = \begin{pmatrix} 0 & 0 & \Upsilon_\nu & 0 \\ 0 & 0 & 0 & \Upsilon_\tau \\ \Upsilon_\nu & 0 & 0 & 0 \\ 0 & \Upsilon_\tau & 0 & 0 \end{pmatrix}, \quad (4.1)$$

where $\Upsilon_\nu, \Upsilon_\tau$ are $N \times N$ mass and mixing matrices. The fluctuated discrete Dirac operator $D_{F,H}$ is:
\[ D_{F,H} = \begin{pmatrix} 0 & \tau e^0_H & \tau e^+ H^0 \\ -\tau e^+_H & 0 & \tau e^0_H \\ \tau e^+_H & \tau e^0_H & 0 \end{pmatrix}, \tag{4.2} \]

where \( H = H^0 + H^- j \) denotes a quaternionic field (Higgs doublet). The discrete part of the Dirac operator has such form also for the quark sector, if we take quarks in the order \( q^u_L, q^d_L, q^c_L, q^t_L \) and the mass and mixing matrices are, respectively \( \Upsilon_u \) and \( \Upsilon_d \).

### 4.1. The fermionic spectral action for the SM

As we have previously seen, the first two leading terms of the fermionic spectral action are the bare mass term and the usual fermionic action. As the Standard Model is chiral, in the Lorentzian version the bare mass term is not possible as it is not a gauge invariant. In the Euclidean version, however, it can appear in the model with the fermion doubling but will have to vanish if one requires that the action terms are restricted to the physical space of fermions (by removing the fermion doubling [7]).

The next term yields the usual part of action, which includes the dynamical term for fermions, minimal coupling to gauge fields and the coupling between the Higgs field and fermions, which gives the mass terms in the broken symmetry phase.

The only possible corrections and new effects can be therefore visible in the term, which is proportional to \( \Lambda^2 \). Of course, we have there similar terms as in the Einstein-Yang-Mills system, that is the nonminimal coupling of fermions to gravity (through the scalar curvature) and the Pauli-type interaction terms (coupling to curvature of connections) [21].

However, we shall additionally have the term of the fermionic spectral action that contains the square of the fluctuated discrete part of the Dirac operator, \( D_F(H)^2 \), that contains the Higgs field. We discuss now two interesting cases of Dirac and Majorana neutrinos, concentrating our analysis on the leptonic sector. Observe that the same could be, of course, used for the spatial part of the Dirac manifold leading to higher-derivative terms in the fermionic action that have been considered in some models [22,23]

### 4.2. Dirac neutrinos

Within the Standard Model, the square of the finite Dirac operator gives the corrections to the fermion masses. Using the notation we have introduced previously, we compute \( D_F(\Phi)^2 \) restricted to the leptonic sector:

\[
(D_{F,H})^2 = \begin{pmatrix} \Upsilon_\nu^* \Upsilon_\nu |H|^2 & \Upsilon_\nu^* \Upsilon_\nu^* e^0_H & 0 & 0 & 0 \\ 0 & \Upsilon_\nu^* \Upsilon_\nu^* e^0_H & \Upsilon_\nu^* e^0_H & 0 & 0 \\ 0 & 0 & \Upsilon_\nu^* \Upsilon_\nu^* e^0_H & \Upsilon_\nu^* e^0_H & 0 \\ 0 & 0 & 0 & 0 & \Upsilon_\nu^* \Upsilon_\nu^* |H|^2 \end{pmatrix}, \tag{4.3} \]

where \( \Upsilon_\nu, \Upsilon_\nu^* \) are the mass and mixing matrices, respectively.

The order of the corrections, when compared to the main mass term are of the order \( 1/\Lambda \) and therefore will be negligible when compared to the Dirac mass terms \( \Lambda \) in the vacuum expectation value of the Higgs field: \( H = H_v \) (that is \( H^0 = H_v, H^- = 0 \)).

### 4.3. Majorana neutrinos

In the noncommutative description of the Standard Model that uses only left-handed neutrinos there is no room for the neutrino mass terms. The natural interpretation of such model is in terms of Majorana neutrinos, as after restricting it to the physical subspace (reducing the fermion doubling) the neutrino spinor fields are their own antiparticles. Of course, there are known mechanisms to generate possible mass terms, yet all of them involve quadratic coupling to the Higgs. In view of the analysis of the fermionic spectral action we discussed previously, we argue below that one can obtain such terms from the next leading term in the heat kernel expansion.

Observe, that if there are no right-handed neutrinos, the fluctuations of the discrete Dirac operators on the leptonic sector, in the basis \( (e_R, 1_L, e_L) \), are:

\[
(D_{F,H})^2 = \begin{pmatrix} 0 & -\Upsilon_e^0 H^- & \Upsilon_e^0 H^0 \\ -\Upsilon_e^0 H^- & 0 & 0 \\ \Upsilon_e^0 H^0 & 0 & 0 \end{pmatrix}. \tag{4.4} \]

Note that by taking the term with the square of the finite part of the Dirac operator would not give anything new. Indeed, computing \( (D_{F,H})^2 \) at the Higgs vacuum expectation value we obtain:

\[
(D_{F,Hv})^2 = \begin{pmatrix} \Upsilon_e^0 \Upsilon_e e_{Hv}^0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \]

which similarly as in the Dirac masses case can only add small corrections to the already nonvanishing mass of charged leptons.

To see that some extra terms are possible we need to generalize the form of the spectral action to nonscalar functions. So far we have assumed that the function \( f_\lambda \), which we have taken to define the even part of the spectral action is scalar, that is for every operator \( T \) commutes with \( D_A \) we assume that \( f_\lambda(D_A) \) commutes with \( T \) as well. However, this is not necessary and we may consider other functions provided the full gauge invariance will be preserved.

Leaving aside the question about the classification of such functions, for the specific model, we observe the existence of a particular one. Let \( \tau \) be the operator mapping \( (\nu_L, e_L) \) to \( (\nu_L^c, -e_L^c) \) where \( (\nu_L^c, e_L^c) \) denotes the respective antiparticles. Taking as \( \frac{1}{2} f_\lambda(D_A) = \tau f_\lambda(D_A) \) we still obtain a selfadjoint operator provided that \( \tau \) is selfadjoint (or antiselfadjoint, as is the case for chosen \( \tau \)).

The operator \( \tau \) could be written using Pauli matrices as \( i\sigma_2 \otimes J \), where \( J \) is the reality operator of the model (see [34]) restricted to the leptonic sector. The action of the quaternionic part of the algebra on the antiparticle sector in the noncommutative description of the Standard Model is through \( h \) for \( h \in \mathbb{H} \), where quaternions are represented as complex matrices in \( M_2(\mathbb{C}) \) and \( h \) denotes complex conjugated matrix. Since for any quaternion we have \( th = \bar{t}h \) then \( D_{F,H}(e_L^c, \nu_L^c) \) is invariant under the \( SU(2) \) part of gauge transformations.

Writing explicitly in the \( (e_R^c, \nu_L^c, e_L^c) \) basis the matrix elements of \( D_{F,H} \):  \[
D_{F,H} \tau = \begin{pmatrix} 0 & -\Upsilon_e^0 H^- & \Upsilon_e^0 H^0 \\ 0 & 0 & 0 \\ -\Upsilon_e^0 H^- & 0 & 0 \end{pmatrix}. \tag{4.5} \]

Then the terms in the fermionic spectral action, that arise from \( \text{Tr}(P \bar{f}_\lambda(D^2)) \) in the next-to-leading order, could be explicitly rewritten as:

\[
\Lambda^2(\Upsilon_e \Upsilon_e^c) \left[ \begin{pmatrix} \nu_L^c & e_L^c \end{pmatrix} \begin{pmatrix} H^0 \ H^- \end{pmatrix} \right] \left[ \begin{pmatrix} H^0 \ H^- \end{pmatrix} \begin{pmatrix} \nu_L^c & e_L^c \end{pmatrix} \right] + \text{h.c.} \tag{4.6} \]

As we have observed before the entire expression is gauge invariant and can be identified as a Weinberg term (sometimes called
Weinberg operator) [24], which is used to describe effective mechanism of neutrino mass generation. As the operator is, in fact, non-renormalizable, one often expects the physics behind the effective term as originating from yet unknown heavy intermediate particles.

After the Higgs field gets its vacuum expectation value, which in our choice of the parametrization is \( H^0 = H_v, H^- = 0 \), a neutrino mass is generated, depending on the scale \( \Lambda \), Higgs vacuum expectation value \( H_v \), masses of charged leptons and the coefficients of the cutoff function \( F_\Lambda \). Recall, however, that the usual mass terms appear at order \( \Lambda^2 \), compared to \( \Lambda^3 \) for the Weinberg term. Therefore if one assumes \( \Lambda \) to be much larger than the Higgs vacuum value (in many models this is around the scale of GUT) then the generated neutrino masses will necessarily be small, which agrees with the experiment.

5. Conclusions and outlook beyond the Standard Model

As we have shown, even the simplest model, which is based on the almost commutative geometry with the finite part described by a spectral triple, leads to the appearance of correction terms that give some non-minimal interactions between gravity and fermions, gauge fields and fermions as well as the Higgs field and fermions. It is interesting that no extra particles are required to explain the appearance of neutrino masses. Of course, we have demonstrated only that the spectral action for fermions in the Euclidean version could be constructed and computed leaving aside the problem whether any restriction could appear when considering the Lorentzian version, in particular with respect to the fermion doubling problem [7].

It is also interesting that the next order corrections lead to terms that have been considered in various models, including Pauli interaction terms and nonminimal coupling to gravity. Connecting their origins to the same spectral action principle as in the case of neutrino masses could help to set possible limits on their observational evidence or set constraints on the models from cosmological observations in a similar way it can be done for the bosonic action [25,26].

The neutrino mass corrections are possible in both Dirac and Majorana neutrino models, and may lead to small neutrino masses. The correction terms are nonrenormalizable (which is similar to higher order terms from the bosonic action), yet could be treated as an effective description.

The model allows an extension of the assumed form of the cutoff function to include also a nonscalar part, which means that some internal permutations of the eigenspaces that are within the range of the spectral projection \( P_\Lambda \) are allowed. This point certainly requires further studies, as it is necessary to understand the allowed freedom in the choice of the function. In particular, to introduce the neutrino mixing matrix one needs to generalize the cutoff function further, by adding a mixing to the function (that is modifying \( \tau \) operator so that it is not diagonal for the three families).
