Non-local exchange effects in zigzag edge magnetism of neutral graphene nanoribbons

Jeil Jung

Department of Physics, University of Texas at Austin, Austin, USA

We study the role of non-locality of exchange in a neutral zigzag graphene nanoribbon within the \( \pi \)-orbital unrestricted Hartree-Fock approximation. Within this theory we find that the magnetic features are further stabilized for both the intra-edge and inter-edge exchange compared to mean field theories of zigzag ribbon based on local exchange (like the Hubbard model or the ab-initio Local Density Approximation). The inter-edge exchange produces an enhancement of the band-gap of the magnetic ground-state solutions. The effect of this enhanced exchange on the edge states can not be satisfactorily achieved by a local interaction with renormalized parameters.

I. INTRODUCTION

Zigzag terminated graphene ribbons have recently attracted a lot of attention both by theorists\cite{44,45,46} and experimentalists\cite{47,48,49,50} partly due to the surge in popularity of graphene after seminal transport experiments\cite{51,52}. The unique properties of zigzag edge localized states has prompted using zigzag terminated nanoribbons as a testbed for protocols of magnetism in graphitic systems\cite{53} or for illustrating exotic physics related to the bulk topology of single sheet of multilayer graphene in presence of strong spin-orbit coupling\cite{54}.

Recent experiments have found traces of localized spin polarization at zigzag edges of graphene\cite{55,56,57}, in agreement with theories predicting spin polarization at zigzag edges in presence of electron interactions\cite{58,59,60}. The agreement of the qualitative features between solutions predicted by different methods such as the Hubbard model and DFT with different semi-local approximations for the energy functionals point towards a robust underlying property of these systems for which the magnetic solutions are not very sensitive to the specific details of electron interaction. Considering that magnetic ordering is a long-ranged phenomena one natural question that follows is how much physics we are missing by an inadequate treatment of non-local exchange in our solutions. The Hubbard model used in several previous papers\cite{61,62,63} relies on a strictly local onsite interaction term while the common approximations of the energy functionals in DFT\cite{64,65,66} are modeled from local or semi-local exchange and correlation energies\cite{67} of the homogeneous electron gas. In both cases the description of the exchange hole tends to be excessively short ranged in addition to uncertainties associated with self-interaction errors in the case of DFT. In this work we revisit the problem of edge magnetization, predicted by mean field theories in zigzag nanoribbons, within Unrestricted Hartree Fock (UHF) approximation with non-local exchange, that does not suffer from the shortcomings of the previous approximations, and study systematically different truncation ranges for the electron interaction.

We find that a non-local interaction enhances the gaps in the band structure, a feature that can be traced back to both the inter-edge tunneling term and intra-edge magnetic order. As we discuss below models with short-range interaction are unable to mimic the large size of the gap in a consistent way although the solutions remain similar in many aspects.

We start in section II introducing the Hartree-Fock theory in zigzag ribbons and cast it in the form of a two dimensional edge state bands model\cite{68,69} extending beyond the formulation based on the Hubbard model. In section III we show within this framework how the non-local exchange modifies the effective hamiltonian matrix elements when we extend the onsite interaction Hubbard model to include farther neighbor interaction terms. We then move on to discuss in section IV the localization properties of the edge state wave functions along the direction of the ribbon discussing the dependence of the intra-edge band-gap as a function of the electron interaction strength. Subsequently in section V we assess the impact of non-local exchange on the energetics of the inter-edge antiferromagnetic ground state. We finally close the paper with a summary and conclusions section.

II. TWO BANDS HARTREE-FOCK THEORY IN ZIGZAG RIBBONS

A simple and yet fairly accurate way to study edge magnetism in a zig-zag ribbon in a mean field theory is to calculate, for each \( k \)-point, the effect of interaction on the edge state wave functions not allowing edge and bulk to mix their wave functions\cite{70,71}. These edge state wave functions (see appendix for more details) become exponentially localized at the edges whenever \( 2\pi/3a + 1/W \leq |k| \) for sufficiently wide ribbons\cite{66,60} where the ribbon width is \( W = \sqrt{3}aN/2 \) and \( N \) is the number of atom pairs in the unit cell across the ribbon and the lattice constant is \( a = 2.46\AA \). We label in an abbreviated notation the ribbons edge states as \( |k-\rangle \) and \( |k+\rangle \), antisymmetric and symmetric wave functions across the ribbon, that can be symmetrically and antisymmetrically combined to obtain basis functions that are mostly centered either at the (L)eft or (R)ight edge in the ribbon\cite{72}. We denote the respective \( k \)-dependent wave function amplitude at each lattice site \( l \) in the unit cell as \( L_{kl} \) and \( R_{kl} \). We can use this new basis to represent the Hamiltonians as a two by two matrix for each spin \( \sigma = \uparrow, \downarrow \)

\[
H_{\sigma}(k) = \begin{pmatrix}
H_{L\sigma}(k) & H_{LR\sigma}(k) \\
H_{RL\sigma}(k) & H_{R\sigma}(k)
\end{pmatrix}, \quad (1)
\]
The tight-binding band term Hamiltonian is described by a simple nearest neighbor hopping term \( t_{KL} = -2.6 \text{eV} \). In this LR basis representation the Hamiltonian would consist of a tunneling term mixing states located at both edges in the ribbon for each spin

\[
H_{TB}^{\sigma}(k) = \begin{pmatrix}
0 & t_{TB}^{\sigma}(k) \\
t_{TB}^{\sigma}(k) & 0
\end{pmatrix}
\]

(2)

where \( t_{TB}^{\sigma}(k) \) is the energy dispersion for the tight-binding edge conduction band (i.e., the basis we use consists of two eigenstates of \( H_{TB}^{\sigma}(k) \)). For a neutral ribbon the electrostatic Hartree term cancels with the positive background charge and contributes only with a constant term \( C_0 \) in the diagonal elements that can be chosen at our convenience. Then the interaction term of the Hartree-Fock hamiltonian projected on the two-bands LR basis effectively reduces to an exchange contribution on both the diagonal and off diagonal matrix elements

\[
H_{LL,\sigma}(k) = C_0 - \sum_{\ell \ell'} L_{\ell \ell'}^{LR} F_{\ell \ell'}^{\sigma}(k)
\]

(3)

\[
H_{LR,\sigma}(k) = t_{TB}^{\sigma}(k) - \sum_{\ell \ell'} L_{\ell \ell'}^{LR} F_{\ell \ell'}^{\sigma}(k)
\]

(4)

\[
H_{RR,\sigma}(k) = C_0 - \sum_{\ell \ell'} R_{\ell \ell'}^{LR} F_{\ell \ell'}^{\sigma}(k)
\]

(5)

where we have defined

\[
F_{\ell \ell'}^{\sigma}(k) = \sum_{k'} U_{\ell \ell'}^{\sigma}(k') (k' - k) \langle n_{k \ell}, \sigma \rangle
\]

(6)

where \( n_{k \ell}, \sigma \) is the density matrix in the lattice Bloch states and \( U_{\ell \ell'}^{\sigma}(k') \) represents exchange Coulomb integrals whose explicit expressions are presented in the appendix. The Coulomb integrals between the \( \pi \)-orbitals located at different sites can be approximated in Hartree atomic units by effective terms of the forms\(^\text{44,45}\)

\[
V_{\text{eff}}^\pi(d) = \frac{1}{\varepsilon_v \sqrt{a_o^2 + d^2}}
\]

(7)

where \( d \) is the distance between lattice sites and the bonding radius of the carbon atoms \( a_o = a/ (2 \sqrt{3}) \) account for a small damping of the interaction due to the shape and finite spreading of the wave function around the lattice. The on-site repulsion term remains unknown and is commonly bracketed between \( U = 2eV \) and \( U = 6eV \).\(^\text{44,45}\) In our calculation we used a relatively small value of \( U = 2.5eV \), considering that the on-site repulsion strength of \( U = 2eV \) in the Hubbard model where the Coulomb tail is neglected is enough to reproduce the LDA band structures.\(^\text{14,15}\) We include in our calculations an effective screening of \( \varepsilon_v = 4 \) resulting in a global damping of the interaction strength by a factor 1/4 to account for possible effects of dielectric screening (usually \( \varepsilon_v = 2.5 \) in \( SiO_2 \)) and additional screening effects due to \( sp_2 \) orbitals that are neglected in our approximation. The range of the Coulomb interaction is truncated to up 16 nearest neighbors. With the above prescriptions we obtain for the ground state of the neutral system an intra-edge interaction gap near \( ka \sim \pi \) of 1.4eV midway between the B3LYP prediction\(^\text{12}\) of 2.2eV and the LDA prediction\(^\text{2}\) of 0.5eV. We write the two-bands effective Hamiltonian in the following way:

\[
H_\sigma(k) = \Delta_{AF}(k) \sigma \tau_z + \Delta_{F}(k) \sigma I + t_\sigma(k) \tau_z,
\]

(8)

where the pauli matrices \( \tau_z \) and \( I \) are acting in the space of left and right edges and \( \sigma = (+(-)) \) for (up(down) spin). The renormalized inter-edge tunneling \( t_\sigma(k) \) is given by the bare hopping plus a spin dependent enhancement from the exchange interaction. The intra-edge exchange potentials \( \Delta_{AF}(k) \) and \( \Delta_{F}(k) \) correspond to a particular choice of \( \Delta_{AF}(1/2) \) or \( \Delta_{F}(1/2) \) such that they are positive quantities at \( k \sim \pi/a \). Written in terms of the matrix elements defined in Eq. \(^\text{44,45}\) for each momentum \( k \) they are:

\[
t_\sigma(k) = H_{LR,\sigma}(k)
\]

(9)

\[
\Delta_{AF}(k) = \frac{1}{2} (H_{LL,\sigma}(k) - H_{RR,\sigma}(k))
\]

(10)

\[
\Delta_{F}(k) = \frac{1}{2} (H_{LL,\sigma} + H_{RR,\sigma})(k)
\]

(11)

Note that we have assumed a collinear spin arrangement and there is no spin-mixing term. Therefore the 4 \times 4 Hamiltonian matrix is reduced to two block diagonal sub-matrices in Eq. \(^\text{8}\) for each spin sub-space. The energy dispersions associated with the edge states of the two-band Hamiltonian can be written as

\[
E_{\pm}(k) = \sigma \Delta^F(k) \pm \sqrt{\Delta_{AF}^2(k) + t_\sigma^2(k)}.
\]

(12)

In the AF case the term \( \Delta^F(k) \) in equation \(^\text{8}\) amounts to an edge-independent value for both up and down spin and can be set to zero. We notice that the exchange spin splitting terms given by the diagonal elements \( \Delta_{AF}(k) \) have opposite signs for left and right edge states, and a global sign reversal when we consider the opposite spin Hamiltonian. On the other hand, in ferromagnetic self-consistent solutions we get a nonzero net spin polarization in the sample due to edge electrons with spins pointing in the same direction. In this case because \( \Delta_{AF} = 0 \) the intra-edge exchange energy gain included in \( \Delta^F(k) \) is reflected in the overall shift of the band energy for each \( k \). The opposite spin state is shifted in an equal and opposite direction and the bands split in an amount of \( 2\Delta^F(k) \) at each \( k \)-point.

### III. NON-LOCAL EXCHANGE AND THE EFFECTIVE HAMILTONIAN MATRIX ELEMENTS

The non-locality in exchange appear when the Coulomb interaction range is extended beyond the on-site repulsion and is most easily explored comparing the Hartree-Fock Hamiltonian matrix elements of equations \(^\text{13,15}\) with those we obtain using the Hubbard on-site repulsion model. We have used the value of \( U = 2eV \) for our reference Hubbard model calculations following the convention of previous works\(^\text{13,15}\) to match the LDA band gaps. In Fig. 1 we show a comparison of the band structures in the HF and Hubbard model for the lower energy AF and higher energy F configurations.
The effects of non-local exchange in the band structure can be understood more clearly by separating their contributions for the intra-edge exchange potentials corresponding to the diagonal terms of the effective Hamiltonian obtained through equations (3-5) and the off diagonal inter-edge tunneling given in equations (4-9). We discuss our comparison only for AF matrix elements because the effective matrix elements for F solutions remain qualitatively identical. These matrix elements are represented in Fig. 2 for different choices in the truncation of the interaction ranges for the Coulomb integrals in equation (7). Since the left and right basis functions are strictly localized on one of the sublattices the contributions to the diagonal term $\Delta^A_F (k)$ are due to interaction couplings within the same sublattice, therefore these terms contain information of exchange within the same edge atoms. One interesting feature we observe is that the function $\Delta^A_F (k)$ obtained for the fully non-local calculation can be effectively reproduced in most of the edge states zone of the Brillouin zone ($|k| \leq 2\pi/3a+1/W$) by the Hubbard Hamiltonian with a larger effective onsite repulsion. This effective repulsion takes the value of $U_{\text{eff}} = 5.3 \text{ eV}$ for the interaction parameters we have chosen for the HF calculation, which is very close to the critical value of $U_C/|\eta_0| = 2.23$ above which the choice would be unphysical because the ground-state of a 2D graphene sheet develops an antiferromagnetic spin density wave solution. For every choice in the cutoff for the Coulomb interaction range we could obtain different effective choices of $U_{\text{eff}}$ that can reproduce $\Delta^A_F (k)$ satisfactorily. In the Hubbard model the $k$ dependence of the diagonal terms of the Hamiltonian in Eqs. (3-5) is manifestly due to the coefficients $U_{kl}^2$ of the basis function with the largest contributions coming from the lattice sites at the edge and decaying exponentially as we move into the bulk. In the corrections due to farther neighbor interactions (i.e., beyond the Hubbard model) still the dominant contribution to the matrix element $\Delta^A_F$ for a given distance of electron interaction are those connecting to the edge ribbon atom, resulting in a $k$-dependent behavior proportional to that of the $L^2_{\downarrow}$ located at the edge sites. This remarkable behavior for which every additional neighbor contribution in the exchange potential has the same $k$-dependent behavior in the edge states region is most likely the reason for the good overall agreement of the edge state properties in zigzag ribbons calculated within a simple Hubbard model and other mean field calculations. Outside this region of the Brillouin zone we find substantial differences of the potentials for the Hubbard model and Hartree-Fock hamiltonian matrix elements but these differences do not introduce relevant changes in the magnetic configuration of the edges. From the results shown above we expect that the quantitative agreement of the gap at $ka \sim \pi$ between LDA approximation and the Hubbard calculation with $U = 2\text{ eV}$ suggests that the LDA will have a tendency to underestimate the energetics of the ferromagnetic spin alignment along a zig-zag edge. In fact the LDA approximation would introduce a larger gap opening if the spin density of the core electrons of carbon were considered when evaluating the spin dependent LDA exchange potential.

The off diagonal tunneling term $t_{kl} (k)$ given in equation (9) consists of a tight-binding term and an interaction term coupling different sublattices. The onsite interaction term in the Hubbard model cannot couple different sublattices, and therefore the two edge sites, and the matrix elements reduces...
to the tight-binding band dispersion of the conduction edge band. This matrix element can be enhanced in the presence of the long-ranged interaction. The enhanced coherence between left and right edge solutions lead to an increase in the band-gap between the valence and conduction bands of the antiferromagnetic solution. This enhancement of the tunneling term $t_0(k)$ is more pronounced for $k$-points outside the edge states zone because the density tails spread more into the bulk. However it remains essentially zero in the surroundings of $ka \sim \pi$ since the wave functions are strongly localized at the ribbon edge borders.

The ribbon width dependence of both Hartree-Fock and Hubbard solutions remain similar. Previously we illustrated using the Hubbard model that the ribbon width dependence of the solutions can be summarized through the behavior of the Hamiltonian matrix elements near the valley point $k \sim 2\pi/3a$ that obey the following scaling rules as a function of ribbon width $W$

$$\Delta^{AF/F}(k) = W^{-1}\overline{\Delta}^{AF/F}(qW)$$  \hspace{1cm} (13)

$$t(k) = \frac{\gamma_0}{W} \tilde{t}(qW)$$  \hspace{1cm} (14)

where $q = ka - 2\pi/3$ is the dimensionless momentum measured from the valley point and the functions $\Delta^{AF/F}, \tilde{t}$ are functions that do not depend on the width of the ribbon. These rules for wide enough ribbons are not altered with the presence of non-local exchange shown in equations (13) because the additional non-local terms are quadratic in $L_{kl}$ and $R_{kl}$. These in turn follow a similar scaling rule that can be obtained using a continuum model\textsuperscript{1,2}

$$R_{kl} = W^{-1/2} \tilde{R}_{qW,l}$$  \hspace{1cm} (15)

$$L_{kl} = W^{-1/2} \tilde{L}_{qW,l}$$  \hspace{1cm} (16)

where $\tilde{R}_{qW,l}$ and $\tilde{L}_{qW,l}$ are scaled functions that do not depend on the width of the ribbon. Hence the band-gap size and the position of the gap as well as the up and down spin crossover point of the F solution (measured from the valley point) all follow a $W^{-1}$ ribbon width dependence.

IV. INTRA-EDGE LOCALIZATION PROPERTIES OF EDGE STATES

We explore here the properties of localization of the zigzag edge states along the $x$ axis, the direction of periodicity in the ribbon. We estimate this quantity in real space evaluating a partial Fourier transform of the $k$-point dependent density component centered at lattice site $l$ in the ribbon unit cell

$$F_{\sigma}(x) = \int_{k>\pi/3a} dk \ e^{-ikx} |\Psi_{kl}(r)|^2$$  \hspace{1cm} (17)

where $\Psi_{kl}(r)$ is the $l^{th}$ component of edge band Bloch wave function. The integration in $k$ space is over the region of edge states which give the relevant contribution to the edge spin polarization. This definition, reminiscent of the way Wannier functions are calculated,\textsuperscript{8} shows us the way the electrons localize in real space along the edge. In figure 3 we focus on the row of atoms at the ribbon edge and we show that the edge state wave functions spread about seven atomic lattice sites on average, and this spreading length is essentially same for paramagnetic tight-binding solutions and the solutions with edge spin polarization. These features are robust to changes in the ribbon width and the details of the Coulomb interaction with negligibly small departures from this form when we change the strength of the Coulomb interaction or modify the range of the Coulomb interaction. This robust feature of the wide smearing of the electron density on the edge atoms into the neighboring atoms located several lattice constants away along the edge direction is key in producing the long reaching ferromagnetic spin correlation length in a zigzag ribbon edge. Due to this far reaching overlap of the electron density along the edge even short ranged exchange interactions are able to connect edge states centered around different edge atoms and induce an energetically favorable parallel spin alignment.

![FIG. 3: (Color online) Wave function localization along the ribbon centered at different sites in the ribbon unit cell calculated for a ribbon with $N = 12$ corresponding to the antiferromagnetic ground state solution and interaction free tight-binding solution. We can notice a substantial spreading of the wave function at the ribbon edge enveloping about 7 units of lattice constant $a$ along the ribbon.](image)

An intuitive way to relate this edge wave function localization length along the edge with the band structure or the ribbons near $ka \sim \pi$ is by relating the gain of exchange energy per particle for the occupied electrons near the edge atoms through $\Delta_{\text{max}} = \Delta^{AF/F}(\pi/a)$ with an effective localization length $\tilde{\lambda}$ through the formula

$$\Delta_{\text{max}} = \frac{\epsilon^2}{\epsilon_r \tilde{\lambda}}.$$  \hspace{1cm} (18)

We present in table \textsuperscript{4} the values of $\Delta_{\text{max}}$ and $\tilde{\lambda}$ for different choices of $\epsilon_r$ calculated for a ribbon of $N = 12$ atom pairs width. In this analysis we define the onsite term as $U = 10/\epsilon_r$, $eV$ making it dependent of the dielectric screening. The value of $\Delta_{\text{max}}$ remain practically constant as we make the ribbon wider and already for $N = 12$ it gives a good estimate for the tight-binding solution.
of the infinite width limit. The resulting values of \( \lambda \) shows

| \( \varepsilon_r \) | 1 | 2 | 3 | 4 | 5 |
|-----------------|---|---|---|---|---|
| \( \Delta_{\text{max}} \) | 2.35 | 1.16 | 0.78 | 0.58 | 0.46 |
| \( \lambda \) | 2.49 | 2.52 | 2.5 | 2.5 | 2.5 |

TABLE I: Effective localization length \( \lambda \) (in units of lattice constant \( a = 2.46 \AA \)) estimated from the shift from tight-binding bands \( \Delta_{\text{max}} \) (in eV) near \( ka \sim \pi \) for antiferromagnetic spin configuration in graphene nanoribbons. We can observe that \( \lambda \) does not change much as a function of the values of dielectric constants considered. We can observe that the magnitudes of \( \lambda \) are consistent with the estimations that can be extracted for the localization lengths presented in the previous section.

only a very small variation when different values of the relative dielectric constant \( \varepsilon_r \) are used, in agreement with the fact that the shapes of the density localization remains practically unchanged.

V. ENERGETICS OF INTER-EDGE EXCHANGE COUPLING

The nature of antiferromagnetic spin polarization of edge states on different sublattices (and therefore different edges) was studied previously as an unusual type of superexchange interaction\(^\text{15}\) where it is energetically favored with respect to the ferromagnetic state both in the kinetic energy and interaction energy. For the Hubbard model the inter-edge coupling is mediated by the band Hamiltonian tunneling and the local spin-polarization is provided by intra-edge exchange. In the presence of non-local interactions the inter-edge off-diagonal tunneling term plays a role in determining the total exchange energy. In this section we examine the impact of non-locality of exchange in the energetics of the ground-state solution by obtaining the differences in the total energies between AF and F mean field solutions. In a neutral nanoribbon the electrostatic Hartree energy is the same in both AF and F configurations and the total energy difference per edge carbon atom \( \Delta E \) consists of the kinetic energy term and the exchange term

\[
\Delta E = E^F - E^\text{AF} = \Delta T + \Delta E_X. \tag{19}
\]

The kinetic energy difference can be calculated from one-body averages of the tight-binding Hamiltonian for each occupied edge-band states and is essentially the same derivation as in reference\(^\text{15}\) while for the exchange energy we need to sum two body exchange integrals. It will be useful to write it as an integral of a \( k \)-dependent function defining implicitly \( \varepsilon_X (k) \)

\[
E_X = \frac{1}{2} \sum_{i,j} K_{ij} = \int_{BZ} dk \varepsilon_X (k) \tag{20}
\]

where \( K_{ij} \) is the standard definition of exchange integral as can be found in reference\(^\text{61}\). The labels \( i, j \) represent occupied single particle states including the \( k \) quantum numbers, band labels and spin index. In Fig. (4) we show the exchange energy difference as a function of \( k \)-point in the Brillouin zone for the Hubbard model and the Hartree-Fock approximation. We can observe that the details of \( k \)-point dependent contributions to the exchange energy difference is substantially modified in presence of non-local interactions. The global enhancement in magnitude leads to a further stability of AF solutions. In particular the off diagonal interaction terms in the effective Hamiltonian further enhances the stability of AF solutions through an enhanced inter-edge tunneling.

The ribbon width dependence of the total energy differences can be derived from similar considerations as in reference\(^\text{15}\) and follows a \( W^{-2} \) decay law.

VI. SUMMARY AND CONCLUSIONS

In this paper we have addressed the effects of non-locality of exchange in the edge states of a neutral zig-zag graphene ribbon from different points of view. We started with a formal introduction on how the far reaching interaction terms between distant sites can influence the values of the matrix elements of the effective two-bands Hamiltonian describing the edge states, distinguishing the different roles in terms of intra-edge and inter-edge interaction manifested respectively in the diagonal and off diagonal matrix elements, representing respectively the direct exchange energy giving rise to the spin polarization and the tunneling between both sublattices that mix states localized at different edges. Further insight was gained studying the properties of localization of edge states along the direction of the ribbon finding for those states sitting on the edge atoms a rather long ranged enveloping function in the direction of periodicity, a fact that would make possible even for very short ranged interaction terms to connect with
FIG. 5: (Color online) Total energy difference per edge carbon atom as a function of ribbon width showing a $W^{-2}$ decay behavior. The fitting curves in units of $eV$ versus $\AA$ are $6/(W^2 + 300)$ for $\Delta E_{tot}^{HF}$, $1/(W^2 + 50)$ for $\Delta E_{tot}^{Hub}$ with $U = 2eV$ and $2.6/(W^2 - 100)$ for $U = 5.3eV$.

the wave functions centered several lattice constants away in the direction of the ribbon. Finally we analyzed the impact of non-local interaction in the energetics of inter-edge coupling largely responsible for the antiferromagnetic spin polarization of the system.

In light of our studies we have been able to understand better why the Hubbard model based on a strictly short ranged onsite interaction has turned out to give results consistent to solutions found in more elaborate studies. The main reasons would be on the one hand that for edge states the inter-edge tunneling not captured by the Hubbard model is relatively less important with respect to the intra-edge spin splitting contributions whose functional form in $k$-space is accurately captured by an onsite interaction. On the other hand, the spreading of the edge state wave functions along the ribbon allows edge states centered at different atomic sites to connect each other even for strictly short ranged onsite interactions. Edge width depending scaling of band gaps and energy differences of different spin polarized states do also follow a similar law of $W^{-1}$ and $W^{-2}$ respectively as found in the Hubbard model since the width dependence of those quantities are dictated by the wide ribbon asymptotic behavior of the edge state wave functions. Even though the above mentioned qualitative features remain the same both for non-local and local exchange described by the HF and Hubbard models we have also shown that the discrepancies in the total energy differences and the exchange potentials outside the edge states region of the Brillouin zone cannot be modeled accurately with a renormalized effective onsite interaction term. This effect can have a relevant influence in calculating the the spin stiffness or in the band structure of the system when it is shifted away from the neutrality point. The analysis we carried out illustrates the role of non-local exchange in altering the band dispersion and band-gap size due to spin polarized edge states, explaining the relative enhancement of band gaps in the results obtained with non-local B3LYP type functionals with respect to those obtained by more local prescriptions like LDA/GGA functionals.

VII. ACKNOWLEDGMENT.

Appendix I. Hartree-Fock formulation in the two band analysis

The full Hartree-Fock Hamiltonian can be reduced to a two-dimensional matrix representation for each spin. We will represent this Hamiltonian matrix in a suitably chosen basis function, for example the LR basis we have defined in the main text. Given the basis of Bloch functions

\[ \langle r|k\lambda \rangle = \psi_{k\lambda}(r) = \frac{1}{\sqrt{N_K}} \sum_i e^{i(kR_i + \tau_i)} \phi(r - R_i - \tau_i) \eta_\sigma \]

where \( \eta_\sigma \) represents the spinor, \( \tau_i \) represents the displacement vector for sublattices in the unit cell that can be labeled with \( l \), and \( N_K \) is the total number of \( k \)-points, or equivalently, the number of unit cells in the system repeated in the periodic direction. The label \( \lambda = (l, \sigma) \) represents both the lattice site label \( l \) and the spin \( \sigma \). In this basis the general expression of the Hamiltonian is

\[ V_{HF} = \sum_{k\lambda, k\lambda'} U_{k\lambda}^{\lambda\lambda'} \left( \sum_k \langle c_{k\lambda}^+ c_{k\lambda'} \rangle \right) c_{k\lambda}^+ c_{k\lambda'} \]

\[ = \sum_{k\lambda, k\lambda'} U_{k\lambda}^{\lambda\lambda'} (k' - k) \langle c_{k\lambda}^+ c_{k\lambda'} \rangle c_{k\lambda}^+ c_{k\lambda'} \]

where

\[ U_{k\lambda}^{\lambda\lambda'} = \langle k\lambda|k\lambda'\rangle[V|k\lambda'k\lambda'] \]

\[ = \int dr_1 dr_2 \psi_{k\lambda}(r_1)|^2 V(r_1, r_2) |\psi_{k\lambda'}(r_2)|^2 \]

and

\[ U_{k\lambda}^{\lambda\lambda'} = \langle k\lambda|k\lambda'\rangle[V|k\lambda'k\lambda'] \]

\[ = \int dr_1 dr_2 \psi_{k\lambda}(r_1) \psi_{k\lambda'}(r_1) \]

\[ \times V(r_1, r_2) \psi_{k\lambda'}(r_2) \]

where \( \psi_{k\lambda}(r) \) are the Bloch state wave functions.

The matrix elements in the Left-Right (LR) basis can be written in the following way

\[ \langle kL|V_H|kL \rangle = \sum_{\lambda} |L_{k\lambda}|^2 \sum_{k'} N_K U_{k\lambda}^{\lambda\lambda'} \langle n_{k'\lambda'} \rangle \]

where \( N_K \) is the total number of \( k \) points used in the sum. The density matrix operator is defined as \( n_{k\lambda} = c_{k\lambda}^+ c_{k\lambda} \) which represents the quantum numbers that labels the basis set. The explicit forms of the amplitude coefficients \( L_{k\lambda} \) in the tight-binding model can be found in the appendix II. The diagonal \( n_{\lambda} \equiv n_{k\lambda} \) is simply the occupation in the state \( \lambda \) and implicitly means a sum in the \( k \) points

\[ n_{\lambda} = \frac{1}{N_K} \sum_k c_{k\lambda}^+ c_{k\lambda}. \]

We get a similar expression for the other element of the diagonal where we only need to change the \( L \) label into \( R \). The Hartree term averages to zero for the off diagonal matrix element. In a neutral ribbon the presence of the positive background charge neutralizes the electrostatic Hartree-potential

\[ V_{\text{ext}}(l) + \bar{V}_H(l) = 0 \]

so we can focus our attention in the exchange contribution of the interaction.

Now we show the matrix elements of the Fock term. For the diagonal and off diagonal elements we have respectively

\[ U_{k\lambda}^{\lambda\lambda'} = \frac{1}{N_K} \sum_{ij} \left| \langle r_1 - R_i - \tau_i| \phi(r_1 - r_2) |r_2 - R_j - \tau_j \rangle \right|^2 \]

\[ = \frac{1}{N_K} \sum_{ij} |U_{ij}^{\lambda\lambda'}| \]

\[ = \frac{1}{N_K} \sum_{ij} \frac{N_{ij}^{\lambda\lambda'}}{N_K} \]

\[ \sum_{ij} \left| \langle r_1 - R_i - \tau_i| \phi(r_1 - r_2) |r_2 - R_j - \tau_j \rangle \right|^2 \]

\[ = V_{\text{eff}} \left( |L_{ij}^{\lambda\lambda'}| \right) \]

\[ = \frac{1}{N_K} \sum_{ij} \left| \langle r_1 - R_i - \tau_i| \phi(r_1 - r_2) |r_2 - R_j - \tau_j \rangle \right|^2 \]

\[ = V_{\text{eff}} \left( |L_{ij}^{\lambda\lambda'}| \right) \]

The kernels in the Hartree and Fock terms of equation (22), assuming \( \sigma = \sigma' \) and dropping the spin part, can be written as
where we have defined $L''_{ij} = R_i - R_j + \tau_i - \tau_j$ and the Coulomb integrals $V_{\text{eff}} \left( L''_{ij} \right)$ can be approximated through the expression in equation (7).

The Hartree-Fock equations reduce to the Hubbard model when the interactions are reduced to onsite repulsion and the expressions simplify considerably.

$$\langle kL | V_H | kL \rangle = \sum_{l} |L_{kl}|^2 U \left( \langle n_{i\sigma} \rangle + \langle n_{j\sigma} \rangle \right)$$  \hspace{1cm} (33)

$$\langle kL | V_F | kL \rangle = -U \sum_{l} |L_{kl}|^2 \langle n_{i\sigma} \rangle.$$  \hspace{1cm} (34)

Adding both terms we obtain for the diagonal and off diagonal terms

$$\langle kL | V_H | kL \rangle = U \sum_{l} |L_{kl}|^2 \langle n_{i\sigma} \rangle$$  \hspace{1cm} (35)

$$\langle kL | V_F | kL \rangle = -U \sum_{l} |L_{kl}|^2 \langle n_{i\sigma} \rangle.$$  \hspace{1cm} (36)

The last off diagonal term reduces to zero because the coefficients $L_{kl}$ and $R_{kl}$ have zero overlap.

Appendix II. Analytic resolution of the tight-binding LR-functions

In this appendix section we describe the exact tight binding wave functions for the zigzag ribbon edge states. We use periodic boundary conditions in the x-direction and closed boundary conditions in the y direction. Taking advantage of the translational symmetry we may Fourier transform the Hamiltonian and solve a one dimensional problem with some additional details.

The $k$-dependent one dimensional Hamiltonian of graphene is given by:

$$\mathcal{H}_k = \Psi_k^\dagger H_k \Psi_k$$  \hspace{1cm} (37)

$$H_k = \begin{pmatrix} 0 & R + Q \\ R^\dagger + Q & 0 \end{pmatrix}$$  \hspace{1cm} (38)

where $Q = 2 \cos(k/2)$ and the vectors $\Psi$ have $2N$ coordinate, the $N$ top coordinates are the A sublattice sites along the y-direction and the bottom $N$ are the B sublattice sites. The operator $R^\dagger$ is a $N \times N$ matrix which represents a translation by one unit cell in the positive y-direction and $R$ translates in the opposite direction. Employing the ansatz:

$$\Psi_k(n) = \begin{pmatrix} \psi_A \\ \psi_B \end{pmatrix} z^n$$  \hspace{1cm} (39)

we may reduce Schrödinger’s equation to:

$$(1/z + Q) \psi_B = E \psi_A$$

$$(z + Q) \psi_A = E \psi_B$$  \hspace{1cm} (40)

In order to solve these equations with a non-trivial vector $(\psi_A, \psi_B)$ we require that the matrix of coefficients have a zero determinant. This leads to a relation between $z$ and the energy $E$:

$$\begin{pmatrix} -E & z + 2 \cos(k/2) \\ 1/z + 2 \cos(k/2) & -E \end{pmatrix} = 0$$

$$E^2 = 1 + (z + 1/z) Q + Q^2$$  \hspace{1cm} (41)

Note that for a solution $z, 1/z$ is also a solution. We can therefore, write two (unnormalized) solutions:

$$\Psi_1(z,E,k) = \begin{pmatrix} 1 + Q \\ E \end{pmatrix} z^n$$  \hspace{1cm} (42)

$$\Psi_2(z,E,k) = \begin{pmatrix} z + Q \\ E \end{pmatrix} z^n$$

In order to complete our description of wave functions we need one more condition on $E$ or $z$. This condition comes from the edges of the ribbon. For pedagogical purposes, let us briefly mention the case of infinite and semi-infinite samples. In an infinite system we require that the wave functions stay finite in the limits $n \to \pm \infty$. This leads to $|z| = 1$ which is obeyed by Bloch waves $z^n = e^{ipn}$ with a real $p$ being the momentum along the y-direction. In a semi-infinite sheet we require only that the wave function be finite at $n \to +\infty$ and a vanishing amplitude on the one edge. In order to satisfy the vanishing amplitude condition we need to combine the two solutions in Eq.(42) and in order to satisfy the condition at infinity we require $|z| \leq 1$. Bloch waves (with $|z| = 1$) can satisfy both conditions thus the bulk states are rearranged to accommodate the edge. In addition, new real solutions with $|z| < 1$ may also satisfy the boundary condition on the edge with $E = 0$. This gives either $z = -2 \cos(k/2)$ or $1/z = -2 \cos(k/2)$ when only one of these solutions is physical and decays away from the edge. The vanishing amplitude condition is trivially satisfied by setting all A (or B) site amplitudes to zero. This gives the flat band states at momenta $k$ which satisfy $|\cos(k/2)| < 1/2$. This condition defines the region between the $K$ and $K'$ points.

In the case of a ribbon with two edges we require a vanishing amplitude on both sides of the ribbon. This translates to $\Psi_k'(0) = \Psi_k'(N+1) = 0$ where $N$ is the number of unit cells in the y direction (i.e., the number of chain pairs, as defined in the main text). Assuming that $\Psi_k(n)$ is a linear combination of the solutions in Eq.(42) we obtain the relation:

$$-Q = \frac{z^N - z^{-N}}{z^{N+1} - z^{-(N+1)}}$$  \hspace{1cm} (43)

which determines all the possible solutions of the tight binding model on the ribbon. Eq.(43) has $N-2$ Bloch like solutions and 2 real (edge like) solutions. For real numbers $z^n$ produce exponentially decaying solutions which are localized to one of the edges. Similarly to the case of the semi-infinite graphene sheet, the real, edge-localized solutions are found in a region between the valleys. The term valleys usually refers to the nodes in the Brillouin zone where the energy vanishes. Here, we can only see their projection on the $k$ axis at $k = \pm \frac{2\pi}{3L}$. 

However, due to the finite size of the ribbon the edge states regime is smaller and extends from $2\pi/3a + 1/W$ to $4\pi/3a - 1/W$ as will be shown shortly.

In order to find the amplitudes of the left and right wave functions all we need to do is combine the two solutions in Eq.\ref{eq:42} in a way that the boundary conditions are satisfied. We may choose to satisfy the boundary condition provided by one of the edges while the other condition would be automatically satisfied by the correct choice of $z$ (a solution to Eq.\ref{eq:43}). This gives:

$$\Psi_{\pm}(E, k, n) = \alpha \left( \left( \frac{1}{z} + \frac{1}{|E|} \right) z^n - \left( \frac{z + Q}{|E|} \right) z^{-n} \right) \tag{44}$$

and the parameter $\alpha$ is given by the normalization:

$$|\alpha|^{-2} = \sum_{n=1}^{N} \left[ \left( \frac{1}{z} + \frac{1}{|E|} \right) z^n - \left( \frac{z + Q}{|E|} \right) z^{-n} \right]^2 + E^2(z^n - z^{-n})^2 \right] = 2(1 - z^2) \left( 1 + z^2(2N+1) \right) \left( 1 - z^2(2N+1) \right)^2 \tag{45}$$

Please note that $z$ is assumed real (but may be negative). It is worth mentioning that the lower energy solution (with $-|E|$) is antisymmetric about the ribbon center while the higher energy solution is symmetric. For this (anti)symmetry to hold we require $\Psi^\dagger(n) = \pm \Psi^\dagger(N+1-n)$ which is satisfied by $\Psi_{\pm}$.

To gain some intuition about interacting edge states we prefer to work with edge localized states $\Psi_L$ and $\Psi_R$. These are constructed by combining the $\Psi_{\pm}$. Since the parameters $z, Q$ and $\alpha$ only depend on the absolute value of $E$ we get:

$$\Psi_L = \frac{1}{\sqrt{2}}(\Psi_+ + \Psi_-) = \sqrt{\alpha(z + Q)z^n - (z + Q)z^{-n}} \begin{pmatrix} 1 \\ 0 \end{pmatrix}$$

$$\Psi_R = \frac{1}{\sqrt{2}}(\Psi_+ - \Psi_-) = \sqrt{2E|\alpha(z^n - z^{-n})} \begin{pmatrix} 0 \\ 1 \end{pmatrix} \tag{46}$$

Note that the left and right wave functions are localized on one sublattice, determined by the boundary conditions.

In the above discussion we left $z$ as a parameter. However, the value of $z$ is defined by the solutions to Eq.\ref{eq:43} which unfortunately does not provide a closed form. Let us define the inverse localization length, $\lambda$ such that $z = \exp(\lambda)$. Eq.\ref{eq:43} can be rewritten as

$$-Q = \frac{\sinh(N\lambda)}{\sinh((N+1)\lambda)}. \tag{47}$$

Then the energy of this localized solution can be simplified by substituting Eq.\ref{eq:47} into Eq.\ref{eq:41}:

$$E = \pm \frac{\sinh(\lambda)}{\sinh((N+1)\lambda)}. \tag{48}$$
