ABSTRACT

We report the discovery of a warm sub-Saturn, TOI-257b (HD 19916b), based on data from NASA’s Transiting Exoplanet Survey Satellite (TESS). The transit signal was detected by TESS and confirmed to be of planetary origin based on radial-velocity observations with the MINerva-Australis telescope array. An analysis of the TESS photometry, the MINerva-Australis, FEROS, and HARPS radial velocities, and the asteroseismic data of the stellar oscillations reveals that TOI-257b has a mass of $M_P = 0.134_{-0.023}^{+0.023}$ $M_\text{Jupiter}$ ($42.6_{-3.8}^{+4.0}$ $M_\text{Earth}$), a radius of $R_P = 0.626_{-0.012}^{+0.012}$ $R_\text{Jupiter}$ (7.02_{-0.17}^{+0.16} R_\text{Earth})$, and an orbit with eccentricity 0.242_{-0.040}^{+0.040} and period 18.38827 ± 0.00072 days. TOI-257b orbits a bright ($V = 7.570$ mag) somewhat evolved late F-type star with $M_* = 1.390 \pm 0.046 M_\odot$, $R_* = 1.888 \pm 0.033 R_\odot$, $T_{\text{eff}} = 6075 \pm 90$ K, and $v \sin i = 11.3 \pm 0.5$ km s$^{-1}$. Additionally, we statistically validate a second non-transiting sub-Saturn mass planet on a ~ 71 day orbit using the radial velocity data. This system joins the ranks of a small number of exoplanet host stars that have been characterized with asteroseismology. Warm sub-Saturns are rare in the known sample of exoplanets, and thus the discovery of TOI-257b is important in the context of future work studying the formation and migration history of similar planetary systems.

Key words: planetary systems – techniques: radial velocities – techniques: photometric – techniques: spectroscopic – asteroseismology – stars: individual (TIC 200723869/TOI-257)

1 INTRODUCTION

When Mayor & Queloz (1995) announced the discovery of the first hot Jupiter, 51 Pegasi b, astronomers were baffled by the existence of a Jovian planet orbiting its host star with such a short orbital period (about 4.2 days). That discovery revolutionized our understanding of the planet formation process, revealing the situation to be more complex than had been expected based on studies of the Solar system (e.g., Lissauer 1993). Radial velocity and transit surveys over the past two decades have uncovered numerous warm and hot giant exoplanets with orbital periods shorter than 100 days (see, e.g., Butler et al. 1997; Bayliss et al. 2013; Brahm et al. 2016; Van Eylen et al. 2018; Dawson et al. 2019; Kipping et al. 2019), and occurrence studies based on those discoveries suggest that such planets can be found orbiting ~ 1% of all Sun-like stars (e.g., Howard et al. 2010, 2012; Wright et al. 2012; Zhou et al. 2019) (in comparison to an occurrence rate of at least 7% for more distant planets; see, e.g., Foreman-Mackey et al. 2016; Wittenmyer et al. 2020).

In addition to the Solar System lacking a hot Jupiter, it also lacks other broad classes of planets such as super-Earths and mini-
Neptunes (∼ 1.5 – 3 $R_\oplus$) as well as planets larger than Neptune and smaller than Saturn, known as sub-Saturns (which we have defined as planets with a radius between ∼ 5 – 8 $R_\oplus$). Despite the lack of sub-Saturns in the Solar System, they appear to be nearly twice as common as Jovians (∼ 8 – 24 $R_\oplus$) for orbital periods between 5 – 100 days, which are surprisingly rare around solar type stars (2.9% for sub-Saturns versus 1.6% for Jovians, Petigura et al. 2013).

Sub-Saturns are a key class of planets to study for understanding the formation, migration, and compositions of giant planets in general. Their large size requires a significant H/He envelope that comprises a majority of their planetary volume, yet their masses are sufficiently small that their cores are not degenerate (unlike for planets near the mass of Jupiter). This means that modeling the interiors of sub-Saturns can be simplified as a planet consisting of a high-density core surrounded by thick H/He envelope and where measurements of mass and radius provide a unique solution for the planet’s core and envelope mass fraction (e.g. Weiss & Marcy 2014; Petigura et al. 2016; Pepper et al. 2017; Petigura et al. 2017).

It is commonly thought that close-in giant planets, such as hot/warm Jupiters and sub-Saturns, do not form in situ, but instead originate beyond the protostellar ice line (typically located at several astronomical units from the host star) where there is sufficient solid material available to build up – ∼ 20 $M_\oplus$ cores (Pollack et al. 1996; Weidenschilling 2005; Rafikov 2006). In the case of Jovian planets, once their cores reach this critical mass regime, they begin to rapidly accrete gas from the protoplanetary disk to form their gaseous envelopes. This process continues until the disk is dispersed (Rafikov 2006; Tanigawa & Ikoma 2007), resulting in Jupiter-sized planets with masses of ∼ 100 – 10,000 $M_\oplus$. For sub-Saturns, however, the runaway accretion of gas appears to either not have occurred at all or did occur but in a gas-depleted disk (Lee et al. 2018). As a result, sub-Saturns have masses that range from ∼ 10 to 100 $M_\oplus$. The mass of a sub-Saturn is strongly correlated with the metallicity of its host star, but is uncorrelated with the resulting radial size (Petigura et al. 2017).

The sample of measurements for longer period ‘warm’ giants and sub-Saturns thus far is small. The detection of more of these systems is then important to better constrain the formation and migration mechanisms of close-in planets.

One such source of warm giant planetary systems is NASA’s Transiting Exoplanet Survey Satellite (TESS, Ricker et al. 2015), launched on 18th April, 2018. As of 6th November, 2019, the TESS mission has delivered a total of 1361 planetary candidates – objects that require further observations from ground-based facilities to confirm the existence of the candidate exoplanets. To date, such follow-up observations have resulted in a total of 34 confirmed planetary discoveries (e.g. Nielsen et al. 2019; Vanderburg et al. 2019; Quinn et al. 2019; Wang et al. 2019) – and it is likely that many more planets will be confirmed in the months to come.

During its initial two-year primary mission, TESS is expected to discover several dozen warm Jupiters, Saturns, and sub-Saturns orbiting bright (V < 10 mag) stars (Sullivan et al. 2015; Barclay et al. 2018; Huang et al. 2018). Those planets will be ideal targets for follow-up observations to measure their masses, through radial velocity measurements, to probe their atmospheric compositions, through transmission and emission spectroscopy, and to determine their spin-orbit angles through measurements of the Rossiter-McLaughlin effect.

In this work, we report the discovery of one such planet, TOI-257b (HD 19916b and TIC 200723869), based on photometric data obtained by TESS, and follow-up observations using the Minerva-Australis facility at the University of Southern Queensland’s Mt. Kent Observatory (Wittenmyer et al. 2018; Addison et al. 2019). The Minerva-Australis facility is an array of five independently operated 0.7 m CDK700 telescopes located at the Mount Kent Observatory in Queensland, Australia (see, Addison et al. 2019, for a detailed description of the facility). Designed as a robotic observatory, instruments are remotely accessible and can be operated both in manual or automatic configurations. Four of the telescopes in the array (T1, T3, T4, T5) simultaneously feed stellar light to a single KiwiSpec R4-100 high-resolution spectrograph via fiber optic cables. The details of the spectrograph and spectroscopic observations are provided in Section 2.3.

In Section 2 we describe the TESS photometric data, and the reduction of the Minerva-Australis spectroscopic data and the radial velocity pipeline, as well as radial velocities collected with other instruments. Section 3 presents the analysis of the data, including the characterization of the host star, the derived properties of the planet, and the limits on any additional planets in the system. In Section 4 we compare TOI-257b with the demographics of the known exoplanets, and discuss the significance of the system. We provide concluding remarks and suggestions for future work in Section 5.

2 OBSERVATIONS AND DATA REDUCTION

TOI-257 (HD 19916) is a bright (V = 7.570 mag) late F-type star, located at a distance of 77.1 ± 0.2 pc (parallax of 12.9746 ± 0.0327 mas from Gaia DR2, Gaia Collaboration et al. 2018). The star is slightly evolved with a radius of 1.888 ± 0.033 $R_\odot$, mass of 1.390 ± 0.046 $M_\odot$, and surface gravity of log $g$ = 4.030 ± 0.011 dex, derived from the asteroseismic analysis of the TESS photometry in Section 3.2. The star has an effective temperature of 6075 ± 90 K and metallicity of [M/H] = 0.19 ± 0.10 derived from the analysis of Minerva-Australis spectra in Section 3.1 as well as a rotational velocity of $v \sin i$ = 11.3 ± 0.5 km s$^{-1}$ in Section 3.3. TOI-257 has rotational period of 8.072 ± 0.268 days based on analysis of the TESS photometry in Section 3.3.

2.1 TESS Photometry

The star TOI-257 (HD 19916, TIC 200723869 Stassun et al. 2019) was observed in Sectors 3 and 4 by Camera 3 of the TESS spacecraft in 2-minute cadence mode nearly continuously between 2018 September 22 and 2018 November 15. The photometric data were processed by the Science Processing Operations Center (SPOC) pipeline as described in Jenkins et al. (2016). Overall, three transits were detected with depth of ~ 1500 parts per million (ppm) and duration of ~ 6 hours. Two transits are detected in sector 3 (on BJD 2458386 and BJD 2458404), and one in sector 4 (on BJD 2458422). The transit at the beginning of sector 3 was observed during an experiment to improve the spacecraft pointing, and the transit in sector 4 was observed during the thermal ramp.

The TESS light curves were accessed from the NASA’s Mikulski Archive for Space Telescopes (MAST). The light curves had been processed by the TESS team using two different techniques: Pre-search Data Conditioning (PDC, the usual way of light curve

2.2 Direct Imaging Follow-up

If a target star has a close companion, the additional flux from the second source can cause photometric contamination, resulting in an underestimated planetary radius, or be the source of an astrophysical false positive. To rule out the presence of close companions, speckle imaging observations were taken of TOI-257 with the SOAR and Zorro instruments.

2.2.1 SOAR Speckle Imaging

TOI-257 was observed with SOAR speckle imaging (Tokovinin 2018) on 18 February 2019 UT, observing in a similar visible bandpass as TESS. The 5σ detection sensitivity and the speckle auto-correlation function from the SOAR observation are plotted in Figure 3. Further details of the observations are available in Ziegler et al. (2020). No nearby stars were detected within 3″ of TOI-257.

2.2.2 Gemini-South High-Resolution Speckle Imaging using Zorro

Direct imaging observations of TOI-257 was also carried out on 12 Sept. 2019 UT using the Zorro speckle instrument on Gemini-South. Zorro simultaneously provides speckle imaging in two bands, 562 nm and 832 nm, with output data products including a reconstructed image, and robust limits on companion detections (Howell et al. 2011). Figure 4 shows our 562 nm result and phase folded custom light curve along with the PDC light curve and the individual transits color coded.

were not removed. The resulting detrended SAP light curve was used for recovering the first transit observed by TESS in Sector 3 but excluded from the global fit analysis as systematics were not removable as seen in Figure 1.

To include the first transit from Sector 3 in the global fit analysis, we created a custom light curve following the procedures of Vanderburg et al. (2019) to obtain a cleaner light curve relatively free from systematics and stellar variability. We started by using a larger 4.5 pixel radius aperture to extract the Sector 3 photometry, which reduced the amplitude of the systematics observed in the early part of the light curve compared to the TESS pipeline’s SAP light curve. We then removed systematics from a small segment of the light curve surrounding the first transit (2458383.7 ≤ t ≤ 2458388.0) by decorrelating against the median background flux value from outside the aperture for each 2-minute image and the standard deviation of the Q1, Q2, and Q3 quantile within each 2-minute exposure. We excluded points during the planet transit in our decorrelation to prevent the systematics correction from biasing or distorting the shape of the transit. Next, we simultaneously fit the low-frequency variability (which we modeled as a baseline spline) with a transit model in a similar manner to Vanderburg et al. (2016a), except that we did not also simultaneously fit for the systematics and we introduced a discontinuity at BJD 2458138.95 where we switch from the custom light curve to the PDC light curve. The combination of our custom light curve and the PDC light curve are what we use in the final global fitting analysis with EXOFASTv2 (Eastman et al. 2013; Eastman 2017; Eastman et al. 2019). Figure 2 is the resulting 30 minute binned and phase folded custom light curve along with the PDC light curve and the individual transits color coded.
Figure 1. TESS light curves of TOI-257 from Sector 3 (left panel) and Sector 4 (right panel). The Pre-search Data Conditioning (PDC, upper panels) and Simple Aperture Photometry (SAP, lower panels) versions of the light curves before (shown in red) and after detrending (shown in black and shifted down arbitrarily to avoid overlap with the red points). The detrending function is blue and transits are grey. Top left: A single transit event was recovered by PDC in Sector 3. Top right: A single transit event was recovered by PDC in Sector 4. Bottom left: Two transit events were recovered by SAP from Sector 3. Bottom right: A single transit event was recovered by SAP in Sector 4.

within 1.75′′. This limit corresponds to approximately an M3V star at the inner working angle of ~0.25′′ and M5V at the outer working angle of ~1.75′′.

2.3 Spectroscopy

We obtained high-resolution spectroscopic observations of TOI-257 with Minerva-Australis, FEROS, and HARPS to confirm and measure the mass of the TESS transiting planet candidate. Here we describe the observations from each spectrograph and list the derived radial velocities in Table 2.

2.3.1 High-Resolution Spectroscopy with Minerva-Australis

We carried out an intensive radial velocity follow-up campaign with the Minerva-Australis facility to confirm the planetary nature of the transit-like signals in the TESS photometry, measure the mass and orbital properties of the planet, search for any additional planets in the system, and measure the stellar atmospheric properties of the host star. A total of 53 spectra (observations taken simultaneously from multiple telescopes in the array are counted as one observation) of TOI-257 were obtained at 28 epochs between 2019 July 12 and October 15. Telescopes T1, T3, T4, and T5 in the Minerva-Australis array simultaneously feed via 50 μm circular fiber cables a single KiwiSpec R4-100 high-resolution (R = 80,000) spectrograph (Barnes et al. 2012) with wavelength coverage from 500 to 630 nm.

Radial velocities are derived for each telescope using the least-squares technique of Anglada-Escudé & Butler (2012) and corrected for spectrograph drifts with simultaneous Thorium-Argon arc lamp observations. We observed TOI-257 with up to four telescopes simultaneously with one or two 30 to 60-minute exposures per epoch. The radial velocities from each telescope are given in Table 2 labeled by their fiber number. Each telescope (fiber) has its own velocity zero-point which is modeled as a free parameter, and the mean uncertainty of the Minerva-Australis observations is 7.6 m s⁻¹. The radial velocities collected by Minerva-Australis show a ~10 m s⁻¹ sinusoidal variation that is in phase with the photometric ephemeris.
with an amplitude compatible with a sub-Saturn-sized planet in a moderately eccentric orbit as shown in Figures 9 and 10. Additionally, we measured the bisector velocity span (BVS) values using the cross-correlation functions (CCFs) as a check to ensure that the radial velocity variation observed is not from stellar activity or a background eclipsing binary system. As shown in Figure 11, no correlations are apparent in the BVS values.

2.3.2 High-Resolution Spectroscopy with the Fiber-fed Extended Range Optical Spectrograph (FEROS)

TOI-257 was observed with the FEROS instrument ($R = 48,000$, Kaufer et al. 1999) on the MPG 2.2 m telescope at La Silla Observatory between 15 December 2018 and 22 January 2019. We collected a total of eight spectra and the observations were performed in simultaneous calibration mode, utilizing the ThAr lamp on the secondary fiber to track and remove instrumental variations due to changes in the temperature and pressure during the science exposures. The exposure times were set to 300 s, resulting in signal-to-noise ratio between 270 and 370 per resolution element. We produced radial velocities by cross-correlation with a G2-type binary mask template using the CERES pipeline (Brahm et al. 2017), which also corrects the radial velocities for instrumental systematics and the Earth’s motion.

3 ANALYSIS

3.1 Host Star Properties from Spectroscopy

We used the MINERVA-Australis spectra to determine TOI-257’s atmospheric stellar parameters. Through the PYTHON package iSpec (Blanco-Cuaresma et al. 2014; Blanco-Cuaresma 2019), we stacked the stellar spectra to derive the effective temperature, surface gravity, and overall metallicity ([M/H]) of the star. We configured the iSpec synthetic grid to incorporate a MARCS atmospheric model (Gustafsson et al. 2008) and utilized the SPECTRUM (Gray & Corbally 1994) radiative transfer code. [M/H] was derived using version 5.0 of Gaia-ESO Survey’s (GES) line-list (Heiter et al. 2015) normalized by solar values obtained by Asplund et al. (2009). Our synthetic spectra fit was constructed by setting initial values for $T_{\text{eff}}$, log $g$ and
Normalised Flux

produced by analysis. Figure 5 depicts our observed spectra and synthetic model parameters from a broadband spectral energy distribution (SED) \([\text{M/H}] = 6050\text{K}, 4.44\text{dex}, \text{and } 0.00\text{dex}, \text{respectively, based on the}

Table 2. Journal of radial velocity observations of TOI-257. Notes.—M-A Tel3, M-A Tel4, and M-A Tel6 are Minerva-Australis Telescope3, Telescope4, and Telescope6, respectively. (This table is available in its entirety in machine-readable form.)

Figure 5. The best fit synthetic model spectrum from iSpec (the red dashed line) of TOI-257 to that of the combined stellar spectrum obtained from the Minerva-Australis spectroscopic observations (the blue solid line) for the wavelength region between 624.0nm and 625.5nm. The residuals of the fit are shown as the green solid line.

3.2 Astroseismology

3.2.1 Global Astroseismic Parameters

To perform astroseismic analysis on TOI-257 we produced a custom light curve using the TESS Astroseismic Science Operations Center (TASOC, Lund et al. 2017) photometry pipeline\(^4\) (Handberg et al., in prep.), which is based on software originally developed to generate light curves for data collected by the K2 Mission (Lund et al. 2015). The TASOC pipeline implements a series of corrections to optimize light curves for an astroseismic analysis (Handberg & Lund 2014), including the removal of instrumental artefacts and of the transit events using a combination of filters utilizing the estimated planetary period. The photometric performance of the TASOC light curve was comparable to the light curve produced by the SPOC pipeline.

Solar-like oscillations are broadly described by a frequency of maximum oscillation power (\(\nu_{\text{max}}\)) and a large frequency separation (\(\Delta \nu\)), which approximately scale with \(\log g\) and the mean stellar density, respectively (see, Garcia & Ballot 2019). The power spectrum of the sector 3 light curve of TOI-257 displays a power excess near \(\sim 1200\mu \text{Hz}\) (Figure 6), consistent with the spectroscopic \(\log g\) and the expected frequency range from the TESS astroseismic target list (ATL, Schofield et al. 2019). An autocorrelation of the power spectrum reveals a peak at a frequency spacing consistent with the location of the excess power (e.g. Stello et al. 2009). Furthermore, the amplitude of the power excess (\(\sim 9\text{ppm}\)) is consistent with the expected value from observations by \textit{Kepler} (Huber et al. 2011).

The addition of the Sector 4 light curve reduced the significance of the astroseismic detection due to the slightly elevated noise level, and was thus discarded for the remainder of our analysis.

To test the significance of the detection and measure \(\nu_{\text{max}}\) and \(\Delta \nu\) we used 15 independent analysis methods within working

\[\text{[M/H]} = 6050\text{K}, 4.44\text{dex}, \text{and } 0.00\text{dex}, \text{respectively, based on the parameters from a broadband spectral energy distribution (SED) analysis. Figure 5 depicts our observed spectra and synthetic model produced by iSpec. Our derived \(T_{\text{eff}}, \log g\text{ and } [\text{M/H}]\text{ values were then fed into the Bayesian isochrone modeler iSCHRONES (Morton 2015; Montet et al. 2015).}

iSCHRONES uses nested sampling scheme called MULTINEST (Feroz et al. 2009) to determine the stellar mass, radius, and age, which was then used to derive the stellar density and luminosity of TOI-257. For this particular analysis, we used the stellar parameter results from iSpec as well as the parallax value from \textit{Gaia} DR2 with \(G, H, J, K, V\text{ and } W1\text{ magnitudes as priors in the global fit. The spectroscopic stellar iSpec and iSCHRONES values can be found in Table 1 and are in good agreement with the SED analysis performed using EXOFASTv2 and the astroseismology. We then incorporated the }T_{\text{eff}}\text{ and } [\text{M/H}]\text{ values derived from the iSpec analysis of the Minerva-Australis spectra as priors in the final EXOFASTv2 global fit of the data in Section 3.4.}

\[\Delta \nu\text{ and } \nu_{\text{max}}\text{ of TOI-257} = 6075\pm 90, \log g = 3.97\pm 0.10, [\text{M/H}] = 0.19\pm 0.10\text{.}

group 1 of the TESS Asteroseismic Science Consortium (e.g. Huber et al. 2009; Mathur et al. 2010; Mosser et al. 2012; Benomar et al. 2012; Kallinger et al. 2012; Corsaro & De Ridder 2014; Davies & Miglio 2016; Campante 2018). All but one pipeline reported a significant detection of solar-like oscillations. The final parameters are ν\text{max} = 1188 ± 40µHz and ∆ν = 61.4 ± 1.5μHz, with the central value taken from the solution closest to the median of all solutions, and uncertainties calculated from the median formal uncertainty returned by individual pipelines added in quadrature to the scatter over individual methods.

3.2.2 Grid-Based Modeling

We used a number of independent approaches to model the observed
global asteroseismic parameters, including different stellar evolution
codes (ASTEC, GARSTEC, MESA, and YREC. Christensen-

Dalsgaard 2008; Weiss et al. 2008; Paxton et al. 2011, 2013, 2015;

Choi et al. 2016a; Demarque et al. 2008) and modeling methods

(BeSPP, BASTA, PARAM, isoclassify, Silva Aguirre et al. 2015;

Serenelli et al. 2017; Rodrigues et al. 2014, 2017; Huber et al.

2017; Garcia Saravia Ortiz de Montellano et al. 2018). Model inputs

included the spectroscopic temperature and metallicity (see Section 3.1), ν\text{max}, ∆ν, and the luminosity derived from the Gaia parallax. To investigate the effects of different input parameters, models were asked to provide solutions with and without taking into account the luminosity constraint.

The modeling results showed a bi-modality in mass (and thus age) at ∼ 1.2 M\odot and ∼ 1.4 M\odot, with all pipelines favoring the higher mass solution once the luminosity constraint was included. We adopted the solution closest to the median of all returned values, with uncertainties calculated by adding the median uncertainty for a given stellar parameter in quadrature to the standard deviation of the parameter for all methods. This method has been commonly adopted for Kepler (e.g. Chaplin et al. 2014) and captures both random and systematic errors estimated from the spread among different methods. The final estimates of stellar parameters are summarized in Table 3.2.2, constraining the radius, mass, density and age of TOI-257
to ∼ 2 %, ∼ 3 %, ∼ 3 % and ∼ 13 %. We emphasize that these uncertainties in stellar parameters are robust against systematic errors from different stellar model grids, which are frequently neglected when characterizing exoplanets. The stellar mass and radius derived from this analysis is used as priors in the final EXOFASTv2 global fit of the data in Section 3.4.

The period and amplitude from the two Sectors is reasonably consis-
tent for Stellar Rotation Period Estimates

The rotation period of TOI-257 was estimated by performing Lomb-
Scargle (Scargle 1982) periodogram and auto-correlation function

analysis (e.g., McQuillan et al. 2013) on the TESS lightcurve, and

by measuring the projected stellar rotation velocity (v\sin i) from

MINERVA-Australis spectra.

We calculated the Lomb-Scargle periodograms for the raw

TESS light curves from Sectors 3 and 4 individually and from

the combined light curve of the two Sectors, after masking the transit events. For Sector 3, the periodogram shows that the vari-

ability has a period of P = 5.01 ± 0.46 days and amplitude of

A = 114 ± 2 ppm. Sector 4 light curve has a variability with a pe-

riod of P = 4.13 ± 0.22 days and amplitude of A = 144 ± 2 ppm.

The period and amplitude from the two Sectors is reasonably consis-
tent. Performing this analysis on the combined light curves reveals that the variability has a period of P = 4.04 ± 0.13 d, amplitude of A = 88 ± 1 ppm, and false alarm probability (FAP)< 0.01. A second very strong peak is observed at ∼ 2.69 days (or 2P/3) in the Lomb-Scargle periodograms. The FAP was computed from Monte Carlo simulations (e.g., Messina et al. 2010) and the uncertainty in the period of variability was calculated following the procedure of Lamm et al. (2004). The variability from both sectors combined phases-up well at a period of 4.036 days as shown in Figure 7, which indicates that the variability is likely to be astrophysical in nature (from stellar rotation and star spots) and not systematics. We therefore have adopted the period of variability as 4.04 ± 0.13 d.

We also performed an auto-correlation function analysis on the light curves from the individual sectors and combined sectors, and find that the period of variability as P = 5.03 ± 0.61 days and P = 4.12 ± 0.32 days for Sectors 3 and 4, respectively, and a period of P = 4.14 ± 0.22 days for the combined light curves. We also find a strong secondary period in the combined light curves of ∼ 2.7 days. These results are consistent with the periods found from the Lomb-Scargle periodograms.

To determine whether the period of variability is the true ro-

taiton period of the star or one of its harmonics, we calculate an
upper limit on the rotation period from the star’s $v \sin i$ and estimated radius. We measured the $v \sin i$ of TOI-257 by fitting a rotationally broadened Gaussian (Gray 2005) to a least-squares deconvolution profile (Donati & Collier Cameron 1997) obtained from the sum of all the spectral orders from the combined highest S/N spectra of TOI-257. The resulting $v \sin i$ is 11.3 $\pm$ 0.5 km s$^{-1}$ and combined with the stellar radius from asteroseismology of $R_\star = 1.89 \pm 0.33$ $R_\odot$, sets the upper limit on the rotation period for the star of $\sim$ 8.5 days, assuming that the inclination of the stellar rotation axis is near 90 deg to the line of sight.

Given the above analyses, we attribute the 4.04 day period of variability observed in the combined TESS light curve to be half the true rotation period of 8.08 $\pm$ 0.26 days (which gives a $v_{\text{rot}} = 2 \pi R_\star P_{\text{rot}} \approx 11.8$ km s$^{-1}$, consistent with the value of $v \sin i$). The very strong secondary peak observed at $\sim$ 2.7 days in both the Lomb-Scargle periodograms and the auto-correlation function analysis provides further evidence in support of the 8.08 $\pm$ 0.26 days being the true rotation period since the secondary peak corresponds nicely with the $P_{\text{rot}}/3$ harmonic. It is common for the observed rotational modulation to be at one or more of the harmonics, in particular at half and one-third the true rotation period (Vanderburg et al. 2016b). If the rotation period is 4.04 days, we would have expected to find a strong secondary peak at $\sim$ 2.02 days instead of $\sim$ 2.7 days. Given that the rotational period and stellar radius gives a rotational velocity consistent with the measured $v \sin i$, this suggest that the stellar obliquity is low (i.e., $i_\star \approx 90$ deg).

### 3.4 Planetary System Parameters from Global Analysis

To determine the system parameters for TOI-257 and its planet, we used EXOFASTv2 (Eastman et al. 2013; Eastman 2017; Eastman et al. 2019) to perform a joint analysis of the TESS photometry and the radial velocity data. We placed Gaussian priors on $T_{\text{eff}}$ and [Fe/H] from the MINERVA-Australis high-resolution spectroscopy and Gaussian priors on $R_\star$ and $M_\star$ from asteroseismology. We applied an upper limit on the V-band extinction from the Schlafly & Finkbeiner (2011) dust maps at the location of TOI-257. We also performed a separate SED analysis (so as not to double count information used from the asteroseismic priors) as an independent check on the stellar parameters using catalog photometry from Tycho (Hog et al. 2000), 2MASS (Cutri et al. 2003), WISE (Cutri et al. 2013), and Gaia (Gaia Collaboration et al. 2018b) as well as MIST stellar evolutionary models (Dotter 2016; Choi et al. 2016b). Gaussian priors were placed on the parallax from Gaia DR2, adding 82 $\mu$as to correct for the systematic offset found by Stassun & Torres (2018) and adding the 33 $\mu$as uncertainty in their offset in quadrature to the Gaia-reported uncertainty. Table 1 lists the broadband magnitudes used in the SED analysis and the stellar parameters including the ones used as priors in the global analysis.

The resulting best-fit models for the transit light curves are plotted in Figure 8, and for the radial velocities in Figures 9 and 10. A summary of the best-fit model values is given in Table 4. Figure 11 is a plot of the bisector velocity span showing no correlation between the bisectors and the radial velocities for the MINERVA-Australis observations, indicating that the measured radial velocity signal is likely planetary in nature and not due to stellar photospheric activity (Figueira et al. 2013).

From the best-fit Kurucz stellar atmosphere model from the SED and the best-fitting MIST stellar evolutionary model, we find that TOI-257 is a somewhat evolved late-F star with $R_\star = 1.951^{+0.067}_{-0.053}$ $R_\odot$, $M_\star = 1.35^{+0.12}_{-0.38}$ $M_\odot$, $T_{\text{eff}} = 6066^{+88}_{-110}$ K, and log $g = 3.986^{+0.047}_{-0.150}$ (where $g$ is in units of cm s$^{-2}$). These stellar parameters are in reasonably good agreement with the parameters derived from the MINERVA-Australis spectroscopy and asteroseismology. However, we choose not to adopt these stellar parameters since they are not as precise as the ones derived from spectroscopy and asteroseismology and list the stellar parameters derived from the joint analysis of the TESS photometry and the radial velocity data in Table 4. From the joint analysis, we find that TOI-257 hosts a sub-Saturn sized planet with a radius of $R_P = 0.626^{+0.012}_{-0.013}$ $R_J$ (7.02$^{+0.15}_{-0.13}$ $R_\oplus$ and mass of $M_P = 0.134^{+0.027}_{-0.022}$ $M_J$ (42.6$^{+7.2}_{-7.0}$ $M_\oplus$), on a moderately eccentric ($e = 0.242^{+0.048}_{-0.065}$) $\sim$ 18.4 day orbit.

#### 3.5 Complementary Analysis, and Limits on Additional Planets

We further analyze the radial velocity data set in Table 2 with RadVel (Fulton et al. 2018) to provide both an independent analysis for checking consistency in the mass and eccentricity of planet b, and to search for any additional planets. The search for additional planets is motivated by two reasons. First, moderately eccentric Keplerian signals can sometimes resolve into two near-circular resonant signals with additional radial velocity data (e.g. Wittenmyer et al. 2013; Trifonov et al. 2017; Boisvert et al. 2018; Wittenmyer et al. 2019). Second, we wish to evaluate the multiplicity of systems like TOI-257 with warm sub-Saturns.

To apply RadVel, we first median subtract and average the MINERVA-Australis radial velocities from individual telescopes across nights, weighted by the error bars of each measurement. The radial velocity data sets are assumed to be independent in RadVel for the statistical assessment of models. By binning the data across MINERVA-Australis telescopes, we avoid needing to account for the systematics common to all three MINERVA-Australis radial velocities.

The combined analysis of the HARPS, binned MINERVA-Australis, and FEROS data sets are consistent with a planet at the known transiting period and $T_{c}$ from Table 4. However, the circular orbital solution is marginally favored over an eccentric model, according to the relative small-sample Akaike Information Criterion ($\Delta$AICc=4.67) (Akaike 1974; Burnham & Anderson 2002). We fix $P$ and $T_{c}$ to the values independently derived from the ExoFASTv2 analysis of the TESS light curve as they will not be well-constrained from the RVs alone, considering the small baseline compared to the orbital period. Since we do not jointly model the light curve with the radial velocities in RadVel, we are not capturing the additional information from the transit duration ($\sim$ 7.804 hr for circular orbit versus the measured 6.346 hr measured) and shape present in the light curve that may contribute to the increased evidence for an eccentric orbital solution presented earlier with ExoFASTv2. The best fit semi-amplitude from RadVel is similar to the EXOFASTv2 results when using the unbinned MINERVA-Australis radial velocities ($9.2 \pm 1.3$ m s$^{-1}$); however the eccentric model is still not exclusively favored over a circular model ($\Delta$AICc=3.97).

The remaining scatter after removing planet b is consistently larger than the uncertainties of the three instruments and appears structured (see Figure 12). We use a custom modified version of RadVel to generate log-likelihood periodograms (LLPs) with various orbit assumptions to search for additional planets. We start with a single planet model and generate a log-likelihood for a wide range in fixed periods, fitting only for $T_{c}$ and $K$, as well as the relative instrument dependent offsets and additional radial velocity “jitter” noise terms, and then a second LLP assuming a fixed period and
TOI-257b (HD 19916b): A Warm sub-Saturn on a Moderately Eccentric Orbit Around an Evolved F-type Star

Table 4. Median values and 68% confidence interval for TOI-257 from the MCMC EXOFASTv2 analysis. Notes. — M-A T3, M-A T4, and M-A T6 are Mini-ARU-Australis Telescope3, Telescope4, and Telescope6, respectively. *The time of conjunction is closest to the starting time supplied as a prior and is typically a good approximation for the mid transit time. **The optimal conjunction time is the time of conjunction that minimizes the covariance with the orbital period and therefore has the smallest uncertainty. †The equilibrium temperature of the planet assumes no albedo and perfect heat redistribution. The tidal circularization timescale is calculated using Equation 3 from Adams & Laughlin (2006) and assuming a $Q = 10^5$. TESS LC1 is the TESS light curve from PDC and TESS LC2 is the TESS light curve produced using the Vanderburg et al. (2019) procedures.

Figure 7. The left panel shows the TESS light curve of TOI-257 from Sectors 3 and 4 with the best-fit variability. The middle panel is the Lomb-Scargle periodogram for raw light curves from Sectors 3 and 4 combined. The right panel is the phase-folded light curve at the peak period found from the Lomb-Scargle periodogram.

Figure 8. Phase folded TESS light curve of TOI-257 with the individual transits color coded similar to Figure 2. The red solid line is the best-fitting model.

Figure 9. Radial velocity measurements of TOI-257 as a function of time. The radial velocity measurements from each instrument have been binned by day for clarity, however, the analysis was performed using the unbinned data. Minerva-Australis radial velocities are represented by the purple filled-in circles. Radial velocities from FEROS and HARPS are the lime green and gold filled-in circles, respectively. The best-fit model is plotted as the dashed grey line and the center-of-mass velocity has been subtracted. The bottom panel shows the residuals between the data and the best-fit model.
3.6 Assessing the Level of Stellar Activity Present in the Radial Velocities

Next, we consider the possibility that the excess radial velocity residuals after modeling planet b are due to stellar activity rather than a second planet (or both) as presented in the previous subsection. EXOFASTv2 does not permit the inclusion of a stellar activity model for the radial velocities, whereas RadVel does. With our customized version of RadVel, we calculate LLPs using a Gaussian Process (GP) with a quasi-periodic kernel (Rajpaul et al. 2015)\(^5\) to approximate any detectable stellar-activity. We re-run the MCMC analysis for 1- and 2-planet models. We assume broad Gaussian priors on the GP hyper-parameters listed in Table 5. Both \(-4\) or \(8\) day GP period produce qualitatively similar LLPs and mitigate peaks less than the candidate \(P_{\text{rot}}\) and show strong evidence for both the transiting planet and the candidate planet near 71 days (Figure 14). However, the evidence for a GP to model the remaining scatter is minimal. Both 1- and 2-planet models favor a single per-instrument Gaussian noise model over a 4 day GP (\(\Delta\text{AICc} = 3.22\)), while the GP is only marginally favored for the 8 day period case (\(\Delta\text{AICc} = 0.72\)). However, a 2-planet model with a GP is still favored over the corresponding 1-planet model (\(\Delta\text{AICc} = 6.34\)). Figures A3 and A4 in the Appendix show the posterior distributions from RadVel with a quasi-periodic Gaussian Process for a 1-planet and 2-planet circular models, respectively.

Despite being statistically favored (~ 5.1σ detection), we do not claim TOI-257c as a confirmed planet, and relegate it to a “statistically validated” candidate status. Nava et al. (2019) has shown that activity can introduce spurious periodogram peaks at orbital periods longer than the stellar rotation period over the course of a single season, particularly for radial velocities that are unevenly sampled as is the case herein, notably for the HARPS data. However, with adequately sampled data (densely sampled with nightly cadence), Vanderburg et al. (2016b) find no evidence of spurious radial velocity periodogram peaks at periods longer than the stellar rotation period. As such, additional radial velocity monitoring over future seasons or novel stellar-activity mitigation approaches will be necessary to confirm the candidate second planet signal at ~71 days. Lastly, with no evidence for transits elsewhere in the light-curve, we can attribute the significant LLP peaks interior to planet b as a result of stellar-activity and/or a nightly observing cadence.

\(^{5}\) The specific implementation of the quasi-periodic kernel in RadVel can be found on https://radvel.readthedocs.io/en/latest/tutorials/GaussianProcess-tutorial.html.
Table 5. Gaussian and min/max priors for quasi-periodic hyper-parameters for TOI-257 used in RadVel. Notes.—(a) These interpretations are further subject to the specific combination of values for the hyper-parameters, notably for cases with significantly different length and timescale factors. See Angus et al. (2018) for further discussion. (b) Also used for the initial guess.

| Parameter | Unit | Physical Interpretation | $\mu$ | $\sigma$ | Min | Max | Citation |
|-----------|------|-------------------------|-------|---------|-----|-----|----------|
| $\eta_1$  | days | star-spot decay time-scale | 10    | None    | 0   | 100 | stdevs of RVs, over-estimate |
| $\eta_2$  | days | quasi-period             | 10    | 5       | 0   | 100 | Estimated from Giles et al. (2017), Fig. 5 |
| $\eta_3$  | none | period length scale      | 4.036 ($\times$ 2) | 0.134 ($\times$ 2) | 0    | 100 | TESS light curve; Section 3.3, this paper |
| $\eta_4$  | none | period length scale      | 0.3525 | 0.044   | 0   | 100 | Dai et al. (2017); Haywood et al. (2018) |

Figure 13. a) Best-fit 2-planet Keplerian orbital model for TOI-257. The maximum likelihood model(s) is plotted in blue. We add in quadrature the radial velocity jitter terms listed in Table 4 with the measurement uncertainties for all radial velocities to determine individual error bars. b) Residuals to the best fit 2-planet model. c) Same, but radial velocities phase-folded to the period of planet b. d) Same, but radial velocities phase-folded to the period of a possible planet c. Red circles (if present) are the individual velocities binned in 0.08 units of orbital phase.

4 DISCUSSION

Here we have presented the discovery of TOI-257b, the first MINERVA-Australis led confirmation of a TESS transiting planet candidate. TOI-257b is a warm sub-Saturn planet with a radius ~25% smaller than Saturn ($R_P = 7.02^{+0.15}_{-0.13}$ $R_\oplus$) and a mass ~55% less than Saturn ($M_P = 42.6^{+7.3}_{-7.0}$ $M_\oplus$) on a moderately eccentric ($e = 0.242^{+0.040}_{-0.065}$) orbit of $P = 18.38827 \pm 0.00072$ days. The measured mass and radius give a mean density of $0.67^{+0.13}_{-0.12}$ g cm$^{-3}$, consistent with the density of Saturn ($0.687$ g cm$^{-3}$) and less dense than Jupiter ($1.326$ g cm$^{-3}$). Therefore, based on the mass, radius, and bulk density of this planet, it lies within the regime of planets classified as ‘Neptunian worlds’ by Chen & Kipping (2017). Further analysis of the radial velocity data also reveals strong evidence for a second sub-Saturn mass planet in the system with an orbit of ~71 days. We consider this second planet as a ‘statistically validated’ candidate.

To understand the planet formation process, we must determine the compositions of warm sub-Saturns such as TOI-257b, a class of planet which is completely absent from the Solar System. Such objects provide important data for models studying planetary interiors because their masses are sufficiently small that their cores are not degenerate. That is, their mass and radius are dependent on each other such that the core and envelope mass fraction has a unique solution (e.g. Weiss & Marcy 2014; Petigura et al. 2016; Pepper et al. 2017; Petigura et al. 2017). For planets near the mass of Jupiter, cores are degenerate, and planetary radii are essentially independent of mass. Warm sub-Saturns represent an observational sweet

Figure 14. Log-likelihood periodograms generated using RadVel. Shaded from right to left are the period of planet b (insignificant width), the estimated stellar rotation period $P_{\text{rot}}$ from Table 4 (width is ±1σ), and aliases $P_{\text{rot}}/2, P_{\text{rot}}/3$. The orange line includes a Gaussian Process (GP) to model stellar-activity with a quasi-periodic kernel with priors listed in Table 5, while the black line models remaining jitter as per-instrument Gaussian noise. Top: A 1-planet circular model tested at a wide range in fixed periods, fitting for $K, T_c$ and the relative instrument dependent offsets and noise terms (or single GP). Bottom: Same, but for a 2-planet model assuming a fixed period and $T_c$ for planet b from Table 4, but varying both semi-amplitudes to search for additional planets.
spot where mass and radius are comparatively easy to measure, and where those measurements deliver a unique solution for the planet’s core/envelope mass ratio. This is particularly true for sub-Saturns with incident flux less than the \( \sim 0.2 \times 10^5 \) erg s\(^{-1}\) cm\(^{-2}\) limit where stellar irradiation can inflate planetary radii (Demory & Seager 2011). The incident flux for TOI-257b is \( \sim 0.25 \times 10^5 \) erg s\(^{-1}\) cm\(^{-2}\) and is very near this limit. Thus the effects of stellar irradiation on the radius of TOI-257b is likely negligible, allowing its internal structure to be modeled and highlights the significant value of discovering other similar planets with low incident flux.

Figure 15 shows the radius-density diagram for Neptunian worlds (similarly defined after Chen & Kipping 2017 as those with radii from \( \sim 2 \) to \( 10 \) \( R_\oplus \)). We show those planets for which the density has been measured to a precision of better than 50%. TOI-257b has a mean density that is comparable to other exoplanets around the same size. Figure 15 also shows the apparent trend of decreasing bulk density as a function of planet radius, indicative of the increasingly large volatile gas envelope up to around the radius of Saturn.

In Figure 16 we plot the orbital period versus eccentricity for well-characterized transiting exoplanets with a measured mass from radial velocity measurements. The size of the symbols scales with \( \log_{10} \) of the planet mass. TOI-257b is on an eccentric orbit of \( e = 0.242^{+0.040}_{-0.085} \) and lies near the upper range of eccentricity values for other ‘warm’ Neptune and Jovian planets that have orbital periods of \( P \geq 10 \) days in this sample. Figure 16 also shows that planets on short period orbits of \( P \leq 10 \) days tend to have nearly circular orbits, likely due to affects of tidal interactions with the host star circularizing the orbits that were once more eccentric (Fabrycky & Tremaine 2007). For planets orbiting beyond \( P \sim 10 \) days, tidal effects with the host star are expected to be too weak to fully circularize the orbits and a more broad distribution of orbital eccentricity is observed.

Measurements of the spin-orbit alignment for transiting warm Neptunian and Jovian worlds via the Rossiter-McLaughlin effect can provide powerful insights into the origins and migration histories of these planets (e.g., Queloz et al. 2000; Chatterjee et al. 2008; Winn et al. 2010; Naoz et al. 2011; Addison et al. 2018; Wang et al. 2018). Both classes of planets are strongly believed to have been formed beyond their hosts’ protostellar ice line and then experienced inward migration through one of two types of migration channels, quiescent migration through the disk (Lin et al. 1996) or violently dynamical high-eccentricity migration (Fabrycky & Tremaine 2007; Ford & Rasio 2008; Naoz et al. 2011). The latter migration mechanism is thought to be responsible for producing many of the known hot Jupiters due to the large observed range in their spin-orbit angles (e.g., see, Albrecht et al. 2012; Addison et al. 2013, 2018). However, it is unknown if this is the case for the warm sub-Saturn and Neptunian worlds like TOI-257b with orbits greater than 10 days. The limited sample of spin-orbit angles measured for these planet populations (only seven so far according to the TEP-Cat catalog, see Southworth 2011) makes it difficult to draw any firm conclusions and more measurements are urgently needed. This planet presents a suitable candidate for studying the spin-orbit via the Rossiter-McLaughlin effect. We predict that the radial velocity semi-amplitude of the Rossiter-McLaughlin effect for TOI-257 to be \( \sim 8 \) m s\(^{-1}\) based on the stellar and planetary parameters we obtained for this system. The predicted signal, while small, should be detectable on very high-precision (\( \sim 1 \) m s\(^{-1}\)) radial velocity facilities in the south such as on HARPS (Rupprecht et al. 2004), PFS (Crane et al. 2006), and ESPRESSO (Pepe et al. 2010). We predict, given the stellar rotational velocity (as determined from the rotational period and stellar radius) is consistent with the measured \( v \sin i \) from spectroscopy (i.e., suggesting that the stellar obliquity is near 90 deg), that the projected spin-orbit angle \( \lambda \) when measured should be close to the true spin-orbit angle \( \psi \).
5 CONCLUSIONS

We report the discovery of TOI-257b, a $R_P = 0.626^{+0.013}_{-0.012} R_J$ ($R_P \sim 7.0 R_E$) and $M_P = 0.134^{+0.023}_{-0.022} M_J$ ($M_P \sim 42.6 M_E$) transiting planet found by TESS and confirmed using radial velocity data from MINERVA-Australis, FEROS, and HARPS as well as direct imaging from SOAR and Zorro. We also statistically validate an additional non-transiting long-period ($\sim 71$ day) sub-Saturn mass planet candidate orbiting TOI-257 from analysis of the radial velocity data. TOI-257b belongs to a population of exoplanets between the sizes of Neptune and Saturn that appears to be rare. Furthermore, TOI-257b transits a very bright star ($V = 7.570$ mag) on a relatively long-period orbit of 18.423 days making it a great candidate for future follow-up observations to measure its spin-orbit alignment. Warm sub-Saturns such as TOI-257b are important population of planets to study for understanding the formation, internal structures and compositions, and evolution and migration of giant planets. Future observational work of this planetary system will help to elucidate our understanding of these rare sub-Saturn planets that are absent in the Solar System.

ACKNOWLEDGEMENTS
