(Dated: March 8, 2008)

We present a careful and thorough microscopic derivation of the Kondo Hamiltonian for single-molecule magnets (SMMs) transistors. When the molecule is strongly coupled to metallic leads, we show that by applying a transverse magnetic field it is possible to topologically induce or quench the Kondo effect in the conductance of a SMM with either an integer or a half-integer spin $S > 1/2$. This topological Kondo effect is due to the Berry phase interference between multiple quantum tunneling paths of the spin. We calculate the renormalized Berry phase oscillations of the two Kondo peaks as a function of the transverse magnetic field by means of the poor man’s scaling. In particular, we show that the Kondo exchange interaction between itinerant electrons in the leads and the SMM pseudo spin 1/2 depends crucially on the SMM spin selection rules for the addition and subtraction of an electron and can range from antiferromagnetic to ferromagnetic. We illustrate our findings with the SMM Ni$_4$, which we propose as a possible candidate for the experimental observation of the conductance oscillations.

Keywords: Single molecule magnets, Kondo effect, Berry phase

I. INTRODUCTION

Single-molecule magnets (SMMs), such as Mn$_{12}$ (see Refs. 1,2 and Fe$_8$ (see Refs. 3,4), have become the focus of intense research since experiments on bulk samples demonstrated the quantum tunneling of a single magnetic moment on a macroscopic scale. These molecules are characterized by a large total spin, a large magnetic anisotropy barrier, and anisotropy terms which allow the spin to tunnel through the barrier. Electronic transport through SMMs offers several unique features with potentially large impact on applications such as high-density magnetic storage as well as quantum computing.5 Recent experiments have pointed out the importance of the interference between spin tunneling paths in molecules. For instance, measurements of the magnetization in bulk Fe$_8$ have observed oscillations in the tunnel splitting $\Delta_{\mu_0,\mu'_0}$ of the uncharged single-molecule magnet ($q = 0$) for both full- and half-integer spins leads to oscillation of the Kondo effect as a function of $H_{\perp}$. This means that the Kondo effect is observable at zero bias for all values of the magnetic field $H_{\perp,0}$ such that $\Delta_{\mu_0,\mu'_0}(H_{\perp,0}) = 0$.

It is interesting to note that at a finite bias the Kondo effect in a quantum dot in the presence of a magnetic field can be restored by tuning the bias to $eV = \pm q\mu_B H_{\perp}$ (see Ref. 13). For SMMs, however, the interference between the Berry phases of the molecule total spin makes the distance between the split Kondo peaks, which is equal to $eV = \pm \Delta_{\mu_0,\mu'_0}$, oscillate as a function of $H_{\perp}$. A necessary condition for observing these oscillations is a large enough tunnel splitting. Recently a new SMM based on tetranuclear nickel clusters Ni$_4$ with a $S = 4$ ground state has been synthesized.14 Our motivation for studying this particular nanomagnet stems partly from its high symmetry ($S_4$) but, more importantly, from the large tunnel splittings: $\Delta_{\mu_0,\mu_0'} \sim 0.01$ K or larger (depending on the transverse field $H_{\perp}$) between the $|m\rangle = |4\rangle$ and $|m'\rangle = |-4\rangle$ ground states.

Recently, some authors have argued that the Kondo effect is absent at the diabolic points of the Berry-phase interference.12 This conclusion came from considering an ad hoc Kondo Hamiltonian10,11 which was not derived microscopically. Moreover, in recent analysis of the sequential tunneling regime, an ad hoc exchange Hamiltonian mixed with an Anderson-type Hamiltonian was also used without a proper microscopic derivation.16 In this paper, we provide a careful microscopic derivation of the Kondo Hamiltonian suitable for full- and half-integer spin single-molecule magnets by means of a Schrieffer-Wolff transformation.15 By using the exact eigenstates of the positively and negatively charged single-molecule magnet, it is sufficient to apply the Schrieffer-Wolff transformation to second order in the tunneling matrix.
element. The resulting Kondo exchange parameters exhibit the interference between the second-order transition paths going over the two virtual charged states. We show that this very same interference phenomenon is also responsible for the Berry-phase blockade of the current through the single-molecule magnet in the cotunneling regime, which extends our previous results obtained for the Berry-phase blockade in the sequential tunneling regime.

Our derivation of the Kondo Hamiltonian reveals an important detail: The Anderson-type Hamiltonian of the single-molecule magnet can be mapped onto a spin-1/2 Kondo Hamiltonian in two different ways: Let \( S_{q=0} \) be the total spin of the uncharged single-molecule magnet.

1. If the total spins \( S_{q=1} \) and \( S_{q=-1} \) in the ground state of the positively (\( q = -1 \)) and negatively (\( q = 1 \)) charged single-molecule magnet are equal to \( S_{q=\pm 1} = S_{q=0} - 1/2 \), then the Kondo Hamiltonian exhibits an antiferromagnetic exchange coupling, which corresponds to the Kondo problem for spin 1/2 impurities or spin 1/2 quantum dots.

2. If \( S_{q=\pm 1} = S_{q=0} + 1/2 \), then the Kondo Hamiltonian exhibits a ferromagnetic exchange coupling that leads to a vanishing renormalized transverse exchange coupling (Ising interaction), in which case the Kondo effect is absent.

This point is at the very heart of the Kondo problem. The Kondo effect depends crucially on the selection rules for the addition and subtraction of a spin on the molecule. This result is in contrast to the Kondo effect seen in lateral quantum dots where the exchange coupling is always antiferromagnetic due to fact that spin states are degenerate in the absence of anisotropies.

In the following, we provide a complete and detailed description of the Kondo effect in SMMs. Starting from a microscopic model (Sec. III), we derive the effective Kondo Hamiltonian for a SMM attached to metallic leads through tunneling barriers (Sec. III). In Sec. IV we derive expressions for the conductance through a SMM for both zero and finite bias as a function of a transverse magnetic field and use the new SMM Ni_{12} to comment the experimental significance of our theoretical results. Our conclusions are summarized in Sec. VII.

II. MICROSCOPIC HAMILTONIAN

The total Anderson-impurity-like Hamiltonian of a system formed by a single-molecule magnet (SMM) attached to two metallic leads can be separated into three terms (see Fig. 1).

\[
\mathcal{H}_{\text{tot}} = \mathcal{H}_{\text{SMM}} + \mathcal{H}_{\text{lead}} + \mathcal{H}_{\text{SMM–lead}}.
\]

The first term on the right-hand side of Eq. (1) denotes the SMM part, which can be broken into spin, orbital, charging, and gate contributions,

\[
\mathcal{H}_{\text{SMM}} = \mathcal{H}^{(q)}_{\text{spin}} + \mathcal{H}_{\text{orbital}} + \frac{q^2}{2} U - q e V_g,
\]

where \( U \) denotes the charging energy, \( q \) is the number of excess electrons (the charge state of the molecule), and \( V_g \) is the electric potential due to an external gate voltage. In the presence of an external magnetic field, the spin Hamiltonian of the SMM reads

\[
\mathcal{H}^{(q)}_{\text{spin}} = -A q S_{q,z}^2 + \frac{B_2 q}{2} (S_{q,+}^2 + S_{q,-}^2) + \frac{B_4 q}{3} (S_{q,+}^4 + S_{q,-}^4)
\]

\[
+ \frac{1}{2} \left( h_{\perp}^* S_{q,+} + h_{\perp} S_{q,-} \right) + h || S_{q,z},
\]

where the easy axis is taken along the \( z \) direction and \( S_{q,\pm} = S_{q,x} \pm i S_{q,y} \). The magnetic field components were rescaled to \( h_{\perp} = g \mu_B (H_x + i H_y) \) and \( h_{||} = g \mu_B H_z \) for the transversal and longitudinal parts, respectively, where \( g \) denotes the electron gyromagnetic factor. Note that the transverse magnetic field lies in the \( xy \) plane. In this Hamiltonian, the dominant longitudinal anisotropy term creates a ladder structure in the molecule spectrum where the \( | \pm m_q \rangle \) eigenstates of \( S_{q,z} \) are degenerate. The weak transverse anisotropy terms couple these states. The total spin as well as the coupling parameters depend on the charging state of the molecule. For example, it is known that Mn_{12} changes its easy-axis anisotropy constant (and its total spin) from \( A_0 = 56 \mu \text{eV} \) (\( S_{q=0} = 10 \)) to \( A_{-1} = 43 \mu \text{eV} \) (\( S_{q=1} = 19/2 \)) and \( A_{-2} = 32 \mu \text{eV} \) (\( S_{q=2} = 10 \)) when singly and doubly charged, respectively.

![FIG. 1: (Color online) Schematic illustration of a single-molecule field-effect transistor formed by a single-molecule magnet attached to two metallic leads (source and drain) and controlled by a back gate voltage.](image-url)
and

$$\mathcal{H}_{\text{SMM-lead}} = - \sum_{a, k', \sigma, n} \left[ t_{n, k}^{(a)} \psi_{k, \sigma, a}^{\dagger} \psi_{n, \sigma} + \text{H.c.} \right], \tag{6}$$

where $s_a = \sum_{k', \sigma, \sigma'} \sum_{a = R, L} \psi_{k, \sigma, a}^{\dagger} (\sigma \sigma' / 2) \psi_{k', \sigma', a}$ and $t_{n, k}^{(a)}$ is the lead-molecule tunneling amplitude. The operator $\psi_{k, \sigma, a}^{\dagger}$ (\psi_{k, \sigma, a}) creates (annihilates) electronic states in the $a$ lead ($a = R, L$) with linear momentum $k$, spin orientation $\sigma$, and energy $E_k$.

### III. THE KONDO HAMILTONIAN

The weak tunneling amplitudes between the leads and the molecule and the large charging energy cause an effective exchange interaction between electrons in the leads and the spin of the molecule. Although this interaction at first glance seems to have the familiar Kondo form, it is actually unusual because the transversal coupling involves only a subspace of the spin of the molecule. Below, we use perturbation theory to carefully derive an expression for the effective Kondo Hamiltonian of a SMM.

We begin by considering only the SMM and SMM-lead terms in Eq. (1). We divide the Hilbert space into subspaces corresponding to distinct charge sectors of the SMM. Using a block matrix representation, we have

$$\mathcal{H}_{\text{SMM}} + \mathcal{H}_{\text{SMM-lead}} = \begin{pmatrix} \cdots & \mathcal{H}_q & \mathcal{V} & 0 & 0 \\ \mathcal{V}^\dagger & \mathcal{H}_q & \mathcal{W} & 0 & 0 \\ 0 & \mathcal{W}^\dagger & \mathcal{H}_{q+1} & \cdots \end{pmatrix}, \tag{7}$$

where $\mathcal{H}_q$ is the SMM Hamiltonian for the charge sector $q$ [see Eq. (2)], while $\mathcal{V}$ and $\mathcal{W}$ represent the lead-SMM tunneling Hamiltonian, Eq. (6). For certain values of the gate voltage, the charging energy is compensated and Coulomb blockade is lifted. Away from these resonant points, there is an energy gap of order $U$ between consecutive diagonal elements in Eq. (7). Since $U \gg |t_{n, k}|$, we can assume that the off-diagonal elements $\mathcal{V}$ and $\mathcal{W}$ are small perturbations and use a Schrieffer-Wolf Wolff transformation to decouple distinct charge sectors up to terms of order $O((|t_{n, k}|^2 / U)^2)$.  

For simplicity, let us consider the sectors $q = -1, 0, +1$ only, where $q$ denotes the number of excess electrons, and write

$$\mathcal{H} = A + B, \tag{8}$$

where

$$A = \begin{pmatrix} \mathcal{H}_{-1} & 0 & 0 \\ 0 & \mathcal{H}_0 & 0 \\ 0 & 0 & \mathcal{H}_{+1} \end{pmatrix}, \quad B = \begin{pmatrix} 0 & \mathcal{V} & 0 \\ \mathcal{V}^\dagger & 0 & \mathcal{W} \\ 0 & \mathcal{W}^\dagger & 0 \end{pmatrix}. \tag{9}$$

Using the similarity transformation $\tilde{\mathcal{H}} = e^{T} \mathcal{H} e^{-T}$, where $T$ is anti-Hermitian, we have

$$\tilde{\mathcal{H}} = \mathcal{H} + [T, \mathcal{H}] + \frac{1}{2} [T, [T, \mathcal{H}]] + \cdots. \tag{10}$$

We want to determine $T$ such that $B + [T, A] = 0$. For that purpose, it is sufficient to assume that $T$ has the form

$$T = \begin{pmatrix} 0 & C & 0 \\ -C^\dagger & 0 & D \\ 0 & -D^\dagger & 0 \end{pmatrix}, \tag{11}$$

with $C$ and $D$ satisfying

$$\mathcal{H}_{-1} C - C \mathcal{H}_0 = \mathcal{V} \tag{12}$$

and

$$\mathcal{H}_0 D - D \mathcal{H}_{+1} = \mathcal{W}, \tag{13}$$

respectively. Thus,

$$\tilde{\mathcal{H}} = A + \frac{1}{2} [T, B] + O(B^2), \tag{14}$$

where

$$[T, B] = \begin{pmatrix} C \mathcal{V}^\dagger + \mathcal{V} C^\dagger & 0 & \mathcal{V}^\dagger C \mathcal{W} - \mathcal{W}^\dagger C \\ 0 & D \mathcal{W}^\dagger + \mathcal{W} D^\dagger & 0 \\ \mathcal{W}^\dagger C^\dagger - D^\dagger \mathcal{V} & 0 & -D^\dagger \mathcal{W} - \mathcal{W}^\dagger D \end{pmatrix}. \tag{15}$$

Note that the neutral sector ($q = 0$) has been decoupled from the charged sectors at the expense of adding two contributions of order $O(\mathcal{V}, \mathcal{W})^2$ to $\mathcal{H}_0$. To specify the form of these contributions, we use the eigenbasis $\{|\alpha\rangle_q\}$ of $\mathcal{H}_q$, namely,

$$q \langle \alpha | \mathcal{H}_q | \beta \rangle_q = |\alpha\rangle_q \langle \alpha | \mathcal{H}_q | \beta \rangle_q = \delta_{\alpha, \beta} E_{\alpha}^{(q)}. \tag{16}$$

Equations (12) and (13) can be solved in this representation to yield

$$-1 \langle \alpha | C | \beta \rangle_0 = |C\rangle_{\alpha \beta} = \frac{|\mathcal{V}|_{\alpha \beta}}{E_{\alpha}^{(-1)} - E_{\beta}^{(0)}}. \tag{17}$$
In the Coulomb blockade valley, when \( V_g = 0 \) in Eq. (2), the eigenstates of the Hamiltonian \( H_q \) are expressed in terms of symmetric and antisymmetric combinations of the eigenstates of the \( S_{q,2} \) operator, namely,

\[
|s, a\rangle_{m_q} = \frac{1}{\sqrt{2}} \left[ |m_q\rangle_0 \pm |m_q\rangle_0 \right],
\]

with \( m_q = 0, 1, 2, \ldots, S_q \) if \( S_q \) is integer and \( m_q = \frac{1}{2}, \frac{3}{2}, \ldots, S_q \) if \( S_q \) is half-integer. Note that since the matrices \( \mathcal{W} \) and \( \mathcal{V} \) represent the addition (subtraction) of an electron to (from) the SMM, only \( q = 0 \) states that differ in spin projection by 1 are coupled through Eqs. (19) and (20). Conservation of angular momentum upon electron tunneling requires that the intermediate states in the \( q = 1 \) or \( q = -1 \) sectors obey \( |S_{q+1} - S_0| = 1/2 \). For instance, the SMM total spin is lowered by the addition of an electron, longitudinal spin components satisfy \( m_{q+1} = S_{q+1} = S_0 - 1/2 \) and \( m_{q-1} = -S_{q+1} = -S_0 + 1/2 \). Therefore, we define the spin states of the ground state to be \( |\uparrow_q\rangle = |m_q\rangle \) and \( |\downarrow_q\rangle = |-m_q\rangle \). The corresponding eigenenergies are represented in Fig. 2.

Let us first consider intermediate states involving the \( q = 1 \) sector. This situation corresponds to a small positive gate voltage \( (V_g > 0) \). Equation (19) can be used to write the matrix elements of the reduced Hamiltonian of the \( q = 0 \) sector in terms of a product of energy denominators and matrix elements of \( \mathcal{W} \). Using the \( \{ |\uparrow q\rangle, |\downarrow q\rangle \} \) basis and inserting complete eigenvector sets for each sector, i.e. \( \mathcal{F}^{(q)} = \{ |s\rangle_{q0} \langle s| + |a\rangle_{q0} \langle a| \} \), we find

\[
o(\uparrow |D\mathcal{W}^\dagger + WD^\dagger| \uparrow) = 0(\uparrow |s\rangle_{q0} \langle s|D|s\rangle_{11} (s|\mathcal{W}^\dagger | \uparrow) + 0(\uparrow |a\rangle_{q0} \langle a|D|s\rangle_{11} (s|\mathcal{W}^\dagger | \uparrow)) + 0(\uparrow |s\rangle_{q0} \langle a|D|a\rangle_{11} (a|\mathcal{W}^\dagger | \uparrow)) + 0(\uparrow |a\rangle_{q0} \langle a|D|a\rangle_{11} (a|\mathcal{W}^\dagger | \uparrow)) + \text{H.c.},
\]

and

\[
o(\downarrow |D\mathcal{W}^\dagger + WD^\dagger| \downarrow) = 0(\downarrow |s\rangle_{q0} \langle s|D|s\rangle_{11} (s|\mathcal{W}^\dagger | \downarrow) + 0(\downarrow |a\rangle_{q0} \langle a|D|s\rangle_{11} (s|\mathcal{W}^\dagger | \downarrow)) + 0(\downarrow |s\rangle_{q0} \langle a|D|a\rangle_{11} (a|\mathcal{W}^\dagger | \downarrow)) + 0(\downarrow |a\rangle_{q0} \langle a|D|a\rangle_{11} (a|\mathcal{W}^\dagger | \downarrow)) + \text{H.c.},
\]

where

\[
o(\uparrow |D\mathcal{W}^\dagger | \downarrow) = 0(\uparrow |s\rangle_{q0} \langle s|D|s\rangle_{11} (s|\mathcal{W}^\dagger | \downarrow) + 0(\uparrow |a\rangle_{q0} \langle a|D|a\rangle_{11} (a|\mathcal{W}^\dagger | \downarrow)),
\]

and

\[
o(\downarrow |D\mathcal{W}^\dagger | \uparrow) = 0(\downarrow |s\rangle_{q0} \langle s|D|s\rangle_{11} (s|\mathcal{W}^\dagger | \uparrow) + 0(\downarrow |a\rangle_{q0} \langle a|D|a\rangle_{11} (a|\mathcal{W}^\dagger | \uparrow)).
\]
Using Eq. (18) and the fact that $E^{(+1)}_a = E^{(+1)}_a + \Delta_1$, $0\langle \uparrow | s\rangle_0 = 0\langle \downarrow | s\rangle_0 = 0\langle \uparrow | a\rangle_0 = 1/\sqrt{2}$, and $0\langle \downarrow | a\rangle_0 = -1/\sqrt{2}$, we find, after some algebra,

$$0\langle \uparrow | DW^\dagger + WD^\dagger | \uparrow\rangle_0 = \frac{1}{\sqrt{2\Delta_a\Delta_{sa}}} \left[ 0\langle s | (\Delta_a W T^{(1)} W^\dagger - \Delta_1 W | s\rangle_{11} (s | W^\dagger) | \uparrow\rangle_0 \right. + \frac{1}{\sqrt{2\Delta_a}} \left[ 0\langle a | (\Delta_{as} W T^{(1)} W^\dagger - \Delta_1 W | s\rangle_{11} (s | W^\dagger) | \uparrow\rangle_0 \right] + \text{H.c.},$$

(27)

$$0\langle \downarrow | DW^\dagger + WD^\dagger | \downarrow\rangle_0 = \frac{1}{\sqrt{2\Delta_a\Delta_{sa}}} \left[ 0\langle s | (\Delta_a W T^{(1)} W^\dagger - \Delta_1 W | s\rangle_{11} (s | W^\dagger) | \downarrow\rangle_0 \right] - \frac{1}{\sqrt{2\Delta_a}} \left[ 0\langle a | (\Delta_{as} W T^{(1)} W^\dagger - \Delta_1 W | s\rangle_{11} (s | W^\dagger) | \downarrow\rangle_0 \right] + \text{H.c.},$$

(28)

$$0\langle \uparrow | DW^\dagger | \downarrow\rangle_0 = \frac{1}{\sqrt{2\Delta_a\Delta_{sa}}} \left[ 0\langle s | (\Delta_a W T^{(1)} W^\dagger - \Delta_1 W | s\rangle_{11} (s | W^\dagger) | \downarrow\rangle_0 \right] + \frac{1}{\sqrt{2\Delta_a}} \left[ 0\langle a | (\Delta_{as} W T^{(1)} W^\dagger - \Delta_1 W | s\rangle_{11} (s | W^\dagger) | \downarrow\rangle_0 \right],$$

(29)

and

$$0\langle \downarrow | DW^\dagger | \uparrow\rangle_0 = \frac{1}{\sqrt{2\Delta_a\Delta_{sa}}} \left[ 0\langle s | (\Delta_a W T^{(1)} W^\dagger - \Delta_1 W | s\rangle_{11} (s | W^\dagger) | \uparrow\rangle_0 \right] - \frac{1}{\sqrt{2\Delta_a}} \left[ 0\langle a | (\Delta_{as} W T^{(1)} W^\dagger - \Delta_1 W | s\rangle_{11} (s | W^\dagger) | \uparrow\rangle_0 \right],$$

(30)

where $\Delta_a = E^{(0)}_a - E^{(+1)}_a$, $\Delta_{sa} = E^{(0)}_s - E^{(+1)}_s$, $\Delta_1 = E^{(0)}_n - E^{(+1)}_n$, and $\Delta_{as} = E^{(0)}_a - E^{(+1)}_a$. To calculate the matrix elements in Eqs. (27), (23), (24), and (25) we use the following definition for the operator $W$ that originates from the lead-SMM Hamiltonian in Eq. (6):

$$W = -\sum_{a,k,\sigma,n} t_{n,k}^{(a)} \psi_{k\sigma,a} \psi_{n\sigma},$$

(31)

which leads to

$$W T^{(1)} W^\dagger = -\sum_{a,k,\sigma,n,a',k',\sigma',n'} t_{n,k}^{(a)} t_{n',k'}^{(a')} \psi_{k\sigma,a} \psi_{n\sigma} \psi_{k'\sigma',a'} \left( \psi_{n\sigma} T^{(1)} \psi_{n'\sigma'} \right),$$

(33)

and

$$W | s\rangle_{11} (s | W^\dagger = -\sum_{a,k,\sigma,n,a',k',\sigma',n'} t_{n,k}^{(a)} t_{n',k'}^{(a')} \psi_{k\sigma,a} \psi_{n\sigma} \psi_{k'\sigma',a'} \left( \psi_{n\sigma} | s\rangle_{11} (s | \psi_{n'\sigma'} \right).$$

(34)

### A. First set of spin selection rules

We will now consider the case when adding or subtracting an electron always decreases the SMM total spin, namely, $S_q=\pm 1 = S_{q=0} - 1/2$. This selection rule can be enforced through the adoption of the following matrix elements:

$$0\langle \uparrow | \psi_{n\sigma} | \downarrow\rangle_1 = \delta_{-m_0,-m_1} - \delta_{\sigma,\uparrow},$$

(36)

$$1\langle \uparrow | \psi_{n\sigma} | \uparrow\rangle_0 = \delta_{m_0,m_1} - \delta_{\sigma,\downarrow},$$

(37)

$$0\langle \uparrow | \psi_{n\sigma} | \uparrow\rangle_1 = \delta_{m_0,m_1} - \delta_{\sigma,\downarrow},$$

(35)

$$1\langle \downarrow | \psi_{n\sigma} | \downarrow\rangle_0 = \delta_{m_0,m_1} - \delta_{\sigma,\uparrow},$$

(38)
Using a similar procedure, we also find \( \sigma \) to (42) and Eqs. (43) to (46), we have only taken into account the leading terms in the small ratio \( \Delta_{q}/U \). For in-
stance, in Eqs. (39) and (40) we have neglected spin-flipping terms which carry an amplitude smaller than the direct, non spin-flipping terms by \( \Delta_0/U \). Note that the longitudinal exchange coupling is positive, i.e. antiferromagnetic. Moreover, since \( U \gg \Delta_0, \Delta_{\perp,1} \), we find that the exchange couplings are strongly anisotropic, with

\[
|J_{k,a;k',a'}^{\perp,\pm}(\pm 1)| \lesssim \frac{\Delta_{\perp,1}}{U} |J_{k,a;k',a'}^{\pm}(\pm 1)|.
\]

Finally, introducing pseudospin operators that act solely on the \( q = 0 \) sector of the SMM, namely,

\[
\Sigma_0^z = \langle |\uparrow\rangle_0 0 |\uparrow\rangle - \langle |\downarrow\rangle_0 0 |\downarrow\rangle, \quad \Sigma_0^y = \langle |\uparrow\rangle_0 0 |\downarrow\rangle, \quad \Sigma_0^x = \langle |\downarrow\rangle_0 0 |\uparrow\rangle,
\]

and assuming, for brevity, that \( \Delta_1 = \Delta_{-1} \), we can write the effective Hamiltonian of the \( q = 0 \) charge sector as

\[
\hat{\mathcal{H}}_0 = \mathcal{H}_0 + \sum_{k',a'} \sum_{k,a} \left[ J_{k,a;k',a'}^z \Sigma_0^z \left( \psi_{k',1,a}^\dagger \psi_{k,1,a'}^\dagger - \psi_{k,1,a}^\dagger \psi_{k',1,a'} \right) - J_{k,a;k',a'}^\perp \left( \Sigma_0^x \psi_{k,1,a}^\dagger \psi_{k',1,a'}^\dagger + \Sigma_0^y \psi_{k,1,a}^\dagger \psi_{k',1,a'} \right) \right],
\]

where the last term in Eq. (55) is a scattering term that does not affect the dynamics of the SMM and can neglected. The effective exchange coupling constants that appear in Eq. (55) are given by the following expressions:

\[
J_{k,a;k',a'}^z = 2t_k^a t_{k'}^{a'} \left[ \frac{U + \Delta_0}{(U + \Delta_0)^2 - \Delta_1^2} + \frac{U - \Delta_0}{(U - \Delta_0)^2 - \Delta_1^2} \right], \quad J_{k,a;k',a'}^\perp = 4t_k^a t_{k'}^{a'} \left[ \frac{\Delta_1}{(U + \Delta_0)^2 - \Delta_1^2} + \frac{\Delta_1}{(U - \Delta_0)^2 - \Delta_1^2} \right],
\]

\[
J_{k,a;k',a'}^\perp = 2t_k^a t_{k'}^{a'} \left[ \frac{\Delta_1}{(U + \Delta_0)^2 - \Delta_1^2} - \frac{\Delta_1}{(U - \Delta_0)^2 - \Delta_1^2} \right]
\]

The longitudinal exchange coupling is positive, which indicates an antiferromagnetic Kondo exchange. We have neglected the dependence of the hopping matrix elements on the SMM molecular orbital number \( n \). This is justified when the addition or subtraction of an electron brings the molecule to the electronic ground state of the particular charge sector. In this sense, only one orbital state can be filled (emptied) when an electron is added (removed).

A diagrammatic representation of the longitudinal and transverse exchange interactions is shown in Fig. 3. These diagrams differ from the usual Kondo effect in the sense that the transverse, spin-flipping interaction in a SMM requires a quantum tunneling of the total magnetization during its virtual state.

**B. Second set of spin selection rules**

If we consider the case where adding or subtracting an electron always increases the total spin in the SMM, namely, \( S_q=\pm 1 = S_{q=0}+1/2 \), we have to modify Eqs. (35), (36), (37), and (55) by adopting instead the following matrix elements:

\[
0(\uparrow | \psi_n & \sigma | \uparrow) = \delta_{m_\sigma,m_{\sigma+1}}, \quad 0(\downarrow | \psi_n & \sigma | \downarrow) = \delta_{m_\sigma,m_{\sigma-1}},
\]

\[
1(\uparrow | \psi_n & \sigma | \uparrow) = \delta_{m_\sigma,m_{\sigma+1}}, \quad 1(\downarrow | \psi_n & \sigma | \downarrow) = \delta_{m_\sigma,m_{\sigma-1}}.
\]

Using these selection rules, we arrive at a Kondo Hamiltonian with exactly the same form as that in Eq. (55). The expressions for the exchange coupling constants are the same as those given in Eqs. (56), (57), and (58), except for the longitudinal coupling \( J_{k,a;k',a'}^z \), which changes its overall sign and becomes negative, signaling a ferromagnetic Kondo exchange interaction. However, the strong anisotropy remains, with the bare longitudinal coupling dominant over the transversal one.

We can summarize our results so far by stating that
spins, it is reasonable to assume that the first zero (coupling constants standard poor man’s scaling to renormalize the effective exchange to the Hamiltonian of Eq. (55), we make use of the stan-

FIG. 3: (Color online) Diagrams representing the (a) longitudinal and (b) transversal exchange interactions between the SMM magnetization and the electrons in the leads.

1. if \( S_{q=\pm 1} = S_{q=0} - 1/2 \) then \( J^z_{k,a;k',a'} \gg J^\perp_{k,a;k',a'} > 0 \) (antiferromagnetic exchange coupling);

2. if \( S_{q=\pm 1} = S_{q=0} + 1/2 \) then \( J^z_{k,a;k',a'} \ll -J^\perp_{k,a;k',a'} < 0 \) (ferromagnetic exchange coupling).

V. CONDUCTANCE AND THE KONDO EFFECT IN A SMM

In order to evaluate the conductance of the SMM subjected to the Hamiltonian of Eq. (55), we make use of the standard poor man’s scaling to renormalize the effective exchange coupling constants \( J^z \) and \( J^\perp \) and the \( g \)-factor. We start by calculating the renormalization flow at the points where the Kondo effect is observable at zero bias, namely, where the tunnel splitting vanishes: \( \Delta_0 (h^{(l)}_\perp) = 0 \). For half-integer spins, it is reasonable to assume that \( h^{(l)}_\perp \gg T_K \), except for the first zero (\( l = 0 \)). The total Hamiltonian reads

\[
\mathcal{H}_{\text{tot}} = \sum_m \left[ \epsilon_m + \frac{1}{2} g (h^z \Sigma_+ + h^{\perp} \Sigma_-) \right] + \sum_{k,s} \xi_k \psi_{k,s} \psi_{k,s} + \mathcal{H}_0,
\]

where \( \epsilon_m \) is the eigenvalue of \( |m\rangle \) for \( h_\perp = 0 \) and, due the Knight shift, \( \eta = 1 - \rho_0 J^z / 2 \), with \( \rho_0 \) denoting the density of states of the itinerant electrons at the Fermi energy.\(^\text{19}\) We do not include the Zeeman term for the itinerant electrons in Eq. (63) because at finite values of \( h^{(l)}_\perp \) one has to cut the edges of the spin-up and spin-down bands in the leads to make them symmetric with respect to the Fermi energy.\(^\text{19}\) We call \( D \) the resulting band width.

The Hamiltonian of Eq. (63) remains invariant under renormalization group transformations (see the appendix for details). Using Eq. (63), we obtain the flow equations

\[
\frac{d J^z}{d \zeta} = 2 \rho_0 J^\perp J^z, \quad (64)
\]

\[
\frac{d J^\perp}{d \zeta} = 2 \rho_0 \left( J^\perp \right)^2, \quad (65)
\]

and

\[
\frac{d \eta}{d \zeta} = -\rho_0 J^z J^\perp, \quad (66)
\]

where \( \zeta = \ln(D/D_0) \) and \( D \) is the rescaled band width. Dividing Eq. (64) by (65) and integrating by parts gives \((J^z)^2 - (J^\perp)^2 = C^2\), where \( C \) is a positive constant.\(^\text{19}\)

We have to distinguish between two cases: \( J^z \) is either positive or negative. If \( J^z \) is positive, the exchange coupling constants remain antiferromagnetic during the flow but the exchange interaction become increasingly isotropic. Solving Eqs. (64) and (65) yields

\[
\text{arctanh} \left( \frac{C}{J^z} \right) = \ln \left( \frac{D}{T_K} \right). \quad (67)
\]

The solution for \( J^z \) is determined by \( J^z = \sqrt{(J^\perp)^2 + C^2} \). The flow of \( \eta \) is shown in Fig. 5. The flow stops at \( D \approx \omega \sim T > T_K \). In the antiferromagnetic case the Berry-phase oscillations get strongly renormalized by the scaling of the Knight shift.

Since \(|J^z| \gg J^\perp\), when \( J^z \) is negative, the transverse exchange coupling \( J^\perp \) renormalizes to zero. Therefore, in this case the Kondo resonance cannot form and the interaction becomes Ising-like. The interesting feature of \( J^\perp = 0 \) is that the Knight shift vanishes.

A. Linear conductance

In order to calculate the linear conductance through the SMM we use the following well-known expression for the weak coupling regime \((T_K \ll T)\)^\text{19}\)

\[
G(T) = G_0 \int_{-\infty}^{\infty} d\omega \left( \frac{d f}{d\omega} \right) \frac{\pi^2 \rho_0^2}{16} |A(\omega)|^2, \quad (68)
\]

where \( G_0 \) is the classical (incoherent) conductance of the molecule, \( df/d\omega \) is the derivative of the Fermi function, and \( A(\omega) \) is the transition amplitude. At the end of the flow, the transition amplitude can be calculated in first-order perturbation theory as

\[
A_{D \approx \omega} = J^\perp + C \left( \frac{\omega/T_K}{(\omega/T_K)^2 + 1} \right), \quad (69)
\]

The Knight shift is related to the transition amplitude by

\[
\eta_{D \approx \omega} = 1 - \frac{\rho_0 A_{D \approx \omega}}{2}, \quad (70)
\]

By making the substitution \( \omega \to T \) into Eq. (69), one finds that the linear conductance diverges when \( T \to T_K \), signaling the onset of the Kondo effect. Since \( C > 0 \), the singularity in Eq. (69) differs from the usual logarithmic behavior found
for isotropic exchange interactions. We note, however, that in reality, the conductance does not diverge but is rather strongly enhanced near the Kondo temperature. The poor man’s scaling breaks down near the Kondo temperature and more accurate nonperturbative methods, such as the density matrix renormalization group, have to be employed for obtaining a quantitative description of the conductance dependence on temperature.

Using Eq. (68), we get for the linear conductance

\[
\frac{G(T)}{G_0} = \frac{\pi^2 T^2}{16} (J_{D=T})^2,
\]

which has the same functional form as the result of Ref. 26 for the resistivity of bulk metals in the presence of Kondo impurities.

All the zero points of the Berry phase oscillation are rescaled by the $g$-factor renormalization: $b^{(i)}(\perp) = h^{(i)}(\perp) / 4D_{\perp=T}$. Thus, the zero points become dependent on the contributing states $|n\rangle$ and $|-n\rangle$. This result indicates that the period of the Berry phase oscillations becomes temperature dependent at $T > T_K$ (see Fig. 4). This fact allows us to conclude that the scaling equations can be checked experimentally by measuring the renormalized zero points of the Berry phase. Furthermore, due to the scale invariance of the Kondo effect, the distance between the zeros should follow a universal function of $T/T_K$ (see Fig. 4).

### B. Nonlinear conductance

Let us now study the conductance for nonzero bias, $V \neq 0$. For this purpose, we first express the current flowing through the SMM in terms of tunneling rates and lead occupation factors, namely,

\[
I = \frac{e}{h} \sum_\sigma \int_0^\infty dE \frac{\Gamma_{L\sigma} \Gamma_{R\sigma}}{\Gamma_{L\sigma} + \Gamma_{R\sigma}} \rho(E) [f_L(E) - f_R(E)],
\]

where $\rho(E)$ is the energy dependent density of states, $\Gamma_{L\sigma}$ ($\Gamma_{R\sigma}$) is the escape rate for the left (right) lead, and $f_L (f_R)$ is the Fermi function for the left (right) lead. For the sake of simplicity, we assume $\Gamma_{L\sigma} = \Gamma_{R\sigma} = \Gamma$. Since, at low temperatures,

\[
f_L(E) - f_R(E) \approx \begin{cases} 
1 & \text{if } E_F - eV/2 \leq E \leq E_F + eV/2, \\
0 & \text{otherwise},
\end{cases}
\]

where $E_F$ is the Fermi energy of the leads, we get the following expression for the differential conductance:

\[
G = \frac{dI}{dV} = \frac{\pi e^2}{2h} \int_0^\infty dE |A(E)|^2 \left[ \delta(E - E_F - eV/2) - \delta(E - E_F + eV/2) \right].
\]

Consider the situation where one moves from zero point $b^{(n)}_\perp$ to the magnetic field value $b_\perp = b^{(i)}_\perp + \Delta b_\perp$, where $\Delta b_\perp = \Delta h_\perp / \eta$. If $|eV| \ll \Delta_0(b_\perp) \ll T_K$, the transmission amplitude is well approximated by Eq. (69). On the other hand, for $|eV| \gg T_K \gg \Delta_0(b_\perp)$, the transmission amplitude is given by $A_{eV} = J_0^\perp$. For the case $|eV| \sim \Delta_0(b_\perp) \gg T_K$, we can expand $A_{D=\max(T,\Delta_0(b_\perp))}$ up to second order in perturbation theory at the end of the flow, yielding

\[
A_D(\omega) = J_D^\perp + \rho_0 \int_{-D+eV/2}^{D-eV/2} d\epsilon J_D^\perp \frac{J_D^\perp}{\omega - \epsilon} - J_D^\perp + \rho_0 J_D^\perp \ln \left| \frac{\omega + \Delta - eV/2}{\omega - D + eV/2} \right|,
\]

where the integration limits account for the asymmetric cut of the bands (see Fig. 3). For $|eV| \sim \Delta_0(b_\perp) > T$, the renormalization flow stops at $\tilde{D} = \Delta_0(b_\perp)$. Substituting Eq. (73) into Eq. (74) and setting $E_F = 0$, we obtain the differential conductance up to third order in $J_D^\perp$ for both positive and negative biases $eV$:

\[
\frac{G}{G_0} = \frac{\pi^2 \rho_0^3}{16} J_D^\perp \ln \left| \frac{\Delta_0}{|eV| - \Delta_0} \right|,
\]

FIG. 4: The graph shows the temperature dependence of the zeros for the Berry phase oscillation as a function of the transverse magnetic field for the tunnel splittings between $|4\rangle$ and $|-4\rangle$ states ($S_0 = 4$) and the following temperature values: (a) $T/T_K = 1.5$, (b) $T/T_K = 1.6$, (c) $T/T_K = 1.7$, (d) $T/T_K = 1.8$, (e) $T/T_K = 1.9$, and (f) $T/T_K = 2.0$. 
for those points where the tunnel splitting is zero, which corresponds to the zeros in Fig. 4. Note that our conductance formula depends only on the bias voltage and not on the individual chemical potentials of the leads, i.e. our conductance is gauge-invariant, which is a result of the asymmetric band cutting shown in Fig. 7.

The two split Kondo peaks appear at $|eV| = \Delta_0(b_\perp)$. Thus the distance between the two peaks oscillates with the magnetic field, following the renormalized periodic oscillations of the tunnel splitting $\Delta_0(b_\perp)$.

V. CONDUCTANCE AND THE KONDO EFFECT IN A SMM IN THE COTUNNELING REGIME

At zero temperature, the current in a single electron transistor can be understood as a sequential process of single electrons tunneling in and out of the left and right electrodes through the SMM, where the transport channel is in between the electrochemical potentials of the source and drain reservoir. The electron transport through the SMM is also possible for any off-resonant energy, which is commonly called the cotunneling effect, where the tunnel coupling $t$ to the leads is very large, and plays a dominant role whenever the sequential tunneling is suppressed, i.e. $\langle f | H | i \rangle = 0$. In contrast to the Kondo effect, where the tunnel coupling $t$ to the leads is very large, in the cotunneling regime $t$ is typically small and thus it is necessary to apply a gate voltage $V_g$ in order to get close to the resonance condition of for example the $q = 1$ charged state. Thus we need to take only the electron scattering into account, thereby neglecting the hole scattering contribution. Using the incoherent spin states for temperatures around 1 K, we can calculate the cotunneling contribution by means of Eq. (77) in the following form

$$w_{\downarrow \rightarrow \uparrow} = \frac{2\pi}{\hbar} \frac{\langle f | H | i \rangle + \sum_m \langle f | H | m \rangle \langle m | H | i \rangle^2}{E_m - E_f} \rho(E),$$

(77)

and plays a dominant role whenever the sequential tunneling is suppressed, i.e. $\langle f | H | i \rangle = 0$. In contrast to the Kondo effect, where the tunnel coupling $t$ to the leads is very large, in the cotunneling regime $t$ is typically small and thus it is necessary to apply a gate voltage $V_g$ in order to get close to the resonance condition of for example the $q = 1$ charged state. Thus we need to take only the electron scattering into account, thereby neglecting the hole scattering contribution. Using the incoherent spin states for temperatures around 1 K, we can calculate the cotunneling contribution by means of Eq. (77) in the following form

$$w_{\downarrow \rightarrow \uparrow} = \frac{2\pi}{\hbar} \frac{\langle \downarrow | \mathcal{H}_{\text{tot}} | \downarrow \rangle \langle \downarrow | \mathcal{H}_{\text{tot}} | \downarrow \rangle}{U/2 - \Delta_1/2} \rho(E) + \frac{\langle \downarrow | \mathcal{H}_{\text{tot}} | \downarrow \rangle \langle \downarrow | \mathcal{H}_{\text{tot}} | \downarrow \rangle}{U/2 + \Delta_1/2} \rho(E),$$

(78)
the molecule. Solving the set of differential equations for where

\[ \langle | \uparrow \rangle \rangle = 0 \]

and

\[ \langle | \downarrow \rangle \rangle = 0 \]

we get

\[ w_{\downarrow \rightarrow \uparrow} = \frac{2\pi}{\hbar} \left| \frac{\langle | \uparrow \rangle \rangle (\langle | \uparrow \rangle \rangle_0 \langle | \uparrow \rangle \rangle_0}{\hat{U} - \Delta_1} \right|^2 \rho(E). \]  

After some simple algebra, we arrive at the following expression for the tunnel rate process,

\[ w_{\downarrow \rightarrow \uparrow} = \frac{2\pi t^4}{\hbar} \left| \frac{\Delta_1}{\hat{U} - \Delta_1} \right|^2 \rho(E), \]  

where \( t \) is the lead-molecule tunneling amplitude. Comparing Eq. (80) with \( J_{\alpha,\beta} \) from Eq. (88) we see that the second contribution to Fermi’s golden rule is a function of the coupling constant, which is to be expected since the Schrieffer-Wolff transformation is a perturbative approach of the second order. The advantage of using the Schrieffer-Wolff transformation is that you can apply the formalism of renormalization theory to get a better description of the physical system near the Kondo temperature.

Focusing on the Ni single-molecule magnet, we use Eq. (80) to calculate the total cotunneling rate between states | \( \downarrow \rangle = | 4 \rangle \) and | \( \uparrow \rangle = | -4 \rangle \) that will contribute to the current flowing through the single-electron transistor,

\[ W_{4,-4} = \frac{2\pi t^4 \Delta_1^2}{\hbar} \int_{-eV/2 - \hat{U}}^{eV/2 - \hat{U}} \rho(E) \left( \frac{\Delta_1^2}{E^2 - \Delta_1^2} \right)^2. \]  

where we integrate over all initial and final states that are available within the range of the bias voltage \( V \). Performing the integration in Eq. (81) yields

\[ W_{4,-4} = \frac{4\pi t^4}{\hbar} \left[ \frac{\hat{U} - eV/2}{(\hat{U} - eV/2)^2 - \Delta_1^2} - \frac{\hat{U} + eV/2}{(\hat{U} + eV/2)^2 - \Delta_1^2} \right] + \frac{1}{2\Delta_1} \ln \left\{ \frac{(\Delta_1^2 + eV/2)^2 - \hat{U}^2}{(\Delta_1 - eV/2)^2 - \hat{U}^2} \right\}. \]  

The total current flowing through the single-molecule magnet can be calculated in terms of the density matrix by using the master equation. Following the same procedure as in Ref. [7], we obtain the coupled differential equations

\[ \dot{\rho}_4 = \frac{(\Delta_1)}{\hbar}^2 \frac{2\gamma_{4,-4}}{V_s^2/\hbar^2 + \gamma_{4,-4}^2} (\rho_{-4} - \rho_4) + W_{4,-4} \rho_{-4} - W_{-4,4} \rho_4, \]

and

\[ \dot{\rho}_{-4} = \frac{(\Delta_1)}{\hbar}^2 \frac{2\gamma_{4,-4}}{V_s^2/\hbar^2 + \gamma_{4,-4}^2} (\rho_4 - \rho_{-4}) + W_{-4,4} \rho_4 - W_{4,-4} \rho_{-4}, \]

where \( \gamma_{4,-4} \) is the incoherent tunneling rate from the lead to the molecule. Solving the set of differential equations for \( \rho_4 \) and \( \rho_{-4} \) for the stationary case, we obtain the current flowing through the SMM for the case where the source and the drain leads are oppositely spin-polarized, as described in Ref. [17].

\[ I = e W_{4,-4} \rho_{-4} = \frac{2e\gamma_{4,-4} \Delta_1^2 W_{4,-4}}{W_{4,-4}(V_s^2 + \gamma_{4,-4}^2 \hbar^2) + 4\gamma_{4,-4}^2 \Delta_1^2}. \]  

Figure 8 shows the cotunneling current as a function of the transverse magnetic field. Interestingly, the current is suppressed at the zeros of the tunnel splittings \( \Delta_1 \) and \( \Delta_0 \), exactly as in the sequential tunneling regime.

\[ \text{FIG. 8: Graph showing } \log_{10} I \text{ versus the transverse magnetic field for } V_s = V_L - V_L = 4 \times 10^{-4} \text{ eV}, V_g = 0.01 \text{ eV and } \gamma_{4,-4} = 10^{12} s^{-1}. \text{ One can see that the current is suppressed at the zeros of the tunnel splittings } \Delta_1 \text{ and } \Delta_0. \]

VI. CONCLUSIONS

The main contribution of this paper is to show how the total Hamiltonian of a single-molecule magnet transistor can be mapped into the Kondo Hamiltonian by means of a Schrieffer-Wolff transformation. While the derivation of the effective Kondo Hamiltonian in other contexts, such as quantum dots and ordinary single (nonmagnetic) molecule coupled to leads is well-known, the case is different for SMM. The dominant Kondo effect is unusual for a SMM, since it involves a pseudospin of the molecule rather than its total spin. We show that if the total spin of the molecule is reduced (increased) for the charged states, the Kondo Hamiltonian exhibits an anti-screening exchange coupling, which is due to the fact that all the spin states are degenerate in the absence of anisotropies. The
standard Kondo screening of the molecule magnetization by itinerant electrons in the leads is a very weak effect in this context given the large spin of a SMM (its onset is therefore likely to occur only at exceedingly small temperatures, inaccessible to current experiments).

A careful derivation of the effective Kondo Hamiltonian shows that the strong dependence of this phenomenon on the amplitude and orientation of an external magnetic field. The strong uniaxial magnetic anisotropy of the SMM combined with the weaker in-plane anisotropy creates a pseudo spin 1/2 involving states with opposite magnetization orientation. A transverse magnetic field modulates the tunnel barrier between these states through a Berry phase interference effect. That, in turn, modulates periodically the Kondo effect in SMMs.

We have calculated the conductance of the single-molecule transistor in the presence of the Kondo effect by using the standard poor man’s scaling approach. We have shown that in the case of antiferromagnetic Kondo exchange coupling by applying a transverse magnetic field to a single-molecule magnet with a large full- or half-integer spin $S > 1/2$ it is possible to topologically induce or quench the Kondo effect of the conductance of a current through the single-molecule magnet that is sufficiently well coupled to metallic leads. We have also shown how the zero points of the Berry phase oscillation become temperature dependent above the Kondo temperature and how they change direction within the plane (Fig. 4). The latter indicates that the parity of the Berry-phase oscillations changes from an integer spin $S = 4$ to a half-integer spin $S = 7/2$. We have also shown how this motion affects the temperature dependence of the conductance (see Fig. 6). Interestingly, the maximum value of the conductance encircles the zeros of the Berry phase oscillation, providing a mechanism for establishing the location of these zeros when the orientation of the molecule symmetry axis with respect to the metallic contacts is not known. We illustrate these features of the conductance of a SMM using as an example the new single-molecule magnet Ni$_4$. In our view, due to its large ground state tunnel splitting this is currently the best SMM available for the experimental observation of the Berry-phase oscillations of the Kondo resonance.
