20 June 2012

ABSTRACT
Observations of hot Jupiters around solar-type stars with very short orbital periods (\(\sim 1\) day) suggest that tidal dissipation in such stars is not too efficient so that these planets can survive against rapid orbital decay. This is consistent with recent theoretical works, which indicate that the tidal quality factor, \(Q_\star\), of planet-hosting stars can indeed be much larger than the values inferred from the circularization of stellar binaries. On the other hand, recent measurements of Rossiter-McLaughlin effects in transiting hot Jupiter systems not only reveal that many such systems have misaligned stellar spin with respect to the orbital angular momentum axis, but also show that systems with cooler host stars tend to have aligned spin and orbital axes. Winn et al. suggested that this obliquity - temperature correlation may be explained by efficient damping of stellar obliquity due to tidal dissipation in the convection zone of the star. This explanation, however, is in apparent contradiction with the survival of these short-period hot Jupiters. We show that in the solar-type parent stars of close-in exoplanetary systems, the effective tidal \(Q_\star\) governing the damping of stellar obliquity can be much smaller than that governing orbital decay. This is because for misaligned systems, the tidal potential contains a Fourier component with frequency equal to the stellar spin frequency (in the rotating frame of the star) and rotating opposite to the stellar spin. This component can excite inertial waves in the convective envelope of the star, and the dissipation of inertial waves then leads to a spin-orbit alignment torque and a spin-down torque, but not orbital decay. By contrast, for aligned systems, such inertial wave excitation is forbidden since the tidal forcing frequency is much larger than the stellar spin frequency. We derive a general effective tidal evolution theory for misaligned binaries, taking account of different tidal responses and dissipation rates for different tidal forcing components.

Key words: planetary systems – stars: rotation – binaries: close – hydrodynamics – waves

1 INTRODUCTION

1.1 Tidal Dissipation in Planet-Hosting Stars: A Conundrum

Recent measurements of stellar obliquity in transiting exoplanetary systems using the Rossiter-McLaughlin effect have shown that a significant fraction of hot Jupiter systems have misaligned stellar spin with respect to the planetary angular momentum axis (e.g., Hébrard et al. 2008; Winn et al. 2009,2010,2011; Johnson et al. 2009; Narita et al. 2009; Triaud et al. 2010; Pont et al. 2010; Simpson et al. 2011; Moutou et al. 2011). This suggests that a large population hot Jupiters are formed through dynamical planet-scatterings (e.g., Rasio & Ford 1996; Weidenschilling & Marzari 1996; Zhou et al. 2007; Chatterjee et al. 2008; Juric & Tremaine 2008) and more importantly, through secular interactions between multiple planets or Kozai effect induced by a distant companion (e.g., Wu & Murray 2003; Fabrycky & Tremaine 2007; Nagasawa et al. 2008; Naoz et al. 2011a,b; Wu & Lithwick 2011; Katz et al. 2011), although other effects involving star-disc interactions (Lai et al. 2011; Foucart & Lai 2011) and the assembly of protoplanetary discs (Bate et al. 2010; Thies et al. 2011) may also play a role in producing spin-orbit misalignment.

Recent observations have also revealed an intriguing correlation between stellar obliquity \(\Theta\) and effective temperature \(T_{\text{eff}}\): Winn et al. (2010) found that the misaligned systems tend to have hotter parent stars \((T_{\text{eff}} \gtrsim 6250\ \text{K})\), cor-
responding to stellar mass $M_\star \gtrsim 1.3 M_\odot$, while the systems containing cooler stars have small obliquities. This trend was also found from a recent analysis of the stellar rotation velocities (Schlaufman 2010). Although this $\Theta - T_{\text{rot}}$ correlation may indicate different planet formation mechanisms for stars of different masses, Winn et al. (2010) pointed out that $T_{\text{rot}} = 6250$ K corresponds to the temperature below which stars contain a large sub-surface convective envelope, and suggested that tidal dissipation in these stars lead to the damping of their obliquities. Indeed, the facts that effective temperature is more closely related to obliquity than stellar mass and that a few low-mass and long-period planets are exceptions to the $\Theta - T_{\text{eff}}$ correlation (Winn et al. 2010, 2011), suggest the idea of tidal damping of spin-orbit misalignment in solar-type stars. Most recently, Triaud (2011) found a correlation between the obliquity and parameterized by a dimensionless quality factor $Q_\star$. When the orbital mean motion $\Omega$ is larger than the stellar spin frequency $\Omega_\star$, the orbital decay timescale (for circular orbits) is
\begin{equation}
t_{\text{a}} = \frac{2a}{a_1} = \frac{2Q_\star}{9} \left( \frac{M_\star}{M_p} \right) \left( \frac{a}{R_p} \right)^5 \frac{1}{\Omega} \\
\simeq 1.28 \left( \frac{Q_\star}{10^4} \right) \left( \frac{M_\star}{10^3 M_p} \right) \left( \frac{\rho_\star}{\rho_p} \right)^{5/3} \left( \frac{P}{1 \text{ d}} \right)^{13/3} \text{ Gyr,}
\end{equation}
where $Q_\star = 3Q_\star / (2k_2)$ is the reduced tidal quality factor, $k_2$ is the Love number, and $\rho_\star$ is the mean density of the star and $\rho_p$ is the solar value. The inspiral time for a planet into its host star is $(2/3) t_\text{a}$. The observations of hot Jupiters with the shortest orbital periods (such as WASP-18b, 0.94 d; WASP-19b, 0.79 d; and WASP-43b, 0.81 d; Hellier et al. 2009, 2011; Hebb et al. 2010) suggest $Q_\star \gtrsim 10^5$ (see Brown et al. 2011). Such a large $Q_\star$ value is consistent with recent theoretical works (see Sec. 1.2) on the physics of tidal dissipation in planet-hosting solar-type stars (Ogilvie & Lin 2007; Barker & Ogilvie 2010, 2011; Penev & Sasselov 2011). On the other hand, in the often-used tidal evolution equations (see Sec. 2.5), the damping time for stellar obliquity $\Theta$ is
\begin{equation}
t_{\text{d}} = \left| \frac{\sin \Theta}{\Theta} \right| = \left( \frac{2S}{L} \right) t_{\text{a}} \\
\simeq 1.13 t_{\text{a}} \left( \frac{\kappa}{0.1} \right) \left( \frac{M_\star}{10^3 M_p} \right) \left( \frac{\rho_\star}{\rho_p} \right)^{2/3} \left( \frac{10 \text{ d}}{P} \right) \left( \frac{1 \text{ d}}{P} \right)^{1/3},
\end{equation}
where $S$ and $L$ are the stellar spin and orbital angular momenta, respectively, $P_\text{c}$ is the spin period and the moment of inertia of star is $\kappa M R^2$. Thus, for typical parameters of hot Jupiter systems, $t_{\text{d}} \sim t_{\text{a}}$, and a tidal quality factor $Q_\star \gtrsim 10^8$ would not cause significant damping of $\Theta$. To put it in another way, a reduction in the stellar obliquity is accompanied by a similar amount of orbital decay, $\Delta a/a \simeq (2S/L) \Delta \Theta / \sin \Theta$. This poses a severe problem to the (otherwise appealing) tidal damping interpretation of the stellar obliquity – effective temperature correlation (Winn et al. 2010). One way out of this problem is to assume that the star’s convective envelope is weakly coupled to its radiative core, thus reducing the obliquity damping time for the stellar envelope (Winn et al. 2010). This assumption, however, is difficult to substantiate, as fluid instabilities may develop in the presence of large differential rotation (especially when the directions of rotation vary across the star) to quickly couple the rotations of the core and the envelope.

To recapitulate, there is a conundrum concerning the efficiency of tidal dissipation in planet-hosting solar-type stars: On the one hand, the survival of hot Jupiters with shortest orbital periods and recent theoretical works both indicate that stellar tidal dissipation induces only modest or negligible orbital decay. On the other hand, the observed stellar obliquity - effective temperature correlation suggests that tidal dissipation is important in damping stellar obliquity.

In this paper, we show that tidal damping of spin-orbit misalignment can be much more efficient than tidal damping of the orbit. In another word, the effective tidal quality factor for the former process can be much smaller than the latter. This provides a natural resolution to the conundrum discussed above.

1.2 Basic Idea

Many previous works on tidal evolution in hot Jupiter systems (e.g., Rasio et al. 1996; Sasselov 2003; Dobbs-Dixon et al. 2004; Barker & Ogilvie 2009; Jackson et al. 2009; Levrard et al. 2009; Leconte et al. 2010; Matsumura et al. 2010). The strength of tidal dissipation is usually parameterized by a dimensionless quality factor $Q_\star$. When the orbital mean motion $\Omega$ is larger than the stellar spin frequency $\Omega_\star$, the orbital decay timescale (for circular orbits) is
\begin{equation}
t_{\text{a}} = \frac{2a}{a_1} = \frac{2Q_\star}{9} \left( \frac{M_\star}{M_p} \right) \left( \frac{a}{R_p} \right)^5 \frac{1}{\Omega} \\
\simeq 1.28 \left( \frac{Q_\star}{10^4} \right) \left( \frac{M_\star}{10^3 M_p} \right) \left( \frac{\rho_\star}{\rho_p} \right)^{5/3} \left( \frac{P}{1 \text{ d}} \right)^{13/3} \text{ Gyr},
\end{equation}
where $Q_\star = 3Q_\star / (2k_2)$ is the reduced tidal quality factor, $k_2$ is the Love number, and $\rho_\star$ is the mean density of the star and $\rho_p$ is the solar value. The inspiral time for a planet into its host star is $(2/3)t_a$. The observations of hot Jupiters with the shortest orbital periods (such as WASP-18b, 0.94 d; WASP-19b, 0.79 d; and WASP-43b, 0.81 d; Helling et al. 2009, 2011; Hebb et al. 2010) suggest $Q_\star \gtrsim 10^5$ (see Brown et al. 2011). Such a large $Q_\star$ value is consistent with recent theoretical works (see Sec. 1.2) on the physics of tidal dissipation in planet-hosting solar-type stars (Ogilvie & Lin 2007; Barker & Ogilvie 2010, 2011; Penev & Sasselov 2011). On the other hand, in the often-used tidal evolution equations (see Sec. 2.5), the damping time for stellar obliquity $\Theta$ is
\begin{equation}
t_{\text{d}} = \left| \frac{\sin \Theta}{\Theta} \right| = \left( \frac{2S}{L} \right) t_{\text{a}} \\
\simeq 1.13 t_{\text{a}} \left( \frac{\kappa}{0.1} \right) \left( \frac{M_\star}{10^3 M_p} \right) \left( \frac{\rho_\star}{\rho_p} \right)^{2/3} \left( \frac{10 \text{ d}}{P} \right) \left( \frac{1 \text{ d}}{P} \right)^{1/3},
\end{equation}
where $S$ and $L$ are the stellar spin and orbital angular momenta, respectively, $P_\text{c}$ is the spin period and the moment of inertia of star is $\kappa M R^2$. Thus, for typical parameters of hot Jupiter systems, $t_{\text{d}} \sim t_{\text{a}}$, and a tidal quality factor $Q_\star \gtrsim 10^8$ would not cause significant damping of $\Theta$. To put it in another way, a reduction in the stellar obliquity is accompanied by a similar amount of orbital decay, $\Delta a/a \simeq (2S/L) \Delta \Theta / \sin \Theta$. This poses a severe problem to the (otherwise appealing) tidal damping interpretation of the stellar obliquity – effective temperature correlation (Winn et al. 2010). One way out of this problem is to assume that the star’s convective envelope is weakly coupled to its radiative core, thus reducing the obliquity damping time for the stellar envelope (Winn et al. 2010). This assumption, however, is difficult to substantiate, as fluid instabilities may develop in the presence of large differential rotation (especially when the directions of rotation vary across the star) to quickly couple the rotations of the core and the envelope.

To recapitulate, there is a conundrum concerning the efficiency of tidal dissipation in planet-hosting solar-type stars: On the one hand, the survival of hot Jupiters with shortest orbital periods and recent theoretical works both indicate that stellar tidal dissipation induces only modest or negligible orbital decay. On the other hand, the observed stellar obliquity - effective temperature correlation suggests that tidal dissipation is important in damping stellar obliquity.

In this paper, we show that tidal damping of spin-orbit misalignment can be much more efficient than tidal damping of the orbit. In another word, the effective tidal quality factor for the former process can be much smaller than the latter. This provides a natural resolution to the conundrum discussed above.
bulge can be damped by turbulent viscosity in the star’s convective envelope (Zahn 1977,1989). The major uncertainty involves how the effective viscosity derived from the mixing-length theory, \( \sim v_l l_t/3 \) (where \( v_l \) and \( l_t \) are the velocity and size of convective eddies, respectively), is reduced when the tidal forcing period \( P_{\text{tid}} \) is shorter than the convective turnover time \( \tau_c = l_t/v_l \) (see Goodman & Oh 1997). Recent simulations (Penev et al. 2009,2011) suggests that the reduction factor is about \( P_{\text{tid}}/(2\pi \tau_c) \) (for a limited range of \( P_{\text{tid}} \)), and the corresponding tidal Q, \( Q_c \), well exceeds \( 10^8 \) (Penev & Sasselov 2011). An even larger \( Q \), will result if the reduction factor \( (P_{\text{tid}}/2\pi \tau_c)^2 \) is used (see Ogilvie & Lin 2007).

(ii) Excitation and damping of internal gravity waves (Goodman & Dickson 1998; Ogilvie & Lin 2007; Barker & Ogilvie 2010,2011). These waves (also called Hough waves when modified by rotation) are launched at the bottom of the star’s convective envelope and propagate toward the stellar center. If they attain sufficient amplitudes at the center, wave breaking will occur; this will produce significant tidal dissipation, corresponding to \( Q_s \sim \text{a few} \times 10^5 (P/\text{1 day})^{6/3} \) [assuming the orbital period \( P \) is much shorter than the spin period; see Barker & Ogilvie (2010)]. If the waves are reflected coherently at the stellar center (e.g., by a small convective core) before nonlinear breaking (Terquem et al. 1998), only weak dissipation will result \( (Q_s \gtrsim 10^7) \). The latest calculations by Barker & Ogilvie (2010,2011) suggest that while the nonlinear wave breaking certainly occurs for binary stars, it is probably unimportant for exoplanetary systems – this would explain the survival of short-period hot Jupiters against orbital decay (see Weinberg et al. 2011).

(iii) Excitation and damping of inertial waves. Recent theoretical works on dynamical tides in rotating planets (Ogilvie & Lin 2004,2007; Ogilvie 2005,2009; Wu 2005a,b; Papaloizou & Ivanov 2005; Goodman & Lackner 2009) and stars (Savonije & Papaloizou 1997; Papaloizou & Savonije 1997; Savonije & Witte 2002; Ogilvie & Lin 2007) have emphasized the importance of inertial waves driven by Coriolis force. When the tidal forcing frequency (in the rotating frame) \( \tilde{\omega} \) is less than twice the spin frequency \( (\Omega_s) \), short-wavelength inertial waves can be excited. In particular, when these waves are confined to a spherical shell (as in the convection zone outside the solid core of a giant planet or in the convective envelope of a solar-type star), tidal disturbances are concentrated in very narrow regions (called “wave attractors”) where dissipation takes place (Ogilvie & Lin 2004; Ogilvie 2009; Goodman & Lackner 2009). It appears that this mechanism can explain the tidal \( Q \sim 10^8 \) of giant planets and, when combined with internal gravity wave damping [see (ii) above], can also explain the dissipation required for the circularization of stellar binaries. However, for solar-type stars in hot Jupiter systems, the inertial wave dissipation mechanism is not expected to operate, since the tidal frequency \( \tilde{\omega} = 2(\Omega - \Omega_s) \) (assuming circular orbit and aligned stellar spin) is larger than \( 2\Omega_s \), for typical parameters (e.g., \( P_s \sim 10\text{ d} \) and \( P \sim 1\text{ d} \)).

The main point of our paper concerns inertial wave dissipation in the parent stars of hot Jupiter systems when the stellar spin \( \mathbf{S} \) is misaligned with the orbital angular momentum \( \mathbf{L} \). For a circular binary, in the inertial coordinate system with the \( Z \)-axis along \( \mathbf{L} \), the tidal potential has two components (to the quadrupole order), with frequencies \( \omega_m = m\Omega \) (where \( m = 0, 2 \)). As seen in the rotating frame of the star, the tidal frequencies become

\[ \tilde{\omega}_{mn\ell} = m'\Omega - m\Omega_s, \]

with \( m = 0, \pm 1, \pm 2 \). For an aligned system, only the \( m = m' = 2 \) component of the tidal potential is nonzero and involved in tidal dissipation. (The \( m = m' = 0 \) component is also nonzero, but it does not transfer energy and angular momentum since it is completely static.) For misaligned systems, however, all seven tidal components [all combinations of \((m, m')\) except \( m = m' = 0 \); note that for \( m' = 0 \), the \( m = -1(2) \) component is physically identical to the \( m = 1(2) \) component] contribute to the transfers of tidal energy and/or angular momentum. In general, each of the 7 distinct components will generate tidal disturbance with its own quality factor \( Q_{mn\ell} \). Of particular interest is the \((m, m') = (\pm 1, 0)\) components. They have \( \tilde{\omega}_{mn\ell} = \pi\Omega_s \) and the angular pattern frequency is \( \tilde{\omega}/m = -\Omega_s \) (the negative sign means it is retrograde with respect to the spin). They can generate inertial waves in the convection zone, and therefore making a significant or dominant contribution to the tidal alignment of spin-orbit inclination. These components, however, do not contribute to orbital decay since they are static in the inertial frame and do not transfer energy (see Sect. 3).

In summary, while for aligned hot Jupiter systems, the effective stellar tidal \( Q_s \) governing orbital decay (and contributing to orbital circularization) may be quite large \((\gtrsim 10^8)\) because channel (i) and channel (ii) (i.e., equilibrium tides and gravity waves) are ineffective and channel (iii) (inertial waves) is forbidden, for misaligned systems, inertial wave excitation becomes possible, which may provide an efficient damping mechanism for the spin-orbit misalignment.

The remainder of this paper is organized as follows. In Sect. 2 we develop a general effective theory for tidal evolution of misaligned binaries. It is “general”, because the theory takes account of the different responses (including both equilibrium and dynamical tides) of the star to different frequency components of the tidal potential. It is “effective”, because the responses and dissipations of different components are treated in a parameterized way. In Sect. 3 we present the tidal evolution equations due to inertial wave dissipation for misaligned hot Jupiter systems. We conclude in Sect. 4.

2 TIDAL EVOLUTION OF MISALIGNED BINARIES: A GENERAL EFFECTIVE THEORY

2.1 Tidal Potential

We consider a star of mass \( M \), radius \( R \) and spin \( \Omega_s \) (along the direction \( \mathbf{S} \)) orbited by a companion (planet) of mass \( M' \). The orbital semi-major axis is \( a \) and the orbital angular frequency is \( \Omega \). We allow for general spin-orbit inclination angle \( \theta \) (the angle between the spin angular momentum \( \mathbf{S} = SS \) and the orbital angular momentum \( \mathbf{L} = LL \)), but

\[ \text{(i)} \]

Tidal dissipation in the planet also contributes to circularization.
consider circular orbit for simplicity. In the spherical coordinate system centered on $M$ with the $Z$-axis along $L$, the tidal potential produced by $M'$ can be expanded in terms of spherical harmonics:

$$U(r, t) = -GM' \sum_{m'} \frac{W_{2m'}r^2}{a^3} e^{-im'\Omega t} Y_{2m'}(\theta_L, \phi_L),$$

where $m' = 0, \pm 2$, with $W_{20} = -(\pi/5)^{1/2}$ and $W_{2\pm 2} = (3\pi/10)^{1/2}$. To study the dynamical response of stellar fluid to the tidal forcing, we need to express $U(r, t)$ in terms of $Y_{lm}(\theta, \phi)$, the spherical harmonic function defined in the inertial frame centered on $M$ with the $z$-axis along $S$. This is achieved by the relation

$$Y_{2m'}(\theta_L, \phi_L) = \sum_{m} D_{mm'}(\Theta)Y_{2m}(\theta, \phi),$$

where $D_{mm'}(\Theta)$ is the Wigner $D$-matrix of $l = 2$ (e.g., Wybourne 1974), and we have chosen the $y$-axis along the direction $\hat{x} \times L$. The relevant $D_{mm'}$s are

$$D_{2 \pm 2} = \frac{1}{4}(1 \pm \cos\Theta)^2,$$

$$D_{2 \pm 1} = \frac{1}{2} \sin\Theta(1 \pm \cos\Theta),$$

$$D_{20} = \frac{\sqrt{6}}{4} \sin^3\Theta,$$

$$D_{10} = -\frac{\sqrt{6}}{2} \sin\Theta \cos\Theta,$$

$$D_{00} = \frac{1}{2}(3 \cos^2\Theta - 1),$$

and

$$D_{m'm} = (-1)^{m-m'}D_{mm'} = D_{-m',-m'},$$

The tidal potential then becomes

$$U(r, t) = -\sum_{m'm'} U_{mm'} r^2 Y_{2m}(\theta, \phi) e^{-im'\Omega t},$$

where

$$U_{mm'} \equiv \frac{GM'}{a^3}U_{mm'} \equiv \frac{GM'}{a^3}W_{2m'}D_{mm'}(\Theta).$$

Note that when expressed in terms of $\phi_{\nu}$ (the azimuthal angle in the rotating frame of the star), each term in Eq. (12) has the dependence $e^{im_{\phi}+im_{m}t-\Omega t+im'\Omega t}$. Thus, the tidal potential is composed of various $(mm')$-components, each with forcing frequency $m'\Omega$ in the inertial frame. In the frame corotating with the star, the forcing frequency of the $(mm')$-component is $\tilde{\omega}_{mm'} = m'\Omega - m\Omega$ [Eq. (3)], with the pattern rotation frequency

$$\tilde{\omega}_{mm'} = \frac{m'}{m} \Omega - \Omega_s.$$

(Obviously, the pattern frequency has no meaning for the axisymmetric $m = 0$ component.) Note that physically, there are 7 distinct components: $(m, m') = (0, 2), (\pm 1, 2), (\pm 2, 2), (1, 0), (2, 0)$ (see also Barker & Ogilvie 2009). The $(0, 0)$ component is static and does not contribute to tidal dissipation. The $(-m, -m')$-component is physically identical to the $(m, m')$-component.

### 2.2 Ansatz for Tidal Response

Each $(mm')$-component of the tidal potential drives fluid perturbation inside the star, which can be specified by the Lagrangian displacement $\xi_{mm'}(r, t)$ and Eulerian density perturbation $\delta\rho_{mm'}(r, t)$. In the absence of dissipation, these perturbations are proportional to $(U_{mm'}/\omega_0^2)e^{i\omega_0 t-\Omega t}$ (where $\omega_0 \equiv \sqrt{GM/R^3}$ is the dynamical frequency of the star), exactly in phase with the tidal potential. When fluid dissipation is present, there will be phase shift between the fluid perturbation and the tidal potential. This phase shift, in general, depends on $m$, the forcing frequency (in the rotating frame) $\tilde{\omega}_{mm'}$, as well as the intrinsic property (including the rotation rate) of the star. We write this phase shift as

$$\Delta_{mm'} = \tilde{\omega}_{mm'}\tau_{mm'},$$

where $\tau_{mm'}$ is the “lag time” associated with the $(mm')$-perturbation. Thus, without loss of generality, we can write $(mm')$-component of the fluid displacement as

$$\xi_{mm'}(r, t) = \frac{U_{mm'}}{\omega_0} \xi_{mm'}(r) \exp(-im'\Omega t + i\Delta_{mm'}).$$

The corresponding density perturbation is

$$\delta\rho_{mm'}(r, t) = \frac{U_{mm'}}{\omega_0^2} \delta\rho_{mm'}(r) \exp(-im'\Omega t + i\Delta_{mm'}),$$

with

$$\delta\tilde{\rho}_{mm'} = -\nabla \cdot (\rho \tilde{\xi}_{mm'}).$$

Note that $\tilde{\xi}_{mm'}(r)$ and $\delta\tilde{\rho}_{mm'}(r)$ are proportional to $e^{im_{\phi}}$; except for this factor, they are real functions. Also note that

$$\frac{U_{mm'}}{\omega_0^2} = \frac{M'}{M} \left(\frac{R}{a}\right)^3 U_{mm'},$$

with $U_{mm'} \equiv W_{2m'}D_{mm'}(\Theta)$. Thus, $\tilde{\xi}_{mm'}(r)$ and $\delta\tilde{\rho}_{mm'}(r)$ specify the amplitudes (and shapes) the fluid perturbations after factoring out the “equilibrium” dimensionless tidal distortion, $(M'/M)(R/a)^3$. Note that although our ansatz of the tidal responses is motivated by the weak friction theory of equilibrium tides, it is actually quite general, provided that one keeps in mind that the lag time $\tau_{mm'}$ depends on $m$, $\tilde{\omega}_{mm'}$ and the intrinsic property of the star.

### 2.3 Tidal Torque and Energy Transfer Rate

The tidal torque on the star is

$$T = \int d^3x \delta\rho(r, t) \times [-\nabla U^*(r, t)],$$

and the tidal energy transfer rate (from the orbit to the star) is

$$\dot{E} = \int d^3x \rho(r) \frac{\partial \tilde{\xi}(r, t)}{\partial t} \cdot [-\nabla U^*(r, t)].$$

Using Eqs. (12) and (17), the $z$-component (along the spin axis) of the tidal torque reduces to

$$T_z = T_0 \sum_{mm'} \bar{n}_{mm'} m\kappa_{mm'} \sin\Delta_{mm'},$$

where

$$T_0 \equiv G \left(\frac{M'}{m^3}\right)^2 R^5,$$
and $\kappa_{m,m'}$ is the “Love coefficient”:

$$\kappa_{m,m'} = \frac{1}{MR^2} \int d^3r \, \delta \rho_{m,m'}(r)r^2 Y_{2m}^* (\theta, \phi).$$

(24)

Similarly, the energy transfer rate is given by

$$\dot{E} = T_0 \sum_{m,m'} t_{m,m'}^2 \kappa_{m,m'} \sin \Delta_{m,m'}.$$  

(25)

Note that the $(m m')$-component of energy transfer and tidal force satisfies

$$\langle \dot{E} \rangle_{m m'} = \frac{m' \Omega}{m} (T_z)_{m m'}. \quad (26)$$

This is expected since the pattern rotation rate (in the inertial frame) of the tidal force is $m' \Omega/m$.

Equations (22) and (25) can be worked out explicitly. Assuming $|\Delta_{m,m'}| \ll 1$, we have

$$T_z = \frac{(W_{22})^2}{2} T_0 \left[ (1 + c_\theta)^4 (\Omega - \Omega_s) \tau_{22} + s_\theta (1 + c_\theta)^2 (2 \Omega - \Omega_s) \tau_{12} + 2 s_\theta (1 - c_\theta)^2 (2 \Omega + \Omega_s) \tau_{-12} + (1 - c_\theta)^4 (\Omega + \Omega_s) \tau_{-22} - 3 (W_{20})^2 T_0 \Omega (s_\phi \tau_{20} + s_\phi' \tau_{10}) \right].$$

(27)

and

$$\dot{E} = \frac{(W_{22})^2}{2} T_0 \Omega \left[ (1 + c_\theta)^4 (\Omega - \Omega_s) \tau_{22} + s_\theta (1 + c_\theta)^2 (2 \Omega - \Omega_s) \tau_{12} + s_\theta^2 (1 - c_\theta)^2 (2 \Omega + \Omega_s) \tau_{-12} + (1 - c_\theta)^4 (\Omega + \Omega_s) \tau_{-22} \right].$$

(28)

where we have defined

$$\tau_{m,m'} = \ell_{m,m'} \kappa_{m,m'},$$

(29)

and $c_\theta \equiv \cos \Theta$, $s_\theta \equiv \sin \Theta$, and we have used the identity $\tau_{-m,-m'} = \tau_{m,m'}$.

The perpendicular component of the tidal torque $T_z$ is less straightforward to evaluate. The $y$-component does not depend on tidal dissipation (for $|\Delta_{m,m'}| \ll 1$) and contributes to the spin precession. Since $T_y$ does change the spin-orbit elements, we will not consider it further. The $x$-component of $T_z$ is

$$T_x = T_0 \sum_{m,m'} U_{m,m'} \mathcal{U}_{m,m'} \kappa_{m,m'} \tau_{m,m'},$$

(30)

where

$$\kappa_{m,m'} \equiv \frac{1}{i MR^2} \int d^3r \, \delta \rho_{m,m'}(r) r^2 \left( \frac{\partial Y_{2m}^*}{\partial \theta} \sin \phi - \frac{m}{\tan \theta} Y_{2m}^* \cos \phi \right).$$

(31)

Since $\delta \rho_{m,m'}(r) \propto \ell_{m,m'}$, $\kappa_{m,m'}$ is nonzero only for $\ell = m \pm 1$. If we define

$$\kappa_{m,m'}^{\pm} \equiv \kappa_{m,m=\pm 1,m'},$$

(32)

then Eq. (30) can be written as

$$T_x = T_0 \sum_{m,m'} U_{m,m'} \Delta_{m,m'} \left( U_{m+1,m} \kappa_{m,m'}^{+} + U_{m-1,m} \kappa_{m,m'}^{-} \right).$$

(33)

### Tidal Dissipation in Planet-Hosting Stars

A direct calculation shows that the coefficients $\kappa_{m,m'}^{\pm}$ are related to the Love coefficients [Eq. (23)] by

$$\kappa_{2m,m'}^{\pm} = \kappa_{2m,m'}, \quad \kappa_{-2m,m'}^{\pm} = \kappa_{-2m,m'},$$

$$\kappa_{1m,m'}^{+} = \kappa_{1m,m'}, \quad \kappa_{-1m,m'}^{-} = \sqrt{3/2} \kappa_{1m,m'},$$

$$\kappa_{0,m,m'}^{\pm} = \sqrt{3/2} \kappa_{0,m,m'},$$

$$\kappa_{-1m,m'}^{+} = \sqrt{3/2} \kappa_{-1m,m'}, \quad \kappa_{-1m,m'}^{-} = \kappa_{-1m,m'}.$$  

(34)

Thus $T_z$ can be worked out explicitly:

$$T_z = \frac{(W_{22})^2}{2} T_0 \left[ s_\theta (1 + c_\theta)^3 (\Omega - \Omega_s) \tau_{22} + s_\theta (1 + c_\theta)^2 (2 - c_\theta) (2 \Omega - \Omega_s) \tau_{12} + 6 s_\theta^2 \Omega \tau_{02} + s_\theta (1 - c_\theta)^3 (2 + c_\theta) (2 \Omega + \Omega_s) \tau_{-12} + 6 s_\theta (1 - c_\theta)^2 (\Omega + \Omega_s) \tau_{-22} + 3 (W_{20})^2 T_0 \Omega (s_\phi \tau_{20} + s_\phi' \tau_{10}) \right].$$

(35)

#### 2.4 Tidal Evolution Equations

Given the tidal torque $T_z$ and energy transfer rate $\dot{E}$, the tidal evolution equations for the stellar spin $\Omega$, and the orbital semi-major axis $a$ are

$$\dot{\Omega} = \frac{T_z}{I} \quad \dot{a} = -\frac{2a \dot{E}}{GM'},$$

(36)

where $I$ is the moment of inertia of the star. The spin-orbit misalignment angle $\Theta$ is given by $\cos \Theta = S \cdot L/(SL)$, where $S = \Omega \Omega_s$ and $L = \mu a^2 \Omega$. Using $S = -L = T_z$, we find

$$\dot{\Theta} = -\frac{N_x}{S} - \frac{N_x}{L} \cos \Theta + \frac{N_x}{L} \sin \Theta.$$  

(37)

Note that the rate of change for the magnitude of the orbital angular momentum satisfies

$$\dot{L} = -T_z \cos \Theta - T_z \sin \Theta = -\frac{\dot{E}}{\Omega} = \dot{E}_{\text{orb}}.$$  

(38)

This can be checked directly using Eqs. (22), (25) and (35). Thus a circular orbit will remain circular, as it should be.

These evolution equations for $\Omega$, $\dot{a}$ and $\Theta$ [with $T_z$, $\dot{E}$, $T_z$ given by Eqs. (27), (25), (35), respectively] are the most general tidal equations for circular binaries. They depend on 7 independent “reduced” tidal lag times $\tau_{m,m'} = \ell_{m,m'} \kappa_{m,m'}$, corresponding to the 7 independent tidal forcing components. In general, each $\tau_{m,m'}$ depends on $m$, $\ell_{m,m'}$, and the intrinsic property (including $\Omega_s$) of the star.

#### 2.5 Special Case: Weak Friction Theory of Equilibrium Tide

When $\tau_{m,m'} = \tau$ are the same for all seven tidal forcing components, we find

$$\dot{E} = \frac{12\pi}{5} T_0 \Omega (\Omega - \Omega_s \cos \Theta) \tau, \quad (39)$$

$$T_z = \frac{6\pi}{5} T_0 \left[ 2 \Omega \cos \Theta - (1 + \cos^2 \Theta) \Omega_s \right] \tau, \quad (40)$$

$$T_x = \frac{6\pi}{5} T_0 \sin \Theta \left[ 2 \Omega - \Omega_s \cos \Theta \right] \tau, \quad (41)$$

© 2011 RAS, MNRAS 000, ??
These give
\[
\frac{\dot{a}}{a} = -\frac{1}{t_a} \left( 1 - \frac{\Omega}{\Omega_a} \cos \Theta \right), \tag{42}
\]
\[
\frac{\Omega}{\Omega_a} = \frac{1}{t_a} \left( \frac{L}{2S} \right) \left[ \cos \Theta - \left( \frac{2 \Omega}{\Omega_a} \right) (1 + \cos^2 \Theta) \right], \tag{43}
\]
\[
\dot{\Theta} = -\frac{1}{t_a} \left( \frac{L}{2S} \right) \sin \Theta \left[ 1 - \left( \frac{\Omega}{\Omega_a} \right) (\cos \Theta - \frac{S}{T}) \right], \tag{44}
\]
where
\[
\frac{1}{t_a} = \frac{3k_2}{Q} \left( \frac{M'}{M} \right) \left( \frac{R}{a} \right)^5 \Omega, \tag{45}
\]
and we have defined
\[
k_2 \Delta t_L \equiv \frac{4\pi}{5} \tau, \quad Q \equiv (2\Omega \Delta t_L)^{-1}. \tag{46}
\]
Here \(k_2\) and \(\Delta t_L\) have the usual meanings as in the equilibrium tide theory: \(k_2\) is the Love number and \(\Delta t_L\) is the tidal lag time [which is related to the viscous time \(t_{\text{vis}}\) by \(\Delta t_L = 1/(\omega_0^2 t_{\text{vis}})\)]. These equations agree with those given in Alexander (1973) and others (Hut 1980; Eggleton et al. 1998).

### 3 TIDAL TORQUE DUE TO INERTIAL WAVE DISSIPATION

The convective envelope of a solar-type star supports inertial waves, which are driven entirely by Coriolis force. The frequency \(\tilde{\omega}\) (in the rotating frame) of an inertial wave is related to its (local) wavenumber vector \(\mathbf{k}\) by the dispersion relation (e.g., Greenspan 1968)
\[
\tilde{\omega}^2 = (2\Omega_s \cdot \mathbf{k}/|\mathbf{k}|)^2. \tag{47}
\]
Thus inertial waves exist only when \(|\tilde{\omega}| < 2\Omega_s\).

In hot Jupiter systems with \(\Omega \gg \Omega_s\), the only tidal forcing component that is capable of exciting inertial waves in the star is \((m, m') = (1, 0)\), with the forcing frequency (in the rotating frame) \(\tilde{\omega} = -\Omega_s\). [The \((-1, 0)\)-component has \(\tilde{\omega} = \Omega_s\) and is physically identical.] The tidal torque associated with this component can be read off directly from Eqs. (27) and (35):
\[
(T_z)_{10} = \frac{3\pi}{5} T_0 \Omega_s \tau_{10} (\sin \Theta \cos \Theta)^2, \tag{48}
\]
\[
(T_x)_{10} = \frac{3\pi}{5} T_0 \Omega_s \tau_{10} (\sin \Theta \cos^3 \Theta), \tag{49}
\]
with \(T_0 = G(M'/a^3)^2 R^5\). Similar to Eq. (16), we define the relevant tidal Love number \(k_{10}\), lag time \(\Delta t_{10}\) and quality factor \(Q_{10}\):
\[
k_{10} \Delta t_{10} \equiv \frac{4\pi}{5} \tau_{10}, \quad Q_{10} \equiv (\Omega_s \Delta t_{10})^{-1}. \tag{50}
\]

Using Eqs. (36) and (37), we find
\[
\left( \frac{\dot{\Omega}}{\Omega} \right)_{10} = -\frac{1}{t_{10}} (\sin \Theta \cos \Theta)^2, \tag{51}
\]
\[
\left( \dot{\Theta} \right)_{10} = -\frac{1}{t_{10}} \sin \Theta \cos^2 \Theta \left( \cos \Theta + \frac{S}{T} \right), \tag{52}
\]
where
\[
\frac{1}{t_{10}} = \frac{3\pi \tau_{10} T_0}{5I} = \frac{3k_{10}}{4Q_{10}} \left( \frac{M'}{M} \right) \left( \frac{R}{a} \right)^5 \left( \frac{S}{T} \right) \Omega. \tag{53}
\]

For \(M = M_\star\) and \(M' = M_p\), the corresponding timescale is
\[
t_{10} = 4.3 \left( \frac{k_0}{0.1} \left( \frac{Q_{10}}{k_{10}} \right) \right) \left( \frac{M_\star}{10^4 M_p} \right)^2 \left( \frac{\tilde{\omega}}{\Omega_{\star}} \right) \times \left( \frac{P}{1\text{d}} \right)^4 \text{Gyr}. \tag{54}
\]

Since the \((1, 0)\)-component of the tidal potential is static in the inertial frame, the associated energy transfer rate \(\dot{E}\) associated with this component is zero, giving
\[
\left( \frac{\dot{a}}{a} \right)_{10} = 0. \tag{55}
\]
This does not imply zero tidal dissipation. In fact, the tidal energy dissipation rate equals the energy transfer rate in the rotating frame,
\[
\dot{E}_r = -\Omega_T T_r > 0. \tag{56}
\]
This is exactly balanced by \((d/dt)(S^2/2I) = \Omega_s \dot{S} = \Omega_T T_r < 0\), so that \(\dot{E} = \dot{E}_r + \Omega_s T_s = 0\). Also note that the \((1, 0)\)-tidal force does not change the magnitude of the orbital angular momentum, \(L = -T_s \cos \Theta - T_s \sin \Theta = 0\). So a circular orbit will remain circular.

Two interesting features of Eq. (52) are worth noting: (i) \(\dot{\Theta} = 0\) when \(\Theta = 90^\circ\). Thus, if the \((1, 0)\)-tidal component is the only tidal force operating in the system, there could be many systems with the spin-orbit misalignment angle stalled around 90°. (ii) \(\dot{\Theta} > 0\) when \(\cos \Theta < -S/L\). This implies that a retrograde system \((\Theta > \pi/2)\) may evolve toward anti-alignment. Of course, other tidal components can also contribute to \(\dot{\Theta}\) (Sect. 2) and will weaken these features. But with enough statistics of misaligned systems, it may be possible to test these or constrain \(k_{10}/Q_{10}\) by this.

A detailed calculation of \(Q_{10}/k_{10}\) is beyond the scope of this paper. Previous works of tidal dissipation in rotating solar-type stars have focused on the \(m = 2\) tide for aligned binaries (Savonije & Papaloizou 1997; Papaloizou & Savonije 1997; Savonije & Witte 2002; Ogilvie & Lin 2007) and demonstrated the importance of inertial waves. In the numerical study by Ogilvie & Lin (2007), inertial waves affect tidal dissipation in two ways: (i) short-wavelength inertial waves in the convection zone are damped by turbulent viscosity; (ii) Inertial waves influences the excitation of gravity (Hough) waves in the radiative zone. Regarding (ii), they assumed that the inward propagating Hough waves are damped near the stellar center; this is appropriate for binary stars, but may lead to an over-estimate of stellar tidal dissipation in hot Jupiter systems (Barker & Ogilvie 2010, 2011; see Sect. 1.2). Ogilvie & Lin (2007) found that when inertial waves are excited \((|\tilde{\omega}| > 2\Omega_s)\), the tidal dissipation rate depends on \(\tilde{\omega}\) in an erratic manner. On average, the energy dissipation rate in the convection zone is significantly increased (by 1-3 orders of magnitude, depending on the spin period) compared to equilibrium tides. For example, Figure 3-6 of Ogilvie & Lin (2007) show that for a solar-type star at \(\tilde{\omega} = -\Omega_s\), the tidal quality factor associated with inertial waves is expected to be large.
tial wave dissipation is \( Q' \approx 6 \times 10^7 \) for \( P_s = 10 \) days and \( Q' \approx 5 \times 10^6 \) for \( P_s = 3 \) days.

Barker & Ogilvie (2009) reported the result of a calculation of the \( l = 2, m = 1 \) tidal dissipation for a specific F-type stellar model (appropriate for the hot Jupiter system XO-3) using the numerical method of Ogilvie & Lin (2007). Intriguingly, they found that at \( \tilde{\omega}/\Omega_s = -1 \), tidal dissipation is significantly enhanced, with the effective tidal \( Q \sim 10^6 \) (see their Fig. 7). They suggested that this prominent feature arises from resonant excitation of the \( l = m = 1 \) Rossby mode. More systematic studies on the \((m, m') = (1, 0)\) tide for a range of stellar models (with different sizes of the convective envelope) would be useful.

4 CONCLUSION

The main point of this paper is that in close-in exoplanetary systems, when the stellar spin axis is misaligned with the orbital angular momentum axis, a new tidal dissipation channel opens up. This channel involves the excitation of inertial waves in the stellar convection zone, and is forbidden for aligned systems. Thus, tidal damping of spin-orbit misalignment can be more efficient than orbital decay. This may explain the stellar obliquity – effective temperature correlation observed by Winn et al. (2010) and the obliquity – age correlation noted by Triaud (2011), while still being consistent with the survival of hot Jupiters with very short orbital period (see Sect. 1.1).

On a more general level, this paper highlights the importance of treating tidal dissipation as being dependent on the tidal forcing frequency, the strength of tidal potential, and the tidal processes involved (e.g., orbital decay vs. spin-orbit alignment), in contrast to the equilibrium tide equations widely used in many applications and empirical works (see references in Sect. 1.2). Indeed, various studies of the physical mechanisms of tidal dissipation (e.g., Ogilvie & Lin 2004, 2007; Goodman & Lackner 2009; Barker & Ogilvie 2010, 2011; see also Zahn 2008 for a review of earlier works) have already made this point clear. While it is recognized that the weak friction theory of equilibrium tides (Darwin 1880; Goldreich & Soter 1966; Alexander 1973; Hut 1981; Eggleton et al. 1998) is a parameterized theory (with the tidal Q or lag time being the single parameter), we have shown in this paper that even at the parameterized level, its equations are sometimes inadequate or misleading, since different tidal processes (e.g., orbital decay vs. spin-orbit alignment) may involve very different tidal dissipation mechanisms.

Given the complicated nature of tidal dissipation, a parameterized “effective” theory of tidal evolution remains useful. We have derived such an effective theory in this paper (see Sect. 2). For misaligned circular binaries, there are seven independent tidal quality factors \( Q_{mm'} \) or lag times \( \tau_{mm'} \) in the theory, related to the tidal responses for different Fourier components of the tidal potential. Obviously, such a system of equations with 7 parameters (Sect. 2.4) is not convenient to use in real applications. For hot Jupiter systems, we suggest that a reduced system of equations involving two tidal

### Tidal Dissipation in Planet-Hosting Stars

**\( Q \)** parameters may be adopted. They are

\[
\begin{align*}
\dot{\alpha}/\alpha & = \left( \frac{\dot{\alpha}}{\alpha} \right)_{eq}, \\
\frac{\dot{\Omega}_s}{\Omega_s} & = \left( \frac{\dot{\Omega}_s}{\Omega_s} \right)_{eq} + \left( \frac{\dot{\Omega}_s}{\Omega_s} \right)_{10} - \left( \frac{\dot{\Omega}_s}{\Omega_s} \right)_{10,eq}, \\
\dot{\Theta} & = (\dot{\Theta})_{eq} + (\dot{\Theta})_{10} - (\dot{\Theta})_{10,eq},
\end{align*}
\]

where \( (\dot{\alpha}/\alpha)_{eq}, (\dot{\Omega}_s/\Omega_s)_{eq} \) and \( (\dot{\Theta})_{eq} \) are given by Eqs. 42–44 and characterized by the parameter \( k_2/Q \), while \( (\dot{\Omega}_s/\Omega_s)_{10} \) and \( (\dot{\Theta})_{10} \) are given by Eqs. 51–52 and characterized by the parameter \( k_{10}/Q_{10} \). The expressions for \( (\dot{\Omega}_s/\Omega_s)_{10,eq} \) and \( (\dot{\Theta})_{10,eq} \) are the same as Eqs. 51–52, except that the the parameter \( k_{10}/Q_{10} \) should be replaced by \( k_2/Q \). These equations (extended to eccentric orbits), combined with similar equations for planetary tides, can be used to assess and constrain the effects of tidal evolution in close-in exoplanetary systems.

### ACKNOWLEDGMENTS

I thank Josh Winn for update on current observations and useful discussion, and Gordon Ogilvie for helpful communication and comment. This work has been supported in part by AST-1008245.
