(Dated: December 11, 2020)

We report electronic transport experiments on a graphene single electron transistor. The device consists of a graphene island connected to source and drain electrodes via two narrow graphene constrictions. It is electrostatically tunable by three lateral graphene gates and an additional back gate. The tunneling coupling is a strongly nonmonotonic function of gate voltage indicating the presence of localized states in the barriers. We investigate energy scales for the tunneling gap, the resonances in the constrictions and for the Coulomb blockade resonances. From Coulomb diamond measurements in different device configurations (i.e. barrier configurations) we extract a charging energy of \( \approx 3.4 \text{ meV} \) and estimate a characteristic energy scale for the constriction resonances of \( \approx 10 \text{ meV} \).

The recent discovery of graphene [1, 2], filling the gap between quasi 1-dimensional (1-D) nanotubes and 3-D graphite makes truly 2-D crystals accessible and links solid state devices to molecular electronics [2]. Graphene, which exhibits unique electronic properties including massless carriers near the Fermi level and potentially weak spin orbit and hyperfine couplings [4, 5], has been proposed to be a promising material for spin qubits [6], high mobility electronics [7, 8] and it may have the potential to contribute to the downscaling of state-of-the-art silicon technology [9]. The absence of an energy gap in 2-D graphene and phenomena related to Klein tunneling [10, 11] make it hard to confine carriers electrostatically and to control transport on the level of single particles. However, by focusing on graphene nanoribbons, which are known to exhibit an effective transport gap [7, 8] this limitation can be overcome. It has been shown recently that such a transport gap allows to fabricate well tunable graphene nanodevices [14, 15, 16]. Here we investigate a fully tunable single electron transistor (SET) that consists of a width modulated graphene structure exhibiting spatially separated transport gaps. SETs consist of a conducting island connected by tunneling barriers to two conducting leads. Electronic transport through the device can be blocked by Coulomb interaction for temperatures and bias voltages lower than the characteristic energy required to add an electron to the island [17].

The sample is fabricated based on single-layer graphene flakes obtained from mechanical exfoliation of bulk graphite. These flakes are deposited on a highly doped silicon substrate with a 295 nm silicon oxide layer [1]. Electron beam (e-beam) lithography is used for patterning the isolated graphene flake by subsequent Ar/O\(_2\) reactive ion etching. Finally, an additional e-beam and lift-off step is performed to pattern Ti/Au (2 nm/50 nm) electrodes. For the detailed fabrication process and the single-layer graphene verification we refer to Refs. [14, 15, 18, 19].

is used as a back gate (BG) to adjust the overall Fermi level ($E_F$).

All measurements have been performed in a variable temperature $^4$He cryostat at a base temperature of $T=1.7$ K and the sample was heated to $135^\circ$C in vacuum for 12 h before cooling down. We have measured the two-terminal conductance through the graphene SET device by applying a symmetric DC bias voltage $V_b$ while measuring the current through the SET device with a resolution better than 10 fA. For differential conductance measurements a small AC bias, $V_{ac} = 50 \, \mu$V has been superimposed on $V_b$ and the differential conductance has been measured with lock-in techniques.

At small bias ($V_b = 250 \, \mu$V $< 4k_BT$) strong current suppression is observed at $-25 \, V < V_{bg} < -15 \, V$, as shown in Fig. 1c. This suppression is in agreement with earlier studies of graphene nanocnstrictions $^2$ $^8$. It can be interpreted as a transport gap forming around the back gate voltage where the system is charge neutral. Hole transport occurs at $V_{bg} < -25 \, V$, electron transport at $V_{bg} > -15 \, V$.

Measurements for varying back gate voltage (Fermi level) and bias voltage allow to estimate the size of the transport gap as shown in Fig. 2f. A value of the order of 10 meV is found. However, the strong modulation of the current shows, that localized states lead to strong transmission resonances. Therefore we refer in the following to an "effective" energy gap or a transport gap.

The geometric design of our structure (see Fig. 1a) gives local electrostatic access to the constriction regions. Fig. 2a shows a measurement of the current where the voltages $V_{b1}$ and $V_{b2}$ on the two barrier gates B1 and B2 have been independently tuned while the back gate voltage was kept fixed at $V_{bg} = -15 \, V$. A vertical and a horizontal stripe of suppressed current is observed. This observation indicates that transport through each of the two constrictions is characterized by a transport gap which can be individually tuned with the respective barrier gate. For example, keeping $V_{b1} = -20 \, V$ constant and sweeping $V_{b2}$ from $-20 \, V$ to $+5 \, V$ keeps constriction 1 conducting well while constriction 2 is tuned from large conductance to very low conductance (into the transport gap). The capacitive cross talk from B1 to constriction 2, and from B2 to constriction 1 is found to be smaller than 2%.

These measurements suggest that the energy diagram shown in Fig. 1d is a useful description of the data. In this figure, high (electron) and low (hole) energy states are separated by two solid lines. Outside the constriction regions these lines are degenerate and represent the en-
ergy of the charge neutrality point in graphene. In the constriction regions the two lines are energetically separated indicating the observed effective energy (transport) gap $E_g$ by hatched areas. As a result of the lack of an energy gap of the two-dimensional graphene material, the exact shape of the effective $E_g(x)$ ($x$ is the transport direction) is given only by lateral confinement, i.e., by the variation of the width $w(x)$ along the device. We assume that electron-hole symmetry holds in the confined geometry and therefore plot an effective conduction band edge at $+E_g(x)/2$, and an effective valence band edge at $-E_g(x)/2$.

It is known from earlier experiments\cite{7,8} that graphene nanoribbons (or constrictions) exhibit an effective energy gap. For ribbons of width $w < 20$ nm the size of this gap scales according to $E_g = h v_F/w$, where $v_F = 10^8$ m/s is the Fermi velocity. The energy gap for nanoribbons wider than 20 nm can be reasonably well described by $E_g(w) = a/w \exp(-bw)$ \cite{12}, where $a = 1$ eV×nm and $b = 0.023$ nm$^{-1}$ are constants extracted from fits of the experimental data in Ref.\cite{8}. Within this model the width $w(x)$ of our graphene structure translates to an effective transport band structure exhibiting two tunnel junctions with barrier height $E_{g,b} = 6.5$ meV and an almost gap free island ($E_{g,i} = 85$ μeV) as shown in Fig. 1d. According to the model the SET is expected to be operational in the regime of $|E_F| < E_{g,b}/2$. The measured transport gap agrees reasonably well with the modeled barrier height, as indicated by the arrow in Fig. 2f.

The local electrostatic influence of the gate electrodes can be incorporated into this heuristic description as a local shift of the energy of the charge neutrality point described by smooth characteristic potentials $\phi_i(x)$ ($i = b1, b2, pg, bg$) which may be derived from purely electrostatic considerations. While $\phi_{bg}(x)$ is independent of $x$, $\phi_{b1}(x)$ and $\phi_{b2}(x)$ are peaked at the respective constrictions, and $\phi_{pg}(x)$ is peaked within the island. For creating the schematic figures in this paper [Figs. 1(d), 2(d), (e)] we have used a convenient peaked $\phi_i(x)$ function (the shape of which is irrelevant for this simple discussion) with peak heights compatible with lever arms extracted from the experiment (see below).

Having established a heuristic energy diagram describing our sample we now return to the discussion of the measurement in Fig. 2a which is facilitated by the diagrams in Fig. 2d. In this measurement $V_{bg} = -15$ V. From Fig. 1c we deduce that the Fermi energy in the contacts of the structure lies within the conduction band, as indicated by the horizontal dashed lines in the four drawings in Fig. 2d. The four drawings represent energy diagrams corresponding to the four corners of Fig. 2a as indicated by the white numbers. In corner 2 transport takes place in the conduction band throughout the whole structure. In corner 1 (4) transport occurs in the conduction band in the right (left) part of the structure. The left (right) constriction is traversed via states in the valence band. The situation is even more complex in corner 3, where the Fermi energy cuts both barrier regions in the valence band. Although these situations imply two or even four p-n-like transitions along the structure, no distinctive features are observed in our measurements. This may be a manifestation of the suppression of backscattering due to Klein tunneling.

Figs. 2b and 2c demonstrate the consistency of our heuristic model with the experimental observations. Fig. 2b shows the current measured as a function of $V_{bg}$ and $V_{b1}$, with $V_{b2}$ being simultaneously swept such that $V_{b2} = V_{b1} + 5$ V (see dashed line in Fig. 2a). In this way the barrier regions are simultaneously shifted up or down (see Fig. 2e). Fig. 2b shows that the transport gap measured as a function of the back gate is shifted correspondingly, with $\Delta V_{bg}/\Delta V_{b1,2} \approx 0.9$. Fig. 2c shows the current measured as a function of $V_{bg}$ and $V_{b1}$, with $V_{b2}$ being simultaneously swept such that $V_{b1} + V_{b2} = 5$ V (see dotted line in Fig. 2a). For $V_{b1} = \pm 15$ V (vertical dashed lines in Fig. 2c) the position of the gaps in energy correspond to diagrams 1 and 4 in Fig. 2d. In these two cases, sweeping the back gate allows to probe the two spatially separated transport gaps individually.

If we focus on a smaller voltage scale much more finestructure in the $V_{b1} - V_{b2}$ parameter plane appears, as shown in Fig. 3. Subplots 3a-c are different close ups of Fig. 2a (see black labeled boxes therein). Although Figs. 3a-c show the current in three different regimes the transport characteristics do not differ significantly. Here, we distinguish between the PP (Fig. 3a), NN (Fig. 3b) and the NP (Fig. 3c) regime, depending on either having the tunnel barriers (according to B1 and B2) shifted down (N) or up (P). We observe in all regimes (Fig. 3) sequences of horizontal and vertical stripes of suppressed current and current resonances. Their direction in the $V_{b1} - V_{b2}$ plane indicates that their physical origin has to be found within constriction 1 (vertical stripes) or constriction 2 (horizontal stripes). A blow-up of a small region in Fig. 3a is shown in Fig. 3d. The current exhibits even finer resonances which are almost equally well tuned by both constriction gates. We therefore attribute these resonances to states localized on the island between the barriers. It will be shown below that these resonances occur in the Coulomb blockade regime of the island. We attribute the deviations from perfectly straight diagonal lines to the presence of rough edges and inhomogeneities within the graphene island which has dimensions (slightly) larger than the elastic mean free path.

This characteristic pattern (Fig. 3d) can be found within a large $V_{b1} - V_{b2}$ parameter range within the regime where the two barrier gaps cross each other (i.e. the inner bright part of Fig. 2a).

So far we mainly focused on the barriers and in the following we concentrate on the charging of the island itself. We fix the barrier gate potentials ($V_{b1}$ and $V_{b2}$) either in the NN regime or in the NP regime in order to study Coulomb blockade. Fig. 4a shows sharp conductance resonances with a characteristic period of about 20 mV ($V_{b1} = 5.570$ V, and $V_{b2} = -2.033$ V are fixed). Their
amplitude is modulated on a much larger voltage scale of about 200 mV by the transparency modulations of the constrictions (cf. Fig. 3d). These resonances in the narrow graphene constrictions can significantly elevate the background of the Coulomb peaks (see e.g. black arrow). The inset of Fig. 4a confirms that transport can also be completely pinched off between Coulomb blockade peaks. Corresponding Coulomb diamond measurements, i.e., measurements of the differential conductance \(G_{\text{diff}} = dI/dV_b\) as function of bias voltage \(V_b\) and plunger gate voltage \(V_{pg}\) are shown in Fig. 4b. Within the swept plunger gate voltage range no charge rearrangements have been observed and the peak positions were stable over more than 10 consecutive plunger gate sweeps. In Fig. 4c we show conductance resonances, which have been measured within the NN regime (for fixed \(V_{b1} = 8.79\ V\) and \(V_{b2} = 8.85\ V\), see Fig. 3b). The \(V_{pg}\) range shown here is wider than in Fig. 4a. Again we observe (i) strong transport modulations on a \(V_{pg}\) scale of about 100 mV, which originate from resonances within the barriers and (ii) Coulomb peaks on a \(V_{pg}\) scale of about 20 mV which are blown up in Fig. 4d. The corresponding Coulomb diamond measurements (Fig. 4e) are similar to those measured in the NP regime (Fig. 4a). The Coulomb peaks (Fig. 4d and inset in Fig. 4a) and the Coulomb diamonds are not very sensitive to the tunnel barrier regime, although in one case a p-n-like junction should be present, whereas in the other case a more uniform island is expected. From the extent of all the diamonds in bias direction we estimate the average charging energy of the graphene
### TABLE I: Capacitances and lever arms of the different gate electrodes, including source and drain contacts, with respect to the graphene island. Most values are independent from the measurement regime, NN or NP. If there is a difference the NP value is given and the NN value is put in brackets.

| Source (S) | B1 | B2 | Drain (D) |
|------------|----|----|-----------|
| Capacitance (aF) | 18.0 | 6.9 | 6.0 (5.5) | 5.0 | 18 (10.1) | 9.6 (1.8) |
| Lever arm | 0.38 | 0.15 | 0.13 (0.12) | 0.1 | 0.04 (0.21) | 0.20 (0.04) |

FIG. 5: Nearest neighbor Coulomb peak spacing statistics in both the NN (left) and NP (right) regime. Several plunger gate sweeps (at different barrier gate potentials) have been evaluated and in total 431 Coulomb peaks in the NN (and 460 peaks in the NP) regime have been considered for the statistics.

In conclusion, we have fabricated and characterized a fully tunable graphene single electron transistor based on an etched width-modulated graphene nanostructure with lateral graphene gates. Its functionality was demonstrated by observing electrostatic control over the tunneling barriers. From Coulomb diamond measurements it was estimated that the charging energy of the graphene island is \( \approx 3.4 \text{ meV} \), compatible with its lithographic dimensions. These results give detailed insights into tunable graphene quantum dot devices and open the way to study graphene quantum dots with smaller dimensions and at lower temperatures.
