(Dated: March 10, 2022)

We calculate the $\beta$-decay of tritium at next-to-leading order in pionless effective field theory. At this order, a low-energy parameter $l_{1,A}$ enters the calculation that is also relevant for a high-accuracy prediction of the solar proton-proton fusion rate. We use the tritium half-life to determine this parameter and provide uncertainty estimates. We show proper renormalization of our calculation analyzing the residual cutoff dependence of observables. We find that next-to-leading order corrections contribute about 4% to the triton decay Gamow-Teller strength. We show that these conclusions are insensitive to different arrangements of the effective range expansion.

I. INTRODUCTION

Weak decays of nuclei are an everyday window to quantum-chromodynamics (QCD). This is the main reason for their extensive use in experiments that try to study the limits of the Standard Model, from measuring the masses of neutrinos using triton $\beta$-decay, to pinpointing the basic symmetries of the theory through the dynamics of $^4$He decay. The triton $\beta$-decay, as the only $A = 3$ $\beta$-decay, can, therefore, probe unique properties of the nuclear force for both $^3$H and $^3$He. Alas, since this reaction is characterized by its low-energy, i.e., $Q < 10$ MeV, one cannot use QCD due to its non-perturbative character at low energies.

In the past two decades, a novel theoretical method named effective field theory (EFT) revolutionized nuclear physics. EFT is a simple, order by order, renormalizable and model-independent theoretical method that is used to describe low-energy processes. The prerequisite for describing a physical process using EFT is that its transfer momentum, $Q$, is small compared to a large scale, $\Lambda_{\text{cut}}$ (i.e., $Q/\Lambda_{\text{cut}} \ll 1$) [1,2] inherent to the system under consideration. This method becomes particularly useful when there is a significant scale separation between $Q$ and $\Lambda_{\text{cut}}$, so that only a small number of the effective operators corresponding to the leading powers in $Q/\Lambda_{\text{cut}}$ need to be retained to reproduce long wavelength observables with the desired accuracy.

The relevant momentum scale $Q$ is small, i.e., $Q \ll \Lambda_{\text{cut}}$, for many other few-body electroweak processes of interest. In these cases, pionless EFT ($\pi$EFT) is an appropriate framework [6,7].

The Coulomb interaction in light nuclei is also an issue that needs to be addressed. Naively, the Coulomb interaction is non-perturbative at low momenta ($\ll 10$ MeV) but should be perturbative in nuclei where the typical momenta are much higher. However, recent calculations done by König et al. [8-10] have shown that for $A = 3$, the Coulomb interaction can be treated perturbatively, as reflected in the $^3$H-$^3$He binding energy difference. Moreover, in Ref. [11], we have shown that, even though the Coulomb interaction does not conserve the three-nucleon isospin, the Coulomb energy difference can be presented in terms of a general matrix element between two $A = 3$ bound-states. At LO, $^3$He (the lightest and, therefore, the simplest nucleus that includes a Coulomb interaction) is described correctly within $\pi$EFT, even when the Coulomb interaction is non-perturbative [12,13]. At next-to-leading order (NLO), the results are not so clear, and some approaches point towards the need for additional, isospin-dependent three-body forces. Therefore, other three-nucleon observables are needed to obtain predictive power within $\pi$EFT at NLO, such as the $^3$He binding energy [8,9,13].

One way to test the predictive power of $\pi$EFT for the three-nucleon system at NLO, and in particular, the effect of the Coulomb interaction of such a system is through the aforementioned electroweak properties of light nuclear systems. This is the goal of this paper, in which we aim at describing tritium $\beta$-decay. This observable is particularly interesting since it is well-known experimentally, and can be used to determine the short-range strength of the axial coupling to nuclei. Specifically, the $\pi$EFT axial-vector current contains an additional two-body operator at NLO whose low-energy constant (LEC), known as $l_{1,A}$, needs to be determined. This is in particular important for a high-accuracy description of the astrophysically relevant proton-proton fusion rate [15-18]. However, its exact value is a matter of discussion in the literature [19-23] and the lack of a $\pi$EFT calculation that is able to consistently determine this counterterm is the reason for this discussion.

Besides determining $l_{1,A}$, we will also use our work to study the convergence pattern of $\pi$EFT for this process and analyze the residual cutoff dependence for this observable. Will also discuss the impact of the Coulomb interaction on the relevant matrix element.

This paper is organized as follows: The general formalism of $\pi$EFT is presented in Section 1. The
II. EFT UP TO NEXT-TO-LEADING ORDER

Originally, EFT was developed in terms of nucleon fields alone. However, dynamical dibaryon fields provide a convenient way to reformulate EFT in a way that simplifies three-body calculations. The fields $t$ and $s$ have quantum numbers of two nucleons coupled to an $S$-wave spin-triplet and -singlet state, respectively. The effective masses and interaction strengths of these dibaryons are related to the two-nucleon scattering lengths and effective ranges in these two channels. This formulation is formally equivalent to the usual single-nucleon theory but in a three-nucleon calculation it reduces the problem to an effective two-body calculation.

For the construction of the EFT Lagrangian, we note that the external momenta $q$ and the deuteron binding momentum $\gamma_\beta$ and the deuteron binding energy $B_2$ through $B_2 = \gamma_2^2 / m$. The renormalization scale $\mu$ enters these equations through the use of the power divergence subtraction scheme \cite{4}. To include the Coulomb interaction, we will also require the proton-proton (pp) scattering length $a_C$ and effective range $\rho_C$. The experimental values for the two-nucleon observables needed here are given in Tab. \ref{Table:1}.

In this work, contrary to previous works on the electroweak properties of light nuclei, that set the renormalization group (RG) scale $\mu$ to $\mu = m_\pi$, we test correct renormalization by taking the UV cutoff $\Lambda$ to infinity at the end of the calculation.

Naively, the effective ranges are fixed from scattering experiments. However, since the triplet channel is bound, the deuteron (spin-triplet, $t$) effective range can be alternatively fixed by the long-range properties of the deuteron wave function.

The long-range properties of the deuteron wave function are set by a quantity that we will call $Z_d$, where $Z_d$ is defined through the deuteron asymptotic $S$-state normalization, $A_S$, such that $A_S = \sqrt{2\gamma_d Z_d}$ and $Z_d = \frac{1}{1 - \gamma_d}$ \approx $1.690(3)$ \cite{20} ($\gamma_d$ is the deuteron binding momentum, $\gamma_d = \sqrt{M E_0(d)}$). In the effective range expansion (ERE), the order-by-order expansion of $Z_d$ is:

$$Z_d^{LO} = 1,$$

$$Z_d^{NLO} = 1 + \gamma_d \rho_t \approx 1.408$$

| Parameter | Value | Reference |
|-----------|-------|-----------|
| $\gamma_t$ | 45.701 MeV | 27 |
| $\rho_t$ | 1.765 fm | 28 |
| $a_s$ | -23.714 fm | 29 |
| $\rho_s$ | 2.73 fm | 28 |
| $a_p$ | -7.8063±0.0026 fm | 30 |
| $\rho_C$ | 2.794±0.014 fm | 30 |

TABLE I. Parameters used in the numerical calculation

This result for the perturbative expansion of the $Z$-factor is based on a matching of the parameters in the EFT to the effective range expansion (ERE). At NLO, the parameters can also be chosen to fix the pole position and wave function renormalization constant of the triplet two-body propagator to the deuteron values. This parameterization is known as the $Z$-parameterization and is advantageous because it reproduces the correct residue about the deuteron pole at NLO, instead of being approached perturbatively order-by-order as in ERE-parameterization \cite{20} \cite{30} \cite{31} \cite{32}:

$$Z_d^{LO} = 1,$$

$$Z_d^{NLO} = 1 + (Z_d^{full} - 1) = 1.690(3).$$

The price is that the value of the triplet effective range at NLO in this parameterization is $\rho_t = \frac{Z_d^{NLO} - 1}{\gamma_d} \approx 0.690 \frac{\gamma_d}{\gamma_t}$.
2.979 fm. In the following, we use both parameterizations at NLO.

A. $A = 3$ nuclear amplitudes, matrix elements, and regularization

While an analytical result for the deuteron wave function can be derived in pionless EFT [19], the three-nucleon scattering amplitude has to be calculated numerically. The different channels for $^3\text{H}$ are the spin-triplet - $t$ (representing an “off-shell” deuteron, $d$, dibaryon), and the spin-singlet - $s$ ($nn, np$). For $^3\text{He}$, the contributing channels are the spin-triplet - $t$, spin-singlet - $s$ ($np$) and $pp$ [34]. The latter is required because of the Coulomb force between the protons, which modifies the long-range scattering properties of these nucleons.

The Faddeev integral equation, used in this EFT, has to be regularized. A simple way to do this is to evaluate the momentum space integrals in the integral equation up to a cutoff $\Lambda$. Since $\pi$EFT is supposed to be order-by-order renormalizable, the theory should not depend on this ultraviolet (UV) cutoff. However, for three-nucleon systems, the numerical and theoretical solution of the integral equations displays a strong dependence on the cutoff. To overcome this problem, one adds a three-body counterterm [35, 36]. In the case of $^3\text{He}$, the addition of Coulomb interaction to the three-nucleon amplitude leads to divergence in the Coulomb Feynman diagrams, which is solved by the redefinition of the proton-proton scattering length [37, 38]. With this redefinition, the $^3\text{He}$ binding energy is renormalization-group invariant at LO. [9, 10].

The calculation of bound-state amplitudes requires the solution of a homogeneous Faddeev equation defined up to a normalization. The calculation of next-to-leading order corrections follows the same formalism, however with a single NLO insertion, e.g., of an effective range. The three-body wave function normalizations, $Z_{^3\text{H}}, Z_{^3\text{He}}$, are calculated diagrammatically, by summing over all possible connections between two identical vertex functions as presented in Ref. [11].

The Coulomb force is included by considering the full $pp$ Coulomb propagator and allowing a single photon insertion in the three-body diagrams. At LO, it was shown that $^3\text{He}$ is described correctly within $\pi$EFT [12, 13, 39], while at NLO, within the power counting considered here, there is a need for an additional, isospin dependent, three-body force to renormalize the $^3\text{He}$ binding energy [8, 9, 11, 14].

The nuclear amplitudes we use here are taken explicitly from Ref. [11], where they were benchmarked numerically, and validated using the binding energy difference between $^3\text{H}$-$^3\text{He}$.

III. THE WEAK INTERACTION IN $\pi$EFT

For low-energy charge lowering processes, the weak-interaction Hamiltonian is

$$\mathcal{H}_\text{Weak} = \frac{G_F V_{ud} l^\mu J_\mu}{\sqrt{2}} , \quad (5)$$

where $G_F$ is the Fermi constant and $V_{ud}$ is the CKM matrix element. $l^\mu$ is the lepton current and $J_\mu$ is the hadronic current. We use the two-body hadronic current $J_\mu$ from the $\pi$EFT effective Lagrangian with dibaryon fields up to NLO.

The hadronic current contains two parts, a polar-vector and axial-vector, $J_\mu = V_\mu - A_\mu$. The part of the polar vector current relevant to $\beta$-decay with a vanishing energy transfer is:

$$V_0^\pm = N^\dagger \frac{\tau^\pm}{2} N , \quad (6)$$

where $\tau^\pm = \tau_1 \pm i \tau_2$.

Here, we utilized the fact that the Conserved Vector Current (CVC) hypothesis is accurate at this order of EFT. The axial-vector part is (see Ref. [24, 25]):

$$A^\pm_i = \frac{g_A}{2} N^\dagger \sigma_i \tau^\pm N + g_A L_{1,A} \left( t_1^i s_\pm + \text{h.c.} \right) , \quad (7)$$

where $\tau^\pm = \tau_1 \pm i \tau_2$ and $s_\pm = s_1 \pm i s_2$ and $g_A$ is the axial coupling constant for a single nucleon, known from neutron $\beta$-decay. We denote the coefficient of the two-body operator with $L_{1,A}$ (see Ref. [11] for more details). A number of previous pionless EFT electroweak calculations were calculated using a Lagrangian with single nucleon fields only. The axial-vector two-body counterterm then takes the form

$$L_{1,A}(N^T P_i N)^\dagger (N^T P_i N) . \quad (8)$$

The coefficients of these two-body operators are related through the relation

$$L_{1,A}(\mu) = - \frac{\rho_+ + \rho_-}{2\sqrt{\rho^+_\mu \rho^-_\mu}} + \frac{L_{1,A}^I}{2\pi g_A \sqrt{\rho^+_\mu \rho^-_\mu}} \left( \mu - \gamma_\mu \right) \left( \mu - \frac{1}{\alpha_s} \right) . \quad (9)$$

It was already pointed out by Kong and Ravndal [20] that renormalization scale dependence of $L_{1,A}^I$ can be made explicit by writing

$$l_{1,A} = \frac{L_{1,A}^I}{2\pi g_A \sqrt{\rho^+_\mu \rho^-_\mu}} \left( \mu - \gamma_\mu \right) \left( \mu - \frac{1}{\alpha_s} \right) , \quad (10)$$

where $l_{1,A}$ is now a cutoff (renormalization scale) independent number that characterizes the physics underlying the coupling of the external axial current to two-nucleon system.

In two-nucleon calculations the renormalization scale $\mu$ was frequently set to the breakdown scale of theory,
usually at $m_e$. In this work, $\mu$, the renormalization scale, is set to the momentum space cutoff employed in the three-nucleon integral equations, $\mu = \Lambda$.

We will show below that by taking $\Lambda \to \infty$ numerically that when we use these relations we can obtain results for the constant $\beta_{1,\Lambda}$ that are converged with respect to the cutoff $\Lambda$.

**IV. $^3\text{H}$ $\beta$-DECAY MATRIX ELEMENTS**

In this section, we outline the calculation of the matrix element of the weak reaction:

$$^3\text{H} \rightarrow ^3\text{He} + e^- + \nu_e.$$  \hspace{1cm} (11)

This $\beta$-decay matrix element can be calculated using the LO and NLO $A = 3$ bound-state wave functions, as introduced in Ref. [11].

**A. $^3\text{H}$ $\beta$-decay observables**

The half-life of $^3\text{H}$ $\beta$-decay can be expressed as [10]:

$$fT_{1/2} = \frac{K/G_V^2}{\langle|\langle F\rangle|^2 + g_A^2 f_A^2/|\langle GT\rangle|^2\rangle},$$ \hspace{1cm} (12)

where $fT_{1/2} = 1129.6 \pm 3$ [10] is the triton comparative half-life, $K = 2\pi^3 \log 2/m_e^2$ (with $m_e$ denoting the electron mass), $G_V$ is the weak interaction vector coupling constant (such that $K/G_V^2 = 6146.66 \pm 0.6$ [11]), $f_V = 2.8355 \times 10^{-6}$ and $f_A = 2.8506 \times 10^{-6}$ are the Fermi functions calculated by Towner, as reported by Simpson in Ref. [22]. $\langle|\langle F\rangle|^2\rangle$ and $\langle|\langle GT\rangle|^2\rangle$ are the reduced matrix elements of the vector and axial current $A = 3$ wavefunction, respectively.

**B. General $A = 3$ matrix element in $\pi$EFT**

The weak transitions $\langle|\langle GT\rangle|^2\rangle$, $\langle|\langle F\rangle|^2\rangle$ are defined as matrix elements between the initial state wave function $\psi^{'H}$, and the final state, $\psi^{'\text{He}}$, using the general mechanism introduced in Ref [11].

**1. $A = 3$ one-body matrix element**

In Ref. [11], we showed that at LO, the three-nucleon normalization can be written as:

$$1 = \sum_{\mu,\nu} \langle \psi^{'i}_{\mu} | O^{\text{norm}}_{\mu\nu} (E_i) | \psi^{'j}_{\nu} \rangle,$$ \hspace{1cm} (13)

where $O^{\text{norm}}_{\mu\nu} (E_i)$ is the normalization operator such that:

$$O^{\text{norm}}_{\mu\nu} (E_i) = \left. \frac{\partial}{\partial E} \left[ \hat{I}_{\mu\nu} (E, p, p') - M y_{\mu} y_{\nu} a_{\mu\nu} K_{\nu} (p', p, E) \right] \right|_{E=E_i},$$ \hspace{1cm} (14)

where:

$$K_{\mu\nu} = \begin{cases} K_0 (p', p, E) & i = ^3\text{H} \\ K_{0} (p', p, E) + K_C (p', p, E) & i = ^3\text{He} \end{cases},$$ \hspace{1cm} (15)

and

$$\hat{I}_{\mu\nu} (p, p', E) = \frac{2\pi^2}{p^2} \delta (p - p') D_{\mu} (E, p)^{-1} \delta_{\mu,\nu},$$ \hspace{1cm} (16)

$$K_0 (p, p', E) = \frac{1}{2pp'} Q_0 \left( \frac{p^2 + p'^2 - ME}{pp'} \right),$$ \hspace{1cm} (17)

where $\delta_{\mu,\nu}$ is the Kronecker delta and:

$$Q_0 (a) = \frac{1}{2} \int_{-1}^{1} \frac{1}{x + a} dx.$$ \hspace{1cm} (18)

Since we will consider a matrix element of triton and Helium-3, it is convenient to express the wave of the triton in terms of three components $t, np$ and $nn$. Note that we assume here that $a_{nn} = a_{np} = a_s$. The coefficients $a_{\mu\nu}$ are then

$$a_{\mu\nu}^{^3\text{H}} = a_{\mu\nu} = \begin{pmatrix} \mu \\ \nu \end{pmatrix} \begin{pmatrix} t & np & nn \\ -1 & 3 & 3 \\ np & 1 & 1 \\ nn & 2 & -2 \end{pmatrix},$$ \hspace{1cm} (19)

and

$$a_{\mu\nu}^{^3\text{He}} = a'_{\mu\nu} = \begin{pmatrix} \mu \\ \nu \end{pmatrix} \begin{pmatrix} t & np & pp \\ -1 & 3 & 3 \\ np & 1 & 1 \\ pp & 2 & -2 \end{pmatrix},$$ \hspace{1cm} (20)

$K_C (p', p, E)$ is the $\mu, \nu$ index of the one-photon exchange matrix, $K_C (p', p, E)$ (see Ref. [11]), $\mu = t, np, nn$ are the different triton channels, $\mu = t, s, pp$ are the different $^3\text{He}$ channels, $y_{\mu,\nu}$ are the nucleon-dibaryon coupling constants for the different channels, $a_{\mu\nu}$ are the result of the $n - d (p - d)$ doublet-channel projection (14) and $D_{\mu} (E, p)$ is the dibaryon propagator (11) [15] [36].

A general one-body operator, can be written as a generalization of a three-nucleon normalization operator for the case of both energy and momentum transfer, between initial (i) and final (j) $A = 3$ bound-state wave functions ($\psi_{i,j}$). The general operator $O_{j,i}$ factorizes into the following parts:

$$O_{j,i} = O_{j,i}^T O_{j,i} (q_0, q),$$ \hspace{1cm} (21)
where \(O^J\), the spin part of the operator whose total spin is \(J\), and \(O^T\), the isospin part of the operator, that depend on the initial and final quantum numbers. The spatial part of the operator, \(O_{j,i}(q_0, q)\), is a function of the three-nucleon wave function’s binding energies, \((E_i, E_j)\) and the energy and momentum transfer \((q_0, q)\), respectively.

In the case of triton \(\beta\)-decay, the spin and isospin one-body operators are combinations of Pauli matrices, so their reduced matrix elements \(\langle |F| \rangle\) and \(\langle |GT| \rangle\) can be easily calculated as a function of the three-nucleon quantum total spin and isospin numbers. In Ref. [11] we showed that the reduced matrix element of such an operator can be written as:

\[
\langle |O_{j,i}(q_0, q)\rangle | = \left\langle \frac{1}{2} \| O^J \| \frac{1}{2} \right\rangle \\
\times \sum_{\mu, \nu} \langle \psi_{i}^{j} | y_{\mu} y_{\nu} \{ d_{\mu \nu}^{ij} \tilde{T}(q_0, q) \} | \psi_{\nu}^{j} \rangle , \tag{22}
\]

such that for \(i = j\):

\[
d_{\mu \nu}^{ii} = \delta_{\mu \nu} \tag{23}
\]

\[
a_{\mu \nu}^{ii} = \begin{cases} a_{\mu \nu} & i = j = 3 \text{ H} \\ a_{\mu \nu}' & i = j = 3 \text{ He} . \end{cases} \tag{24}
\]

The spatial parts of the operator are denoted by \(\tilde{T}(E, q_0, q), \hat{K}(q_0, q)\) and \(\hat{K}_{\mu \nu}(E, q_0, q)\). The full analytical expressions for \(\tilde{T}(E, q_0, q)\) and \(\hat{K}(E, q_0, q)\) are given in Ref. [11] while \(\hat{K}_{\mu \nu}(E, q_0, q)\) are the diagrams that contain a one-photon interaction in addition to the energy and momentum transfer. A derivation of an analytical expression for these diagrams is too complex, so they were calculated numerically only. \(a_{\mu \nu}^{ii}\) and \(d_{\mu \nu}^{ii}\) are a result of the \(N - d\) doublet-channel projection coupled to \(O^J O^T\) (for more details, see Ref [11]).

2. Two-body matrix element

In contrast to the normalization operator given in Eq. (14), which contains only one-body interactions, a typical EFT electroweak interaction contains also the following two-body interactions up to NLO:

\[
t^t t, s^t s, (s^t t + h.c) , \tag{25}
\]

under the assumption of energy and momentum conservation. The diagrammatic form of the different two-body interactions is given in Ref. [11].

C. Fermi and Gamow-Teller matrix elements

The Gamow-Teller operator of the triton \(\beta\)-decay \(\langle |GT| \rangle\) matrix element is given by:

\[
\langle |GT| \rangle = \frac{\langle \psi_{4H}^3 \| A^+ \| \psi_{4H}^3 \rangle}{g_A \sqrt{2}} = \left\langle \frac{1}{2} \right\rangle \left\langle \frac{1}{2} \right\rangle \left( \frac{\sigma^x}{\sqrt{2}} \right) \times \sum_{\mu, \nu} \langle \psi_{3H}^4 | y_{\mu} y_{\nu} \{ d_{\mu \nu}^{ij} \tilde{T}(q_0, q) \} + a_{\mu \nu}^{ij} \left[ \hat{K}(q_0, q) + \hat{K}_{\mu \nu}(q_0, q) \right] \} \| \psi_{4H}^3 \rangle , \tag{26}
\]

where:

\[
A(..., p) \otimes B(p, ...) = \int A(..., p) B(p, ...) \frac{p^2}{2\pi^2} dp . \tag{27}
\]

\(d_{\mu \nu}^{ij}\) is given by:

\[
d_{\mu \nu}^{ij} = \begin{bmatrix} t & 1/3 & 0 & -1 \\ np & 0 & 1/3 & 0 \\ nn & -2/3 & 0 & 0 \end{bmatrix} \tag{28}
\]

and

\[
a_{\mu \nu}^{ij} = \begin{bmatrix} t & -7/3 & 1 & 3 \\ np & 1 & 1 & -1 \\ nn & 2/3 & -2 & -2 \end{bmatrix} \tag{29}
\]

The reduced Fermi matrix element \(\langle |F| \rangle\) is given by:

\[
\langle |F| \rangle = \frac{\langle \psi_{4H}^3 \| V^+ \| \psi_{4H}^3 \rangle}{\sqrt{2}} = \left\langle \frac{1}{2} \right\rangle \left\langle \frac{1}{2} \right\rangle \sum_{\mu, \nu} \langle \psi_{3H}^4 | y_{\mu} y_{\nu} \{ d_{\mu \nu}^{ij} \tilde{T}(q_0, q) \} + a_{\mu \nu}^{ij} \left[ \hat{K}(q_0, q) + \hat{K}_{\mu \nu}(q_0, q) \right] \} \| \psi_{4H}^3 \rangle , \tag{30}
\]

where:

\[
d_{\mu \nu}^{ij} = \begin{bmatrix} t & 1 & 0 & 0 \\ np & 0 & 1 & -1 \\ nn & 0 & 2 & 0 \end{bmatrix} \tag{31}
\]
\[
\begin{array}{c|ccc}
\mu & t & np & pp \\
\nu & t & -1 & 3 & 3 \\
np & 1 & 1 & 1 \\
nn & 2 & -2 & -2 \\
\end{array}
\] (32)

\(\mu, \nu\) denote the different channels of the three-nucleon wave function \((t, np, pp)\) for \(^3\text{He}\) and \((t, np, nn)\) for \(^3\text{H}\), where \(\psi_\mu, \psi_\nu\) are the three-nucleon wave functions for the different channels, defined using the homogeneous solution of the three-nucleon scattering amplitude \(^{11}\) and \(q_0 = E_{3\text{He}} - E_{3\text{H}}\) is the energy transfer.

The general diagrammatic form of \(^3\text{H}\) \(\beta\)-decay, shown in Fig. \(^1\) is similar to the general matrix element introduced in Ref. \(^{11}\). For both Fermi and GT transitions, the left-hand side (LHS) bubbles of the diagrams are \(^3\text{He}\), while the right-hand side (RHS) bubbles are \(^3\text{He}\).

The one-body diagrams that contain a one-body weak interaction contribute to both \(||F||\) and \(||GT||\) transitions. These one-body diagrams are taken up to NLO, and, therefore, contain the NLO insertion for the one-body diagrams, as discussed in Ref. \(^{11}\). The two-body diagrams include a two-body term originating from the ERE term in the Lagrangian, \(\frac{1}{2} \rho_{\mu, \nu} \hat{g}_A\), and the two-body operator whose coefficient is proportional to \(L_{1, A}\). These diagrams contribute to the GT transition only.

V. NUMERICAL RESULTS

A. Fermi operator

In the absence of the Coulomb interaction, \(^3\text{H}\) is identical to \(^4\text{He}\) and the Fermi transition is equal to the triton wave function normalization as defined in Ref. \(^{11}\):

\[
\langle|\langle F \rangle\rangle^0 \rangle = \frac{\langle \psi^3\text{H}^0 | \tau^0 | \psi^3\text{H}^0 \rangle}{\sqrt{2}} = \left\langle \frac{1}{2} \left| \tau^0 \right| \frac{1}{2} \right\rangle \\
\times \sum_{\mu, \nu} y_\mu y_\nu \psi_\mu^3\text{H}^0 (p') \otimes \left[ a_{\mu, \nu}^F \hat{T}(0, 0) + a_{\mu, \nu}^F \hat{K}(0, 0) \right] ^3\text{H}^0 (p) = 1,
\] (33)

where in the absence of the Coulomb interaction:

\[
a_{\mu, \nu}^F = \delta_{\mu, \nu}
\] (34)

\[
a_{\mu, \nu}^F = a_{\mu, \nu}
\] (35)

From comparison between eqs. \(^{19}\) and \(^{20}\) with eqs. \(^{31}\) and \(^{32}\), we expect that \(||F|| = 1 - \epsilon\) \(^{16}\), where \(\epsilon \ll 1\) originates mostly from the isospin breaking due to the Coulomb interaction. We can, therefore, examine the effects of isospin breaking on the Fermi transition due to the Coulomb interaction, and the additional one-photon exchange diagrams and then compare them to the Gamow-Teller transition. In this section, we present our calculations of the Fermi transition. First, we calculate the Fermi transition in the absence of the Coulomb interaction but under the assumption that \(a_{nn, np} \neq a_{pp}\). Second, we calculate the Fermi transition with \(\alpha \neq 0\), and, obviously, \(a_{nn, np} \neq a_{pp}\), as a result, for both Z- and ERE-parameterization. All these calculations result from the LHS of the diagrams in Fig. \(^1\).

We use the experimental data shown in Tab. \(^I\) as input for our numerical calculations shown in Fig. \(^2\) and Tab. \(^II\).

| \(\alpha\) | \(||F||\) |
|---|---|
| One-body, LO \(\alpha = 0\) | 1 |
| One-body, LO \(\alpha = 0\), \(a_{np} \neq a_{pp}\) | 0.9999 |
| LO, ERE | 0.9971 |
| LO, Z | 0.9985 |
| SNPA \(^{16}\) | 0.9993 |

TABLE II. Numerical results of \(||F||\). Note that the second row is without an explicit Coulomb force (\(\alpha = 0\)) but with isospin breaking in the scattering lengths, i.e., with the physical values for the scattering lengths \(a_{np} \neq a_{pp}\).

Our numerical result compares well to the \(||F||\) standard nuclear physics approach (SNPA) calculation by Schiavilla et al. \(^{16}\). The SNPA calculation involves nuclear wave functions derived from high-precision phenomenological nuclear potentials, one-nucleon, and two-nucleon electroweak currents.

\section{VI. Extraction of the Gamow-Teller Strength and Fixing \( l_{1,A} \)}

The GT matrix element can be extracted from the triton half-life calculation using Eq. (12). The axial cou-
pling constant, $g_A$, has been remeasured recently, leading to results whose range is much bigger than the current recommendation. To be on the safe side, we take $g_A = 1.273 \pm 0.003 \pm 0.005$ [45, 46]. The first uncertainty in $g_A$ arises from the difference between the measurements of Refs. [45, 46], and the second uncertainty is the statistical experimental uncertainty. To extract the Gamow-Teller strength, we use our prediction for the Fermi transition: $\langle F \rangle = 0.9993$ [16]. At large cutoff values, we find the empirical GT strength to be $\langle |GT| |^\text{emp} = \sqrt{3} \times 1.213 \pm 0.002$ [16]. The uncertainty here originates mainly from the uncertainty in the triton half-life.

The difference between the empirical GT strength and the numerical result for the GT-transition at NLO is used to fix $l_{1,A}$ such that:

$$l_{1,A}(\Lambda) = \frac{\langle |GT| |^\text{NLO}_{l_{1,A}=0} - \langle |GT| |^\text{emp} \rangle}{\langle |GT| |^\text{NLO}_{l_{1,A}}}, \quad (37)$$

where $\langle |GT| |^\text{NLO}_{l_{1,A}}$ are the two-body diagrams that contribute to the triton $\beta$-decay and are coupled to $l_{1,A}$, while $\langle |GT| |^\text{NLO}_{l_{1,A}=0}$ is the sum over all the diagrams that contribute to the triton $\beta$-decay without the diagrams coupled to $l_{1,A}$. The numerical results for $l_{1,A}$ for both ERE- and $Z$-parameterizations are shown in Fig. 4.

![FIG. 4. Numerical results of $l_{1,A}$, with $g_A = 1.273 \pm 0.003 \pm 0.005$ [45, 46]. The dashed (solid) lines are the upper and lower limits of the calculations in ERE- ($Z$-) parameterization.](image)

Importantly, we find numerically, that for both parameterizations, $l_{1,A}$ converges with increasing UV cutoff, a fact that has been already predicted by theory [21], where:

$$l_{1,A}^{\text{ERE}} = 0.312 \pm 0.004 \pm 0.004 \pm 0.001, \quad (38a)$$

$$l_{1,A}^Z = 0.051 \pm 0.004 \pm 0.004 \pm 0.001, \quad (38b)$$

The first and second uncertainties come from the aforementioned difference between recent experimental determinations of $g_A$ and $g_A$ statistical uncertainties [45, 46] while the third uncertainty comes from the rest of the experimental uncertainties, such as the statistical uncertainties in the measured triton half-life.

VII. PREVIOUS EXTRACTIONS OF $l_{1,A}$

Due to the importance of $l_{1,A}$, as the first two-body LEC that appears in the pionless description of $pp$-fusion, its determination has attracted much attention in the literature. In this subsection, we review previous extractions of $l_{1,A}$ in the $\xi$EFT and the latest predictions of the $pp$-fusion rate.

Two main approaches were taken in previous studies to determine $l_{1,A}$. In the first, an experimental value of a two-body weak interaction process, usually at the cutoff $\mu = m_\pi$, was used for matching. Among these reactions are the deuteron dissociation by anti-neutrinos from reactors [47] and neutrino reactions with the deuteron, as measured in SNO [48]. Both references extract $L_{1,A}$ as defined in Eq. [31] as $4.0 \pm 6.3$ (Ref. [47]) and $3.6 \pm 4.6$ (Ref. [48]). Using Eq. (10) and $\mu = m_\pi$ we can extract $l_{1,A} = 0.09 \pm 0.14$ and $l_{1,A} = 0.08 \pm 0.11$, respectively.

In both cases, the large uncertainties originate from statistical errors in the experiments, due to the small cross-section for neutrino-deuteron reactions. The authors of Ref. [23] proposed, therefore, a precision measurement of muon capture on the deuteron, with the aim of reducing the uncertainties by a factor of 3, reflecting an estimated 2-3% experimental uncertainty in the (then proposed) ongoing MuSun experiment [49]. It is important to note that the $\mu^+d$ capture has a large energy transfer, possibly too large for an application of $\xi$EFT. In all these studies, the uncertainties are mainly experimental, due to the uncertainty in the observable, i.e., neglecting the truncation error.

A different approach was taken by Ando and collaborators in Ref. [24]. They used the hybrid calculation of the $pp$-fusion rate from Park et al. [18]. The authors took the ratio of the two-body strength over the one-body strength was taken from this calculation and fixed $L_{1,A}$ to reproduce this ratio in the $\xi$EFT regime. Ando et al. defined the coefficient of the two-body counterterm as $L_{1,A} = -\left( g_A \frac{\rho_{t} + \rho_{d}}{2 \rho_{d}} + \frac{l_{1,A}^{\text{Ando}}}{M \sqrt{\rho_{d}}} \right)$. Using the value $l_{1,A}^{\text{Ando}} = -0.5 \pm 0.03$, we find $l_{1,A} = 0.038 \pm 0.002$. The small uncertainty in this result is due to the accurate triton half-life measurement that is used to fix the undetermined counterterms in Ref. [18]. However, this work has been criticized since it is not guaranteed that their approach is consistent. It employs two very different models and non-observable quantities to perform the matching.

In 2017, The Nuclear Physics with Lattice Quantum Chromo Dynamics (NPLQCD) collaboration calibrated $L_{1,A}$ using the triton $\beta$-decay [50] for the non-physical pion mass $m_\pi = 805$ MeV and then extrapolated it to the physical pion mass.

VIII. SUMMARY AND OUTLOOK

In this paper, we have used the approach introduced in Ref. [13] to study triton $\beta$-decay in the framework
of pionless effective field theory at next-to-leading order (NLO). The EFT approach used here is useful for robust and reliable theoretical uncertainty estimates, based on neglected orders in the EFT expansion. The results presented in this paper show that tritium $\beta$-decay can be calculated reliably, that the corresponding matrix elements are properly renormalized and that the half-life displays, therefore, the necessary RG invariance at NLO.

We found furthermore that up to NLO, the Coulomb interaction \textit{i.e.}, the one-photon exchange interaction, can be included perturbatively in the calculation of this observable, which is consistent with its effect on the $^3$He binding energy as already discussed in Refs. [8–11].

Tritium $\beta$-decay depends on two matrix elements, the Fermi transition, which includes a one-body polar-vector part, and the Gamow-Teller transition, which includes one- and two-body axial-vector parts.

We have tested the correct renormalization of our perturbative calculation of the Fermi and Gamow-Teller matrix elements with an analysis of the residual cutoff dependence at cutoffs that are significantly larger than the breakdown scale of the EFT.

We have used the NLO calculation to fix the NLO LEC, $l_{1,A}$ that is needed for a high-accuracy prediction of the solar proton-proton fusion rate [19, 20, 24]. The NLO correction that originates from the $l_{1,A}$ counterterm (short-range corrections) is about 3% (15%) of the tritium decay Gamow-Teller strength in the Z-(ERE)-parameterization. The short-range corrections associated with the ERE-parameterization are significantly larger than those associated with the Z-parameterization, which implies that the ERE-parameterization internal error is larger than that of the Z-parameterization. Also, the fact that our calculation is carried out within a consistent perturbative approach allows reliable uncertainty estimates originating from the experimental uncertainties in $g_A$ and the half-life measurement.

Knowledge of $l_{1,A}$ is required for higher-order calculations of a number of weak processes, such as $pp$-fusion [19, 20, 24, 51] and muon capture [23, 52, 55]. In the near future, we intend to examine our result for $l_{1,A}$, and its uncertainty by addressing these low-energy weak processes [56, 57] when theoretical and empirical uncertainties estimations must accompany this prediction. Besides, the calibration of LEC from a $^3$H $\beta$-decay for the prediction of a two-nucleon process (such as $pp$-fusion) is based on the assumption that EFT is the appropriate framework for calculating observables in the $A = 2$ and $A = 3$ systems. However, this consistency cannot be examined using the weak observables only due to the small number of appropriate reactions. Hence, another set of well-measured low-energy $A < 4$ interactions with similar characteristics to those of the weak reactions is needed for validation and verification of EFT. The strong analogy between the electromagnetic to weak observables indicates that well-measured electromagnetic observables can serve as the required candidates. We intend to use our perturbative framework for calculating general matrix element that can predict the low-energy electromagnetic $A < 4$ observables. These observables can serve as a case study for estimating the theoretical uncertainty of EFT and LEC extractions from the $A < 4$ observables predictions [58].

ACKNOWLEDGMENT

We thank Sebastian König for the detailed comparison of the $^4$He wave-functions. We also thank Jared Vanasse and Johannes Kirchner, as well as the rest of the participants of the GSI-funded EMMI RRTF workshop ER15-02: Systematic Treatment of the Coulomb Interaction in Few-Body Systems, for valuable discussions, which have contributed significantly to this work. The research of D.G and H.D was supported by ARCHES and by the ISRAEL SCIENCE FOUNDATION (grant No. 1446/16). The research of L.P was supported by the National Science Foundation under Grant Nos. PHY-1516077 and PHY-1555030, and by the Office of Nuclear Physics, U.S. Department of Energy under Contract No. DE-AC05-00OR2272.
