We use path-integrals to derive a general expression for the semiclassical approximation to the partition function of a one-dimensional quantum-mechanical system. Our expression depends solely on ordinary integrals which involve the potential. For high temperatures, the semiclassical expression is dominated by single closed paths. As we lower the temperature, new closed paths appear, including tunneling paths. The transition from single to multiple-path regime corresponds to well-defined catastrophes. Tunneling sets in whenever they occur. (Our formula fully accounts for this feature.)

\[ Z(\beta) = \int_{-\infty}^{\infty} dx_0 \int_{x(0)=x_0}^{x(\beta h)=x_0} [Dx(\tau)] e^{-S/\hbar}, \] (1a)

\[ S = \int_0^{\beta h} d\tau \left[ \frac{1}{2} M \dot{x}^2 + V(x) \right]. \] (1b)

For an arbitrary potential, \( V(x) \), this integral has been approximated by means of perturbative variational and numerical techniques. Here, we shall concentrate on the semiclassical approximation to the integral in order to: i) derive a general formula for \( Z_{sc}(\beta) \) that does not require a detailed knowledge of the classical motion; ii) discuss the onset of tunneling and relate it to the study of singularities in Catastrophe Theory.

The semiclassical evaluation of (1a) yields:

\[ Z_{sc}(\beta) = \int_{-\infty}^{\infty} dx_0 \sum_{j=1}^{N(x_0,\beta)} e^{-S_j(x_0,\beta)/\hbar} \Delta_j^{-1/2}(x_0, \beta), \] (2)

where \( S_j(x_0, \beta) \) denotes the action and \( \Delta_j(x_0, \beta) \) represents the determinant of the fluctuation operator,

\[ \Delta_j = -M \frac{d^2}{d\tau^2} + V''(x_j(\tau)), \] (3)

both calculated at the \( j \)-th classical trajectory, \( x_j(\tau) \), satisfying the boundary conditions, \( x_j(0) = x_j(\beta h) = x_0; \)

\( N(x_0, \beta) \) is the number of classical trajectories which are minima of the action functional.

The action has a simple expression in terms of the turning points of the classical trajectory:

\[ S_j(x_0, \beta) = \beta \hbar V(x^j_+) \pm 2 \int_{x_0}^{x^j_\pm} dx M v(x, x^j_+) \]

\[ + 2n \int_{x^j_-}^{x^j_+} dx M v(x, x^j_+) \] (4)

Here, \( v(x, y) \equiv \sqrt{2/M}[V(x) - V(y)] \) and \( x^j_\pm \) are turning points to the right (left) of \( x_0 \). The first term in (4) corresponds to the high-temperature limit of \( Z(\beta) \), where the classical paths collapse to a point, i.e., \( x^j_\pm \to x_0 \). For motion in regions where the inverted potential is unbounded (hereafter called unbounded motion), \( n = 0 \). For periodic motion, \( n \) counts the number of periods and the second term is absent. For bounded aperiodic motion, all terms are present. The last two terms will be negligible for potentials which vary little over a thermal wavelength, \( \lambda = \hbar \sqrt{\beta/M} \). However, by decreasing the temperature, quantum effects become important.

For trajectories having a single turning point \( (n = 0) \), \( x^j_\pm \) are given implicitly by

\[ \tau(x_0, x^j_+) \equiv 2 \int_{x_0}^{x^j_\pm} \frac{dx}{v(x, x^j_+)} = \pm \beta \hbar, \] (5)

and the fluctuation determinant by

\[ \Delta_j(x_0, \beta) = \pm 4\pi \hbar \left[ V(x^j_+) - V(x_0) \right] \left[ \frac{\partial \tau(x_0, y)}{\partial y} \right]_{y=x^j_\pm}. \] (6)

The formula above is valid only for trajectories with a single turning point. However, this is not really a restriction, since trajectories with two or more turning points are naturally excluded from our calculations, as it will become clear in the sequel.

Formulas (4) and (6) do not require full knowledge of the classical trajectory, as the dependence on \( x_j(\tau) \) comes only through the turning point. To see how this can simplify the evaluation of \( Z_{sc}(\beta) \), let us take the harmonic oscillator, \( V(x) = \frac{1}{2} M \omega^2 x^2 \), as an example. In this case,
given \( x_0 \) and \( \beta \) there is only one trajectory, with a single turning point, given by \( x_+ (x) = x_0 / \cosh (\beta \omega / 2) \) for \( x_0 < 0 \) (> 0). \( S_1 \) and \( \Delta_1 \) can also be readily calculated, the final result being

\[
Z_{sc} (\beta) = \int_{-\infty}^{\infty} dx_0 e^{- (M \omega x_0^2 / \hbar) \tanh (\beta \omega / 2)} \\
\times \sqrt{\frac{M \omega}{2 \pi \hbar \sinh (\beta \omega)}} .
\]  

(7)

which in this case is exact.

A more interesting situation occurs in the case of the anharmonic oscillator, \( V (x) = \lambda (x^2 - a^2)^2 \). For \( x^2 > a^2 \) only single paths with single turning points exist for fixed \( x_0 \) and \( \beta \). However, there is also a region, \( x^2 < a^2 \), where the classical motion is bounded and a much richer structure exists, one in which more than one classical path may exist for given values of \( x_0 \) and \( \beta \).

In a region of bounded classical motion (a well in \(-V\)), such as \( x^2 < a^2 \) for the anharmonic oscillator, the number of classical trajectories changes as the temperature drops. If \( 0 \leq \beta < \pi / \hbar \omega_m \) (where \( \omega_m \equiv \sqrt{-V''(x_m) / M} \) and \( x_m \) is a local minimum of \(-V\)), for every \( x_0 \) in this region, there is only one closed path, with a single turning point, satisfying the classical equations of motion. For \( x_0 < x_m \) (\( > x_m \)) this path goes to the left (right) and returns to \( x_0 \) for \( x_0 = x_m \), it sits still at the bottom of the well. It is this single-path regime which goes smoothly into the high-temperature limit.

For \( \beta = \pi / \hbar \omega_m \), the solution that sits still at \( x_m \) becomes unstable. Its fluctuation operator is that of a harmonic oscillator with \( \omega^2 = \omega_m^2 \). Its finite temperature determinant is \( \Delta (x_m , \beta) = 2 \pi \hbar \sin (\beta \hbar \omega_m) / M \omega_m \). This goes through zero at \( \beta = \pi / \hbar \omega_m \) and becomes negative for \( \beta > \pi / \hbar \omega_m \), thus signaling that \( x (\tau) = x_m \) becomes unstable. At the same time, two new classical paths appear, symmetric with respect to \( x_m \), as depicted in Fig. 5. Therefore, at \( x_0 = x_m \), we go from a single-path regime to a triple-path regime as we cross \( \beta = \pi / \hbar \omega_m \). The two new paths degenerate minima, whereas the path that sits still at \( x_m \) becomes a saddle-point of the action, with a single negative mode.

As \( \beta \) grows beyond \( \pi / \hbar \omega_m \), an analogous situation occurs for other values of \( x_0 \) inside the well. When the fluctuation determinant around the classical path for a given \( x_0 \) vanishes, a new classical path appears. Its single turning point lies opposite, with respect to \( x_m \), to that of the newly unique path. It may be interpreted as a tunneling trajectory, since it traverses a classically forbidden region of \( V \). If \( \beta \) is increased further, this tunneling trajectory splits into two, as illustrated in Fig. 5. One is a local minimum of the action, whereas the other is a saddle-point, with only one negative mode. Again, we have transitioned from a single to a triple-path regime. As \( \beta \) grows, the triple-path region spreads out around \( x_m \). The frontiers of that region are defined by the points \( x_0 \) such that \( [\partial \tau (x, y) / \partial y]_{y = x_\pm} = 0 \).

The phenomenon just described is an example of catastrophe. It takes place whenever the number of classical trajectories changes, with one or more of them becoming unstable, as we lower the temperature. Conversely, we may say that the phenomenon is characterized by the coalescence of two or more of the classical trajectories, as we increase the temperature. This is akin to the occurrence of caustics in Optics [3], where light rays play the role of classical trajectories and the action is replaced with the optical distance.

If we denote by \( s_1 \) the coordinate associated with the direction of instability of our example, the action can be viewed as \( S = S (s_1, \ldots; x_0, \beta) \). If we use the basis of eigenfunctions of the fluctuation operator around classical paths, \( s_1 \) will correspond to the direction along the one eigenfunction whose eigenvalue goes through zero, with the dots referring to all others. Catastrophe Theory [3, 4] allows us to write down the “normal form”, \( S_N \), of this generating function in the three-dimensional subspace made up by the unstable direction of state space (the set of paths) and the two control variables (related to \( \beta \) and \( x_0 \)); it is this subspace which is relevant for the study of the onset of instability. As catastrophes are classified by their codimension in control space, which here is two-dimensional, only those of codimension 1 (the fold) or 2 (the cusp) can occur. The pattern of extrema then leads to the cusp, whose generating function is

\[
S_N (s_1; u_1, v_1) = s_1^4 + u_1 s_1^2 + v_1 s_1,
\]

(8)

where \( u_1 \) and \( v_1 \), the control parameters, are related to \( \beta \) and \( x_0 \), respectively. This catastrophe is defined by

\[
\frac{\partial S_N}{\partial s_1} = \frac{\partial^2 S_N}{\partial s_1^2} = 0.
\]

(9)

Eliminating \( s_1 \) from these equations, we can draw the bifurcation set in control space, as well as the pattern of extrema of \( S_N \) (Fig. 5).

We can also plot the classical action (i.e., the action for classical trajectories) as a function of \( x_0 \) for different values of \( \beta \), by exploiting the relation between the cusp and the swallowtail catastrophes. The latter has a generating function whose normal form is

\[
W (s_1; a, b, c) = s_1^5 + a s_1^3 + b s_1^2 + c s_1;
\]

(10)

\( a, b, c \) are control variables. The extremum condition is, then, \( \partial W / \partial s_1 = 0 \). The identifications \( S_N \equiv -c / 3 \), \( u_1 = 3a \) and \( v_1 = 2b \), will make the additional condition that defines the swallowtail, \( \partial^2 W / \partial s_1^2 = 0 \), coincide with the requirement \( \partial S_N / \partial s_1 = 0 \). In the usual jargon, the bifurcation set for the swallowtail coincides with the equilibrium hypersurface of the cusp. We can, then, draw the graphs for \( S_N \) versus \( v_1 \), for various values of \( u_1 \), shown
in Fig. 3(a,b). Note that \(v_1\) is related to \((x_0 - x_m)\) and \(u_1\) to \((\beta - \pi/h\omega_m)\); for small values of both, we expect the relations to be linear.

New tunnelings, accompanied by new catastrophes, will occur as we keep increasing \(\beta\). From \(\beta = 2\pi/h\omega_m\), we start having tunneling trajectories with \(\dot{x}(0) = 0\), i.e., with one full period. For these, the determinant of fluctuations vanishes because the first, not the second bracket of (6) goes trough zero. However, the fluctuation operator around such tunneling trajectories already has a negative eigenmode. This follows from the fact that the zero-mode, given by \(\dot{x}(\tau)\), has a node. Thus, it cannot be the ground-state for the associated Schrödinger problem. This means that a new catastrophe takes place along a second direction in function space.

This new catastrophe is also a cusp. At \(x_m\), as \(\beta\) becomes larger than \(2\pi/h\omega_m\), the solution that sits still acquires a second negative eigenvalue — thus becoming unstable along a new direction in function space — and two other solutions appear. They both have a negative eigenvalue along the first direction of instability and a positive eigenvalue along the new direction of instability. If we combine the information from both directions, we find that we go from two minima and a saddle-point with only one negative eigenvalue (hereafter, a one-saddle) to two minima, two one-saddles and one two-saddle. The two one-saddles are degenerate in action and represent time-reversed periodic paths. As \(\beta\) increases beyond \(2\pi/h\omega_m\), the same phenomenon takes place for \(x_0\) around \(x_m\): the one-saddles that already existed for \(\beta < 2\pi/h\omega_m\) in the three-path region around \(x_m\) become unstable along a second direction, and a five-path region grows around \(x_m\), with two minima, two (time-reversed, degenerate in action) one-saddles and a two-saddle.

The new cusp can be cast into normal form using the second direction of instability:

\[
S_N(s_2; u_2, v_2 = 0) = s_2^4 + u_2 s_2^2 \sim (s_2^2 + u_2^2/2)^2. \tag{11}
\]

The absence of the linear term in Eq. (11) [compare with Eq. (8)] reflects the degeneracy in action of the two one-saddles. However, there is another degeneracy: since \(V\) does not depend on \(\beta\), if \(x_0(\tau)\) is a solution of the Euler-Lagrangian equations, so is \(x_0(\tau + \tau_0)\). If \(x_0(\tau)\) is periodic, \(x_0(\tau + \tau_0)\) describes the same path — and so has the same action —, with another starting point. This can be represented in Eq. (11) by the choice \(u_2 \propto \{x_0 - x_0(\tau)^2 + k(2\pi/h\omega_m - \beta)\}\), with \(k > 0\). See Fig. 3(c).

As we approach \(\beta = 3\pi/h\omega_m\), the situation becomes similar to the one near \(\beta = \pi/h\omega_m\). The difference is that we now have to deal with a tunneling path with more than one and less than two periods. Near \(\beta = 2\pi/h\omega_m\), two-period tunnelings intervene, a situation similar to that at \(\beta = 2\pi/h\omega_m\). The pattern which develops is depicted in Fig. 4.

Despite the fact that we keep adding new extrema as we lower the temperature, many of which represent tunneling solutions, only two of these are stable (i.e., minima). In a semiclassical approximation in euclidean time, these are the only extrema we have to sum over, meaning that \(N(x_0, \beta)\) never exceeds two. The local minimum is a tunneling solution, whereas the global one becomes the unique solution in the high-temperature regime. For \(\beta < \pi/h\omega_m\), there will be regions with either one or two minima of the classical action. The transition from a single-minimum to a double-minimum region occurs at values of \(x_0\) where the fluctuation determinant vanishes due to the appearance of a caustic, thus leading to a singularity in the integrand of Eq. (3). This is not a disaster, however, as this singularity is integrable. (Such a singularity is an artifact of the semiclassical approximation. It disappears in a more refined approximation in which one includes cubic and quartic fluctuations in the direction of function space where the instability sets in.) Explicit calculations for a number of potentials, and the derivation of Eq. (3), will be presented in a future publication.

We thank Roberto Iengo, for useful conversations, Ildeu de Castro Moreira, for pointing out Ref. 6, and Flavia Maximo, for help with the figures. Part of this work was carried out at the ICTP, and had financial support from CNPq.
