Abstract
Percutaneous endoscopic gastrostomy (PEG) is often performed for nutritional management in advanced esophageal cancer. We here report a patient who initially received enteral nutrition via a nasogastric tube and in whom the subsequent use of percutaneous transesophageal gastro-tubing (PTEG) circumvented the need for a gastrostomy. It is believed that PEG is less painful than a nasogastric tube. However, we selected PTEG because a PEG would have been within the planned irradiation field and there was concern about radiation dermatitis. We were
able to administer chemoradiotherapy with sufficient nutrition via an enteral feeding tube via esophagostomy. PTEG is a very useful tool in patients at risk of radiation dermatitis of the abdomen.

**Introduction**

In patients with advanced esophageal cancer, oral intake is often difficult because of esophageal stenosis or peristalsis; percutaneous endoscopic gastrostomy (PEG) [1, 2] is therefore often performed for nutritional management [3, 4]. The present patient had large lymph node metastases around the gastric cardia; thus, the site of construction of a gastrostomy would have overlapped with the planned irradiation area. In general, physical irritation to the skin in irradiated areas should be avoided because it can exacerbate radiation dermatitis [5].

Here, we report a patient with advanced esophageal cancer in whom a tube was constructed using percutaneous transesophageal gastro-tubing (PTEG) [6, 7], instead of using PEG, because there was concern about radiation dermatitis.

**Case Report**

A 71-year-old man was admitted to our hospital for management of advanced esophageal cancer. He was 156 cm tall and weighed 45.2 kg (body mass index 18.6). He had no previous illnesses but was a heavy smoker and drinker. He had first noted a feeling of constriction in his esophagus 2 months before presentation and had lost 9 kg in weight over the previous 6 months. By the time of admission, he was unable to even drink water. Upper gastrointestinal endoscopy, esophagography, and contrast-enhanced computed tomography (CT) resulted in a diagnosis of unresectable advanced esophageal cancer (Fig. 1). Therefore, chemoradiotherapy (CRT) was scheduled.

A nasogastric tube and peripherally inserted central catheter (PICC) port were placed and enteral and parenteral nutrition initiated. PEG was considered because it is considered less painful than a nasogastric tube. However, the radiation therapist pointed out that the region of construction of PEG would have overlapped with the radiation field (Fig. 1), creating the possibility that radiation-induced skin reactions would be exacerbated by placement of a PEG tube. We therefore elected to use a PTEG rather than a PEG as the nutritional route (Fig. 2).

We usually use a PTEG starter kit (Sumitomo Bakelite, Tokyo, Japan), which comprises a rupture-free balloon (RFB) catheter (14 Fr × 70 cm, balloon volume 10 mL), fluorine resin-coated straight guidewire (0.89 mm × 200 cm) for the RFB catheter, puncture needle (18 G × 15 cm), J shaped guidewire (0.89 mm × 100 cm), 8 Fr dilator (2.7 mm × 25 cm), 16 Fr dilator (5.3 mm × 15 cm), 18 Fr peel-away sheath dilator, 18 Fr peel-away sheath (6.0 mm × 10 cm), button type 15 Fr enteral feeding tube, and a fluorine resin-coated guidewire (0.89 mm × 100 cm) for the enteral feeding tube [8]. First, a fluorine resin-coated straight guidewire was placed in the esophagus via the left nostril. Subsequently, an RFB catheter was placed in the esophagus via a guidewire and 10 mL of 60% meglumine diatrizoate diluted 10-fold with normal saline injected into the RFB. Cervical ultrasound was performed while gently pulling on the balloon. Ultrasound images confirmed that the RFB was in the cervical esophagus. After selecting a puncture site in the left neck, local anesthesia and a skin incision (10 mm) were performed, after which, avoiding the thyroid gland and large blood vessels, the RFB was
punctured with an 18 G puncture needle under ultrasonic guidance, the position of the tip of the needle also being confirmed by fluoroscopy. The inner tube of the puncture needle was removed and the J shaped guidewire placed in the RFB after confirming backflow of the contrast agent. The RFB was then collapsed and advanced deep into the esophagus and the guidewire placed into the esophagus. Next, the puncture route was expanded with a dilator with an 18 Fr peel-away sheath (tip 8 Fr; proximal side 18 Fr). The guidewire and dilator were removed and the sheath left in situ. The button type 15 Fr enteral feeding tube (45 cm in length) was successfully placed in the stomach via the sheath beyond the lower esophageal stenosis (Fig. 2).

Because the required intake was secured by administering adequate enteral and parenteral nutrition through the enteral feeding tube via esophagostomy and the PICC port, CRT was successfully completed while maintaining the patient’s general condition. Fortunately, this patient achieved a complete response to CRT and regained the ability to eat foods orally, enabling eventual removal of the enteral feeding tube via esophagostomy and the PICC port (Fig. 3).

Discussion

Patients undergoing CRT often experience acute and/or chronic skin reactions that can compromise their quality of life. Many topical agents and specialized wound dressings are available to facilitate prevention and management of radiation dermatitis; however, it is difficult to avoid it completely. Physical irritation to the skin of the irradiated area should be avoided because it can exacerbate radiation dermatitis [5].

In our patient with unresectable advanced esophageal cancer, the site for a PEG overlapped the proposed radiation area because of the location of his lymph node metastases. Therefore, we chose to use a PTEG rather than a PEG, thus enabling administration of CRT and enteral nutrition safely without risking exacerbation of skin damage in the irradiated area by a PEG. Searches of PubMed and Ichushi, which is a bibliographic database created by the Japan Medical Abstracts Society, revealed no reports on radiation therapy through the skin of a PEG site as of October 2019.

In 2003, Oishi et al. were the first to develop a minimally invasive technique for achieving esophagostomy called PTEG that uses an RFB for enteral nutrition and drainage as well as a PEG [6]. The use of an RFB with PTEG allows the interventional physician to create a nonsurgical esophagostomy, even in patients in whom it would be difficult to construct a PEG (i.e., after total gastrectomy or with massive ascites). As demonstrated by the present patient, CRT may constitute a new indication for PTEG.

PTEG is less painful and more cosmetically acceptable than a nasogastric tube (Fig. 2). In our questionnaire survey, all patients who switched from a nasogastric tube to a PTEG indicated that they preferred a PTEG.

Contraindications common to PEG and PTEG are anticoagulant use, liver cirrhosis and portal hypertension, and esophageal gastric varices. PEG and PTEG can cause uncontrollable bleeding and should not be performed in patients with these conditions. An additional contraindication to PTEG is inability to secure a safe puncture line when puncturing the cervical esophagus under ultrasound guidance because of thyroid enlargement or extensive cervical lymphadenopathy. Recurrent nerve palsy may be present in individuals with hoarseness. When the patient has recurrent nerve palsy contralateral to the puncture site, puncture may result in bilateral recurrent nerve palsy with the attendant risk of difficulty in breathing as a
result of vocal cord closure. Thus, contralateral recurrent nerve paralysis is a contraindication to PTEG; it is therefore important to carefully check for such paralysis prior to performing PTEG. Because the adult cervical esophagus is located on the dorsal side of the left thyroid gland in 90% of individuals, the approach to PTEG is usually on the left. Another contraindication to this procedure is the presence of esophageal lesions such as tumors, ulcers, and stenosis because they may exacerbate complications such as bleeding and perforation. In the absence of the above-listed contraindications, PTEG is a safe procedure if performed carefully.

In conclusion, PTEG is a very useful tool in the nutritional management of patients with esophageal cancer undergoing CRT in whom PEG construction is not possible because of an overlap with the radiation field and the attendant risk of exacerbating radiation dermatitis. We here report our experience of implementing PTEG in patient with the proposed new indication of CRT.

Acknowledgment

We are grateful to members of nutrition support team for helpful discussions.

Statement of Ethics

The patient has given his written informed consent to publish the case.

Disclosure Statement

The authors declare that they have no conflicts of interest related to the present study.
